In financial modeling, it is useful to consider operations performed on ordered arrays of numbers. Ordered arrays of numbers are called vectors and matrices while individual numbers are called scalars. In this entry, we will discuss some concepts, operations, and results of matrix algebra used in financial modeling.

VECTORS AND MATRICES DEFINED

We begin by defining the concepts of *vector* and *matrix*. Though vectors can be thought of as particular matrices, in many cases it is useful to keep the two concepts—vectors and matrices—distinct. In particular, a number of important concepts and properties can be defined for vectors but do not generalize easily to matrices.¹

Vectors

An n -dimensional *vector* is an ordered array of n numbers. Vectors are generally indicated

with boldface lowercase letters, although we do not always follow that convention in this book. Thus a vector \mathbf{x} is an array of the form:

$$\mathbf{x} = [x_1, \dots, x_n].$$

The numbers a_i are called the components of the vector \mathbf{x} .

A vector is identified by the set of its components. Vectors can be row vectors or column vectors. If the vector components appear in a horizontal row, then the vector is called a row vector, as for instance the vector:

$$\mathbf{x} = [1, 2, 8, 7]$$

Here are two examples. Suppose that we let w_n be a risky asset's weight in a portfolio. Assume that there are N risky assets. Then the following vector, \mathbf{w} , is a row vector that represents a portfolio's holdings of the N risky assets:

$$\mathbf{w} = [w_1 \ w_2 \ \dots \ w_N]$$

As a second example of a row vector, suppose that we let r_n be the excess return for a

risky asset. (The excess return is the difference between the return on a risky asset and the risk-free rate.) Then the following row vector is the excess return vector:

$$\mathbf{r} = [r_1 \ r_2 \ \dots \ r_N]$$

If the vector components are arranged in a column, then the vector is called a column vector.

For example, we know that a portfolio's excess return will be affected by what can be different characteristics or attributes that affect all asset prices. A few examples would be the price-earnings ratio, market capitalization, and industry. Let us denote for a particular attribute a column vector, \mathbf{a} , that shows the exposure of each risky asset to that attribute, denoted a_n :

$$\mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_N \end{bmatrix}$$

Matrices

An $n \times m$ matrix is a bidimensional ordered array of $n \times m$ numbers. Matrices are usually indicated with boldface uppercase letters. Thus, the generic matrix \mathbf{A} is an $n \times m$ array of the form:

$$\mathbf{A} = \begin{bmatrix} a_{1,1} & \cdot & a_{1,j} & \cdot & a_{1,m} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{i,1} & \cdot & a_{i,j} & \cdot & a_{i,m} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{n,1} & \cdot & a_{n,j} & \cdot & a_{n,m} \end{bmatrix}$$

Note that the first subscript indicates rows while the second subscript indicates columns. The entries a_{ij} —called the elements of the matrix \mathbf{A} —are the numbers at the crossing of the i -th row and the j -th column. The commas between the subscripts of the matrix entries are omitted when there is no risk of confusion: $a_{i,j} \equiv a_{ij}$. A matrix \mathbf{A} is often indicated by its generic element between brackets:

$$\mathbf{A} = \{a_{ij}\}_{nm} \quad \text{or} \quad \mathbf{A} = [a_{ij}]_{nm}$$

where the subscripts nm are the dimensions of the matrix.

There are several types of matrices. First there is a broad classification of square and rectangular matrices. A *rectangular matrix* can have different numbers of rows and columns; a *square matrix* is a rectangular matrix with the same number n of rows as of columns. Because of the important role that they play in applications, we focus on square matrices in the next section.

SQUARE MATRICES

The $n \times n$ *identity matrix*, indicated as the matrix \mathbf{I}_n , is a square matrix whose diagonal elements (i.e., the entries with the same row and column suffix) are equal to one while all other entries are zero:

$$\mathbf{I}_n = \begin{bmatrix} 1 & 0 & \cdot & \cdot & \cdot & 0 \\ 0 & 1 & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & \cdot & \cdot & \cdot & 1 \end{bmatrix}$$

A matrix whose entries are all zero is called a zero matrix.

A *diagonal matrix* is a square matrix whose elements are all zero except the ones on the diagonal:

$$\mathbf{A} = \begin{bmatrix} a_{11} & 0 & \cdot & \cdot & \cdot & 0 \\ 0 & a_{22} & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & 0 & \cdot & \cdot & 0 & a_{nn} \end{bmatrix}$$

Given a square $n \times n$ matrix \mathbf{A} , the matrix $\text{dg } \mathbf{A}$ is the diagonal matrix extracted from \mathbf{A} . The diagonal matrix $\text{dg } \mathbf{A}$ is a matrix whose elements are all zero except the elements on the

diagonal that coincide with those of the matrix **A**:

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdot & \cdot & \cdot & a_{1n} \\ a_{21} & a_{22} & \cdot & \cdot & \cdot & a_{2n} \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{n1} & a_{n2} & \cdot & \cdot & \cdot & a_{nm} \end{bmatrix} \Rightarrow$$

$$\text{dg}\mathbf{A} = \begin{bmatrix} a_{11} & 0 & \cdot & \cdot & \cdot & 0 \\ 0 & a_{22} & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & \cdot & \cdot & \cdot & a_{nn} \end{bmatrix}$$

The *trace* of a square matrix **A** is the sum of its diagonal elements:

$$\text{tr}\mathbf{A} = \sum_{i=1}^n a_{ii}$$

A square matrix is called *symmetric* if the elements above the diagonal are equal to the corresponding elements below the diagonal: $a_{ij} = a_{ji}$. A matrix is said to be *skew-symmetric* if the diagonal elements are zero and the elements above the diagonal are the opposite of the corresponding elements below the diagonal: $a_{ij} = -a_{ji}, i \neq j, a_{ii} = 0$.

The most commonly used symmetric matrix in financial economics and econometrics is the covariance matrix, also referred to as the variance-covariance matrix. For example, suppose that there are N risky assets and that the variance of the excess return for each risky asset and the covariances between each pair of risky assets are estimated. As the number of risky assets is N , there are N^2 elements, consisting of N variances (along the diagonal) and $N^2 - N$ covariances. Symmetry restrictions reduce the number of independent elements. In fact, the covariance between risky asset i and risky asset j will be equal to the covariance between risky asset j and risky asset i . Notice that the variance-covariance matrix is a symmetric matrix.

DETERMINANTS

Consider a square, $n \times n$, matrix **A**. The *determinant* of **A**, denoted $|\mathbf{A}|$, is defined as follows:

$$|\mathbf{A}| = \sum (-1)^{t(j_1, \dots, j_n)} \prod_{i=1}^n a_{ij}$$

where the sum is extended over all permutations (j_1, \dots, j_n) of the set $(1, 2, \dots, n)$ and $t(j_1, \dots, j_n)$ is the number of transpositions (or inversions of positions) required to go from $(1, 2, \dots, n)$ to (j_1, \dots, j_n) . Otherwise stated, a determinant is the sum of all products formed taking exactly one element from each row with each product multiplied by $(-1)^{t(j_1, \dots, j_n)}$. Consider, for instance, the case $n = 2$, where there is only one possible transposition: $1, 2 \Rightarrow 2, 1$. The determinant of a 2×2 matrix is therefore computed as follows:

$$|\mathbf{A}| = (-1)^0 a_{11}a_{22} + (-1)^1 a_{12}a_{21}$$

$$= a_{11}a_{22} - a_{12}a_{21}.$$

Consider a square matrix **A** of order n . Consider the matrix \mathbf{M}_{ij} obtained by removing the i th row and the j th column. The matrix \mathbf{M}_{ij} is a square matrix of order $(n - 1)$. The determinant $|\mathbf{M}_{ij}|$ of the matrix \mathbf{M}_{ij} is called the *minor* of a_{ij} . The signed minor $(-1)^{(i+j)}|\mathbf{M}_{ij}|$ is called the *cofactor* of a_{ij} and is generally denoted as α_{ij} .

A square matrix **A** is said to be *singular* if its determinant is equal to zero. An $n \times m$ matrix **A** is of *rank* r if at least one of its (square) r -minors is different from zero while all $(r + 1)$ -minors, if any, are zero. A nonsingular square matrix is said to be of full rank if its rank r is equal to its order n .

SYSTEMS OF LINEAR EQUATIONS

A system of n linear equations in m unknown variables is a set of n simultaneous equations of the following form:

$$a_{1,1}x_1 + \dots + a_{1,m}x_m = b_1$$

$$\dots \dots \dots$$

$$a_{n,1}x_1 + \dots + a_{n,m}x_m = b_n$$

It can be demonstrated that in any matrix the number p of linearly independent columns is the same as the number q of linearly independent rows. This number is equal, in turn, to the rank r of the matrix. Recall that a $n \times m$ matrix \mathbf{A} is said to be of rank r if at least one of its (square) r -minors is different from zero while all $(r + 1)$ -minors, if any, are zero. The constant p , is the same for rows and for columns. We can now give an alternative definition of the rank of a matrix:

Given an $n \times m$ matrix \mathbf{A} , its *rank*, denoted $\text{rank}(\mathbf{A})$, is the number r of linearly independent rows or columns as the row rank is always equal to the column rank.

VECTOR AND MATRIX OPERATIONS

Let's now introduce the most common operations performed on vectors and matrices. An operation is a mapping that operates on scalars, vectors, and matrices to produce new scalars, vectors, or matrices. The notion of operations performed on a set of objects to produce another object of the same set is the key concept of algebra. Let's start with vector operations.

Vector Operations

The following three operations are usually defined on vectors: transpose, addition, and multiplication.

Transpose

The *transpose* operation transforms a row vector into a column vector and vice versa. Given the row vector $\mathbf{x} = [x_1, \dots, x_n]$, its transpose, denoted as \mathbf{x}^T or \mathbf{x}' , is the column vector:

$$\mathbf{x}^T = \begin{bmatrix} x_1 \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{bmatrix}.$$

Clearly the transpose of the transpose is the original vector: $(\mathbf{x}^T)^T = \mathbf{x}$.

Addition

Two row (or column) vectors $\mathbf{x} = [x_1, \dots, x_n]$, $\mathbf{y} = [y_1, \dots, y_n]$ with the same number n of components can be added. The addition of two vectors is a new vector whose components are the sums of the components:

$$\mathbf{x} + \mathbf{y} = [x_1 + y_1, \dots, x_n + y_n]$$

This definition can be generalized to any number N of summands:

$$\sum_{i=1}^N \mathbf{x}_i = \left[\sum_{i=1}^N x_{1i}, \dots, \sum_{i=1}^N y_{ni} \right]$$

The summands must be both column or row vectors; it is not possible to add row vectors to column vectors.

It is clear from the definition of addition that addition is a commutative operation in the sense that the order of the summands does not matter: $\mathbf{x} + \mathbf{y} = \mathbf{y} + \mathbf{x}$. Addition is also an associative operation in the sense that $\mathbf{x} + (\mathbf{y} + \mathbf{z}) = (\mathbf{x} + \mathbf{y}) + \mathbf{z}$.

Multiplication

We define two types of multiplication: (1) multiplication of a scalar and a vector, and (2) scalar multiplication of two vectors (inner product).²

The multiplication of a scalar a and a row (or column) vector \mathbf{x} , denoted as $a\mathbf{x}$, is defined as the multiplication of each component of the vector by the scalar:

$$a\mathbf{x} = [ax_1, \dots, ax_n].$$

A similar definition holds for column vectors. It is clear from this definition that multiplication by a scalar is associative as:

$$a(\mathbf{x} + \mathbf{y}) = a\mathbf{x} + a\mathbf{y}$$

The *scalar product* (also called the inner product), of two vectors \mathbf{x}, \mathbf{y} , denoted as $\mathbf{x} \cdot \mathbf{y}$, is defined between a row vector and a column vector. The scalar product between two vectors produces a scalar according to the following rule:

$$\mathbf{x} \cdot \mathbf{y} = \sum_{i=1}^n x_i y_i.$$

Two vectors \mathbf{x}, \mathbf{y} are said to be orthogonal if their scalar product is zero.

MATRIX OPERATIONS

Let's now define operations on matrices. The following five operations on matrices are usually defined: transpose, addition, multiplication, inverse, and adjoint.

Transpose

The definition of the *transpose of a matrix* is an extension of the transpose of a vector. The transpose operation consists in exchanging rows with columns. Consider the $n \times m$ matrix $\mathbf{A} = \{a_{ij}\}_{nm}$. The transpose of \mathbf{A} , denoted \mathbf{A}^T or \mathbf{A}' is the $m \times n$ matrix whose i th row is the i th column of \mathbf{A} :

$$\mathbf{A}^T = \{a_{ji}\}_{mn}$$

The following should be clear from this definition:

$$(\mathbf{A}^T)^T = \mathbf{A}$$

and that a matrix is symmetric if and only if

$$\mathbf{A}^T = \mathbf{A}$$

Addition

Consider two $n \times m$ matrices $\mathbf{A} = \{a_{ij}\}_{nm}$ and $\mathbf{B} = \{b_{ij}\}_{nm}$. The sum of the matrices \mathbf{A} and \mathbf{B} is defined as the $n \times m$ matrix obtained by adding the respective elements:

$$\mathbf{A} + \mathbf{B} = \{a_{ij} + b_{ij}\}_{nm}.$$

Note that it is essential for the definition of addition that the two matrices have the same order $n \times m$.

The operation of addition can be extended to any number N of summands as follows:

$$\sum_{s=1}^N \mathbf{A}_s = \left\{ \sum_{s=1}^N a_{sij} \right\}_{nm}$$

where a_{sij} is the generic i, j element of the s th summand.

Multiplication

Consider a scalar c and a matrix $\mathbf{A} = \{a_{ij}\}_{nm}$. The product $c\mathbf{A} = \mathbf{A}c$ is the $n \times m$ matrix obtained by multiplying each element of the matrix by c :

$$c\mathbf{A} = \mathbf{A}c = \{ca_{ij}\}_{nm}.$$

Multiplication of a matrix by a scalar is distributive with respect to matrix addition:

$$c(\mathbf{A} + \mathbf{B}) = c\mathbf{A} + c\mathbf{B}.$$

Let's now define the product of two matrices. Consider two matrices $\mathbf{A} = \{a_{it}\}_{np}$ and $\mathbf{B} = \{b_{sj}\}_{pm}$. The product $\mathbf{C} = \mathbf{A}\mathbf{B}$ is defined as follows:

$$\mathbf{C} = \mathbf{A}\mathbf{B} = \{c_{ij}\} = \left\{ \sum_{t=1}^p a_{it} b_{tj} \right\}.$$

The product $\mathbf{C} = \mathbf{A}\mathbf{B}$ is therefore a matrix whose generic element $\{c_{ij}\}$ is the scalar product of the i th row of the matrix \mathbf{A} and the j th column of the matrix \mathbf{B} . This definition generalizes the definition of scalar product of vectors: The scalar product of two n -dimensional vectors is the product of an $n \times 1$ matrix (a row vector) for a $1 \times n$ matrix (the column vector).

Inverse and Adjoint

Consider two square matrices of order n \mathbf{A} and \mathbf{B} . If $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A} = \mathbf{I}$, then the matrix \mathbf{B} is called the *inverse* of \mathbf{A} and is denoted as \mathbf{A}^{-1} . It can be demonstrated that the two following properties hold:

Property 1: A square matrix \mathbf{A} admits an inverse \mathbf{A}^{-1} if and only if it is nonsingular, that is, if and only if its determinant is different from zero. Otherwise stated, a matrix \mathbf{A} admits an inverse if and only if it is of full rank.

Property 2: The inverse of a square matrix, if it exists, is unique. This property is a consequence of the property that, if \mathbf{A} is nonsingular, then $\mathbf{AB} = \mathbf{AC}$ implies $\mathbf{B} = \mathbf{C}$.

Consider now a square matrix of order n $\mathbf{A} = \{a_{ij}\}$ and consider its cofactors α_{ij} . Recall that the cofactors α_{ij} are the signed minors $(-1)^{i+j}|M_{ij}|$ of the matrix \mathbf{A} . The *adjoint* of the matrix \mathbf{A} , denoted as $\text{Adj}(\mathbf{A})$, is the following matrix:

$$\begin{aligned} \text{Adj}(\mathbf{A}) &= \begin{bmatrix} \alpha_{1,1} & \cdot & \alpha_{1,j} & \cdot & \alpha_{1,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \alpha_{i,1} & \cdot & \alpha_{i,j} & \cdot & \alpha_{i,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \alpha_{n,1} & \cdot & \alpha_{n,j} & \cdot & \alpha_{n,n} \end{bmatrix}^T \\ &= \begin{bmatrix} \alpha_{1,1} \cdot \alpha_{2,1} \cdot \alpha_{n,1} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \alpha_{1,i} \cdot \alpha_{2,i} \cdot \alpha_{n,i} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \alpha_{1,n} \cdot \alpha_{2,n} \cdot \alpha_{n,n} \end{bmatrix} \end{aligned}$$

The adjoint of a matrix \mathbf{A} is therefore the transpose of the matrix obtained by replacing the elements of \mathbf{A} with their cofactors.

If the matrix \mathbf{A} is nonsingular, and therefore admits an inverse, it can be demonstrated that:

$$\mathbf{A}^{-1} = \frac{\text{Adj}(\mathbf{A})}{|\mathbf{A}|}$$

A square matrix of order n \mathbf{A} is said to be orthogonal if the following property holds:

$$\mathbf{AA}' = \mathbf{A}'\mathbf{A} = \mathbf{I}_n$$

Because in this case \mathbf{A} must be of full rank, the transpose of an orthogonal matrix coincides with its inverse: $\mathbf{A}^{-1} = \mathbf{A}'$.

EIGENVALUES AND EIGENVECTORS

Consider a square matrix \mathbf{A} of order n and the set of all n -dimensional vectors. The matrix \mathbf{A} is a linear operator on the space of vectors. This means that \mathbf{A} operates on each vector producing another vector subject to the following restriction:

$$\mathbf{A}(a\mathbf{x} + b\mathbf{y}) = a\mathbf{A}\mathbf{x} + b\mathbf{A}\mathbf{y}$$

Consider now the set of vectors \mathbf{x} such that the following property holds:

$$\mathbf{A}\mathbf{x} = \lambda\mathbf{x}.$$

Any vector such that the above property holds is called an *eigenvector* of the matrix \mathbf{A} and the corresponding value of λ is called an *eigenvalue*.

To determine the eigenvectors of a matrix and the relative eigenvalues, consider that the equation $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ can be written as:

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = 0$$

which can, in turn, be written as a system of linear equations:

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = \begin{bmatrix} a_{1,1} - \lambda & \cdot & a_{1,j} & \cdot & a_{1,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{i,1} & \cdot & a_{i,i} - \lambda & \cdot & a_{i,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{n,1} & \cdot & a_{n,j} & \cdot & a_{n,n} - \lambda \end{bmatrix} \begin{bmatrix} x_1 \\ \cdot \\ x_i \\ \cdot \\ x_n \end{bmatrix} = 0$$

This system of equations has nontrivial solutions only if the matrix $\mathbf{A} - \lambda\mathbf{I}$ is singular. To determine the eigenvectors and the eigenvalues of the matrix \mathbf{A} we must therefore solve the equation:

$$|\mathbf{A} - \lambda\mathbf{I}| = \begin{vmatrix} a_{1,1} - \lambda & \cdot & a_{1,j} & \cdot & a_{1,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{i,1} & \cdot & a_{i,i} - \lambda & \cdot & a_{i,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{n,1} & \cdot & a_{n,j} & \cdot & a_{n,n} - \lambda \end{vmatrix} = 0$$

The expansion of this determinant yields a polynomial $\phi(\lambda)$ of degree n known as the *characteristic polynomial* of the matrix \mathbf{A} . The equation $\phi(\lambda) = 0$ is known as the *characteristic equation* of the matrix \mathbf{A} . In general, this equation will have n roots λ_s which are the eigenvalues of the matrix \mathbf{A} . To each of these eigenvalues corresponds a solution of the system of linear equations as illustrated below:

$$\begin{bmatrix} a_{1,1} - \lambda_s & \cdot & a_{1,j} & \cdot & a_{1,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{i,1} & \cdot & a_{i,i} - \lambda_s & \cdot & a_{i,n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ a_{n,1} & \cdot & a_{n,j} & \cdot & a_{n,n} - \lambda_s \end{bmatrix} \begin{bmatrix} x_{1s} \\ \cdot \\ x_{is} \\ \cdot \\ x_{ns} \end{bmatrix} = 0$$

Each solution represents the eigenvector \mathbf{x}_s corresponding to the eigenvalue λ_s . The determination of eigenvalues and eigenvectors is the basis for principal component analysis.

KEY POINTS

- An n -dimensional vector is an ordered array of n numbers with the numbers referred to as the components. An $n \times m$ matrix is a bidimensional ordered array of $n \times m$ numbers.
- A rectangular matrix can have different numbers of rows and columns; a square matrix is a rectangular matrix with the same number of rows and columns. An identity matrix is a square matrix whose diagonal elements are equal to one while all other entries are zero.

A diagonal matrix is a square matrix whose elements are all zero except the ones on the diagonal.

- The trace of a square matrix is the sum of its diagonal elements. A symmetric matrix is a square matrix where the elements above the diagonal are equal to the corresponding elements below the diagonal. The most commonly used symmetric matrix in finance is the covariance matrix (or variance-covariance matrix).
- The rank of a matrix is used to determine the number of solutions of a system of linear equations.
- An operation is a mapping that operates on scalars, vectors, and matrices to produce new scalars, vectors, or matrices. The notion of operations performed on a set of objects to produce another object of the same set is the key concept of algebra. Five vector operations on matrices are transpose, addition, multiplication, inverse, and adjoint.

NOTES

1. Vectors can be thought of as the elements of an abstract linear space while matrices are operators that operate on linear spaces.
2. A third type of product between vectors—the vector (or outer) product between vectors—produces a third vector. We do not define it here as it is not typically used in economics, though widely used in the physical sciences.

Difference Equations

SERGIO M. FOCARDI, PhD

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: The theory of linear difference equations has found applications in many areas in finance. A difference equation is an equation that involves differences between successive values of a function of a discrete variance. The theory of linear difference equations covers three areas: solving difference equations, describing the behavior of difference equations, and identifying the equilibrium (or critical value) and stability of difference equations.

Linear difference equations are important in the context of dynamic econometric models. Stochastic models in finance are expressed as linear difference equations with random disturbances added. Understanding the behavior of solutions of linear difference equations helps develop intuition about the behavior of these models. The relationship between *difference equations* (the subject of this entry) and differential equations is as follows. The latter are great for modeling situations in finance where there is a continually changing value. The problem is that not all changes in value occur continuously. If the change in value occurs incrementally rather than continuously, then differential equations have their limitations. Instead, a financial modeler can use difference equations, which are recursively defined sequences.

In this entry we explain the theory of linear difference equations and describe how to

compute explicit solutions of different types of equations.

THE LAG OPERATOR L

The *lag operator* L is a linear operator that acts on doubly infinite time series by shifting positions by one place:

$$Lx_t = x_{t-1}$$

The difference operator $\Delta x_t = x_t - x_{t-1}$ can be written in terms of the lag operator as

$$\Delta x_t = (1 - L)x_t$$

Products and thus powers of the lag operator are defined as follows:

$$(L \times L)x_t = L^2x_t = L(Lx_t) = x_{t-2}$$

From the previous definition, we can see that the i -th power of the lag operator shifts the

series by i places:

$$L^i x_t = x_{t-i}$$

The lag operator is linear, that is, given scalars a and b we have

$$(aL^i + bL^j)x_t = ax_{t-i} + bx_{t-j}$$

Hence we can define the polynomial operator:

$$A(L) = (1 - a_1L - \dots - a_pL^p) \equiv \left(1 - \sum_{i=1}^p a_iL^i\right)$$

HOMOGENEOUS DIFFERENCE EQUATIONS

Homogeneous difference equations are linear conditions that link the values of variables at different time lags. Using the lag operator L , they can be written as follows:

$$\begin{aligned} A(L)x_t &= (1 - a_1L - \dots - a_pL^p)x_t \\ &= (1 - \lambda_1L) \times \dots \times (1 - \lambda_pL)x_t = 0 \end{aligned}$$

where the $\lambda_i, i = 1, 2, \dots, p$ are the solutions of the characteristic equation:

$$\begin{aligned} z^p - a_1z^{p-1} - \dots - a_{p-1}z - a_p &= 0 \\ &= (z - \lambda_1) \times \dots \times (z - \lambda_p) = 0 \end{aligned}$$

Suppose that time extends from $0 \Rightarrow \infty, t = 0, 1, 2, \dots$ and that the initial conditions $(x_{-1}, x_{-2}, \dots, x_{-p})$ are given.

Real Roots

Consider first the case of real roots. In this case, as we see later in this entry, solutions are sums of exponentials. First suppose that the roots of the characteristic equation are all real and distinct. It can be verified by substitution that any series of the form

$$x_t = C(\lambda_i)^t$$

where C is a constant, solves the homogeneous difference equation. In fact, we can write

$$(1 - \lambda_iL)(C\lambda_i^t) = C\lambda_i^t - \lambda_iC\lambda_i^{t-1} = 0$$

In addition, given the linearity of the lag operator, any linear combination of solutions of the

homogeneous difference equation is another solution. We can therefore state that the following series solves the homogeneous difference equation:

$$x_t = \sum_{i=1}^p C_i \lambda_i^t$$

By solving the linear system

$$\begin{aligned} x_{-1} &= \sum_{i=1}^p C_i \lambda_i^{-1} \\ x_{-p} &= \sum_{i=1}^p C_i \lambda_i^{-p} \end{aligned}$$

that states that the p initial conditions are satisfied, we can determine the p constants C_s .

Suppose now that all m roots of the characteristic equation are real and coincident. In this case, we can represent a difference equation in the following way:

$$A(L) = 1 - a_1L - \dots - a_pL^p = (1 - \lambda L)^p$$

It can be demonstrated by substitution that, in this case, the general solution of the process is the following:

$$x_t = C_1(\lambda)^t + C_2t(\lambda)^t + \dots + C_p t^{p-1}(\lambda)^t$$

In the most general case, assuming that all roots are real, there will be $m < p$ distinct roots $\varphi_i, i = 1, 2, \dots, m$ each of order $n_i \geq 1$,

$$\sum_{i=1}^m n_i = p$$

and the general solution of the process will be

$$\begin{aligned} x_t &= C_1^1(\lambda_1)^t + C_2^1t(\lambda_1)^t + \dots + C_{n_1}^1 t^{n_1-1}(\lambda_1)^t + \dots \\ &\quad + C_1^m(\lambda_m)^t + C_2^m t(\lambda_m)^t + \dots + C_{n_m}^m t^{n_m-1}(\lambda_m)^t \end{aligned}$$

We can therefore conclude that the solutions of a homogeneous difference equation whose characteristic equation has only real roots is formed by a sum of exponentials. If these roots have modulus greater than unity, then solutions are diverging exponentials; if they have modulus smaller than unity, solutions are exponentials that go to zero. If the roots are unity, solutions are either constants or, if the roots have multiplicity greater than 1, polynomials.

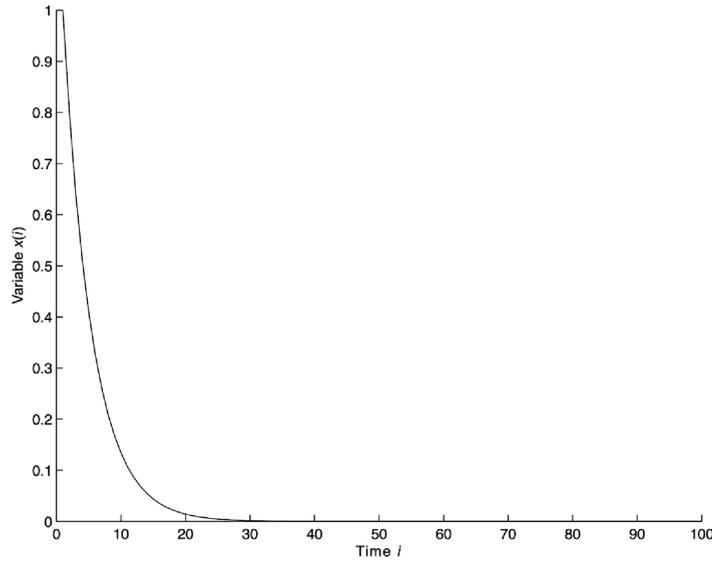

Figure 1 Solution of the Equation $(1 - 0.8L)x_t = 0$ with Initial Condition $x_1 = 1$

Figure 1 illustrates the simple equation

$$A(L)x_t = (1 - 0.8L)x_t = 0, \lambda = 0.8,$$

$$t = 1, 2, \dots, n, \dots$$

whose solution, with initial condition $x_1 = 1$, is

$$x_t = 1.25(0.8)^t$$

The behavior of the solution is that of an exponential decay.

Figure 2 illustrates the equation

$$A(L)x_t = (1 + 0.8L)x_t = 0, \lambda = -0.8,$$

$$t = 1, 2, \dots, n, \dots$$

Simulations were run for 100 time steps

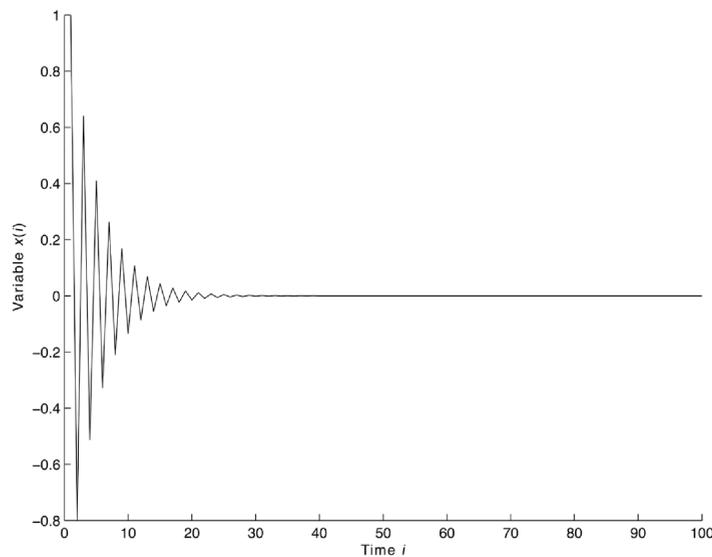

Figure 2 Solution of the Equation $(1 + 0.8L)x_t = 0$ with Initial Condition $x_1 = 1$

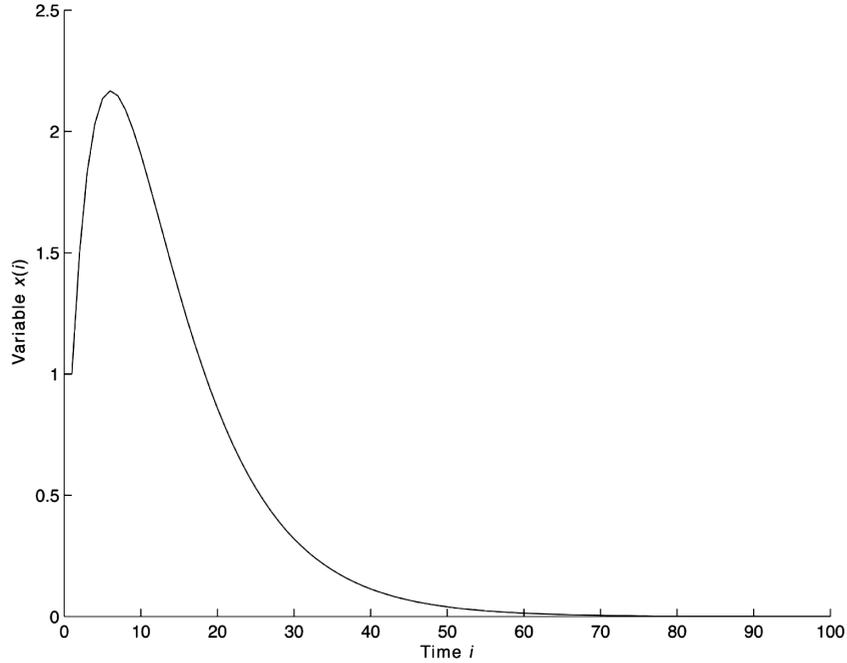

Figure 3 Solution of the Equation $(1 - 1.7L + 0.72L^2)x_t = 0$ with Initial Conditions $x_1 = 1, x_2 = 1.5$

whose solution, with initial condition $x_1 = 1$, is

$$x_t = -1.25(-0.8)^t$$

The behavior of the solution is that of an exponential decay with oscillations at each step. The oscillations are due to the change in sign of the exponential at odd and even time steps.

If the equation has more than one real root, then the solution is a sum of exponentials. Figure 3 illustrates the equation

$$A(L)x_t = (1 - 1.7L + 0.72L^2)x_t = 0, \lambda_1 = 0.8, \\ \lambda_2 = 0.9, \quad t = 1, 2, \dots, n, \dots$$

whose solution, with initial condition $x_1 = 1, x_2 = 1.5$, is

$$x_t = -7.5(0.8)^t + 7.7778(0.9)^t$$

The behavior of the solution is that of an exponential decay after a peak.

Figure 4 illustrates the equation

$$A(L)x_t = (1 - 1.9L + 0.88L^2)x_t = 0, \\ \lambda_1 = 0.8, \lambda_2 = 1.1, \quad t = 1, 2, \dots, n, \dots$$

whose solution, with initial condition $x_1 = 1, x_2 = 1.5$, is

$$x_t = -1.6667(0.8)^t + 2.1212(1.1)^t$$

The behavior is that of exponential explosion due to the exponential with modulus greater than 1.

Complex Roots

Now suppose that some of the roots are complex. In this case, solutions exhibit an oscillating behavior with a period that depends on the model coefficients. For simplicity, consider initially a second-order homogeneous difference equation:

$$A(L)x_t = (1 - a_1L - a_2L^2)x_t$$

Suppose that its characteristic equation given by

$$A(z) = z^2 - a_1z - a_2 = 0$$

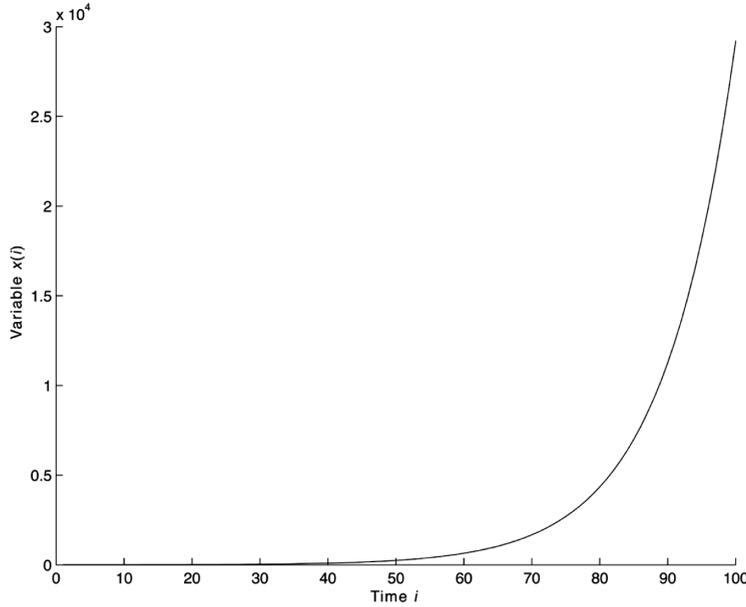

Figure 4 Solution of the Equation $(1 - 1.9L + 0.88L^2)x_t = 0$ with Initial Conditions $x_1 = 1, x_2 = 1.5$

admits the two complex conjugate roots:

$$\lambda_1 = a + ib, \quad \lambda_2 = a - ib$$

Let's write the two roots in polar notation:

$$\lambda_1 = r e^{i\omega}, \quad \lambda_2 = r e^{-i\omega}$$

$$r = \sqrt{a^2 + b^2}, \quad \omega = \arctan \frac{b}{a}$$

It can be demonstrated that the general solution of the above difference equation has the following form:

$$x_t = r^t (C_1 \cos(\omega t) + C_2 \sin(\omega t)) = C r^t \cos(\omega t + \vartheta)$$

where the C_1 and C_2 or C and ϑ are constants to be determined in function of initial conditions. If the imaginary part of the roots vanishes, then ω vanishes and $a = r$, the two complex conjugate roots become a real root, and we find again the expression $x_t = C r^t$.

Consider now a homogeneous difference equation of order $2n$. Suppose that the characteristic equation has only two distinct complex conjugate roots with multiplicity n . We can write the difference equation as follows:

$$A(L)x_t = (1 - a_1 L - \dots - a_{2n} L^{2n})x_t = 0$$

$$= [(1 - \lambda L)^n (1 - \bar{\lambda} L)^n] x_t = 0$$

and its general solution as follows:

$$x_t = r^t (C_1^1 \cos(\omega t) + C_2^1 \sin(\omega t)) + \dots$$

$$+ t^n r^t (C_1^n \cos(\omega t) + C_2^n \sin(\omega t))$$

The general solution of a homogeneous difference equation that admits both real and complex roots with different multiplicities is a sum of the different types of solutions. The above formulas show that real roots correspond to a sum of exponentials while complex roots correspond to oscillating series with exponential dumping or explosive behavior. The above formulas confirm that in both the real and the complex case, solutions decay if the modulus of the roots of the inverse characteristic equation is outside the unit circle and explode if it is inside the unit circle.

Figure 5 illustrates the equation

$$A(L)x_t = (1 - 1.2L + 1.0L^2)x_t = 0,$$

$$t = 1, 2, \dots, n, \dots$$

which has two complex conjugate roots,

$$\lambda_1 = 0.6 + i0.8, \quad \lambda_2 = 0.6 - i0.8$$

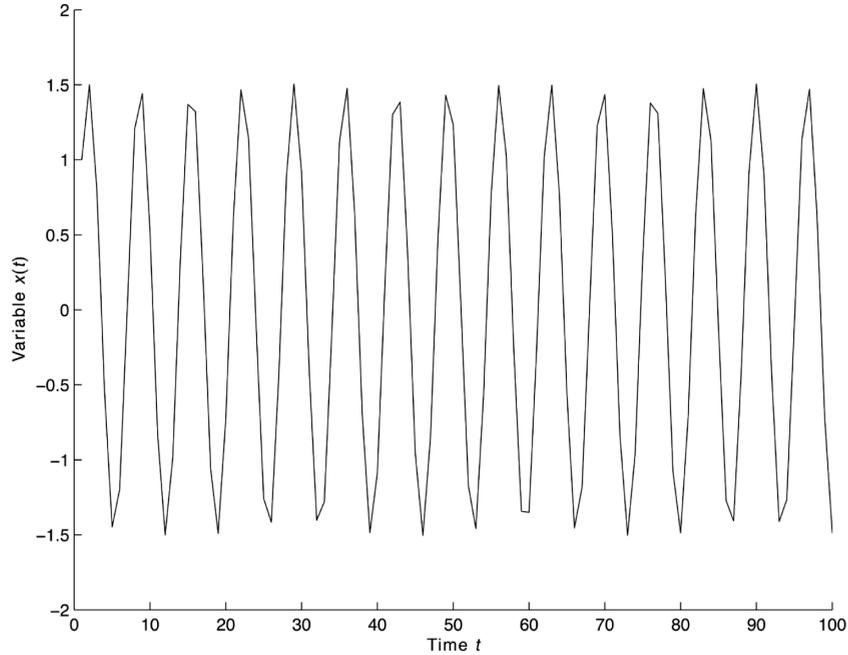

Figure 5 Solutions of the Equation $(1 - 1.2L + 1.0L^2)x_t = 0$ with Initial Conditions $x_1 = 1, x_2 = 1.5$

or in polar form,

$$\lambda_1 = e^{i0.9273}, \quad \lambda_2 = e^{-i0.9273}$$

and whose solution, with initial condition $x_1 = 1, x_2 = 1.5$, is

$$x_t = -0.3 \cos(0.9273t) + 1.475 \sin(0.9273t)$$

The behavior of the solutions is that of undamped oscillations with frequency determined by the model.

Figure 6 illustrates the equation

$$A(L)x_t = (1 - 1.0L + 0.89L^2)x_t = 0, \\ t = 1, 2, \dots, n, \dots$$

which has two complex conjugate roots,

$$\lambda_1 = 0.5 + i0.8, \quad \lambda_2 = 0.5 - i0.8$$

or in polar form,

$$\lambda_1 = 0.9434e^{i1.0122}, \quad \lambda_2 = 0.9434e^{-i1.0122}$$

and whose solution, with initial condition $x_1 = 1, x_2 = 1.5$, is

$$x_t = 0.9434^t (-0.5618 \cos(1.0122t) \\ + 1.6011 \sin(1.0122t))$$

The behavior of the solutions is that of damped oscillations with frequency determined by the model.

NONHOMOGENEOUS DIFFERENCE EQUATIONS

Consider now the following n -th order difference equation:

$$A(L)x_t = (1 - a_1L - \dots - a_pL^p)x_t = y_t$$

where y_t is a given sequence of real numbers. Recall that we are in a deterministic setting, that is, the y_t are given. The general solution of the above difference equation will be the sum of two solutions $x_{1,t} + x_{2,t}$ where $x_{1,t}$ is the solution of the associated homogeneous equation,

$$A(L)x_t = (1 - a_1L - \dots - a_pL^p)x_t = 0$$

and $X_{2,t}$ solves the given *nonhomogeneous equation*.

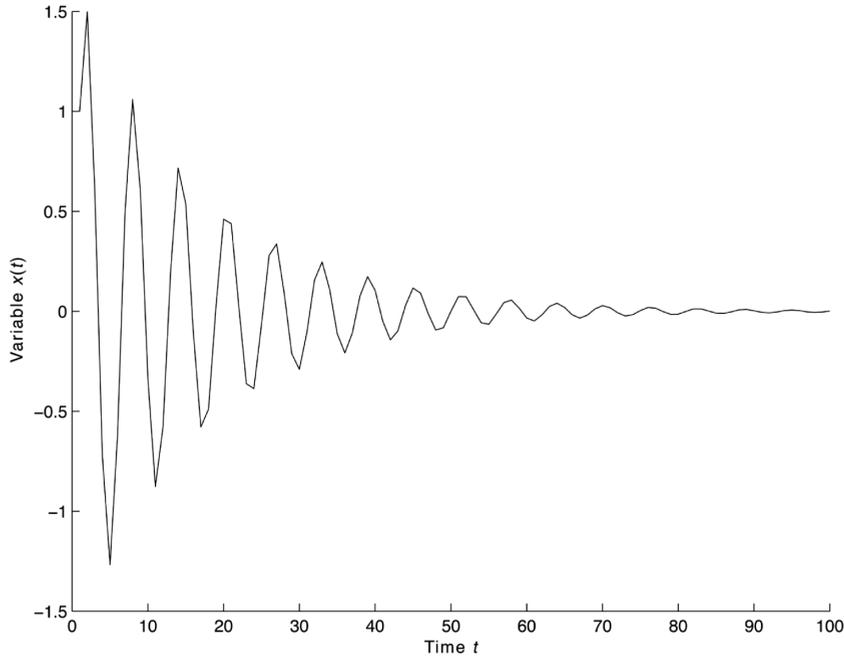

Figure 6 Solutions of the Equation $(1 - 1.0L + 0.89L^2)x_t = 0$ with Initial Conditions $x_1 = 1, x_2 = 1.5$

Real Roots

To determine the general form of $x_{2,t}$ in the case of real roots, we begin by considering the case of a first-order equation:

$$A(L)x_t = (1 - a_1L)x_t = y_t$$

We can compute the solution as follows:

$$x_{2,t} = \frac{1}{(1 - a_1L)}y_t = \left(\sum_{j=0}^{\infty} (a_1L)^j \right) y_t$$

which is meaningful only for $|a_1| < 1$. If, however, y_t starts at $t = -1$, that is, if $y_t = 0$ for $t = -2, -3, \dots, n$, we can rewrite the above formula as

$$x_{2,t} = \frac{1}{(1 - a_1L)}y_t = \left(\sum_{j=0}^{t+1} (a_1L)^j \right) y_t$$

This latter formula, which is valid for any real value of a_1 , yields

$$\begin{aligned} x_{2,0} &= y_0 + a_1y_{-1} \\ x_{2,1} &= y_1 + a_1y_0 + a_1^2y_{-1} \\ x_{2,t} &= y_t + a_1y_{t-1} + \dots + a_1^{t+1}y_{-1} \end{aligned}$$

and so on. These formulas can be easily verified by direct substitution. If $y_t = y = \text{constant}$, then

$$x_{2,t} = y(1 + a_1^2 + \dots + a_1^{t+1})$$

Consider now the case of a second-order equation:

$$\begin{aligned} A(L)x_t &= (1 - a_1L - a_2L^2)x_t \\ &= (1 - \lambda_1L)(1 - \lambda_2L)x_t = y_t \end{aligned}$$

where λ_1, λ_2 are the solutions of the characteristic equation (the reciprocal of the solutions of the inverse characteristic equation). We can write the solution of the above equation as

$$x_{2,t} = \frac{1}{(1 - a_1L - a_2L^2)}y_t = \frac{1}{(1 - \lambda_1L)(1 - \lambda_2L)}y_t$$

Recall that, if $|\lambda_i| < 1, i = 1, 2$, we can write:

$$\begin{aligned} &\frac{1}{(1 - \lambda_1L)(1 - \lambda_2L)} \\ &= \frac{1}{\lambda_1 - \lambda_2} \left(\frac{\lambda_1}{(1 - \lambda_1L)} - \frac{\lambda_2}{(1 - \lambda_2L)} \right) \\ &= \frac{\lambda_1}{\lambda_1 - \lambda_2} \left(\sum_{j=0}^{\infty} (\lambda_1L)^j \right) - \frac{\lambda_2}{\lambda_1 - \lambda_2} \left(\sum_{j=0}^{\infty} (\lambda_2L)^j \right) \end{aligned}$$

so that the solution can be written as

$$x_{2,t} = \frac{\lambda_1}{\lambda_1 - \lambda_2} \left(\sum_{j=0}^{\infty} (\lambda_1 L)^j \right) y_t - \frac{\lambda_2}{\lambda_1 - \lambda_2} \left(\sum_{j=0}^{\infty} (\lambda_2 L)^j \right) y_t$$

If the two solutions are coincident, reasoning as in the homogeneous case, we can establish that the general solutions can be written as follows:

$$x_{2,t} = \frac{1}{(1 - a_1 L)^2} y_t = \left(\sum_{j=0}^{\infty} (a_1 L)^j \right) y_t + t \left(\sum_{j=0}^{\infty} (a_1 L)^j \right) y_t$$

If y_t starts at $t = -2$, that is, if $y_t = 0$ for $t = -3, -4, \dots, -n, \dots$, we can rewrite the above formula respectively as

$$x_{2,t} = \frac{\lambda_1}{\lambda_1 - \lambda_2} \left(\sum_{j=0}^{t+2} (\lambda_1 L)^j \right) y_t - \frac{\lambda_2}{\lambda_1 - \lambda_2} \left(\sum_{j=0}^{t+2} (\lambda_2 L)^j \right) y_t$$

if the solutions are distinct, and as

$$x_{2,t} = \frac{1}{(1 - a_1 L)^2} y_t = \left(\sum_{j=0}^{t+2} (a_1 L)^j \right) y_t + t \left(\sum_{j=0}^{t+2} (a_1 L)^j \right) y_t$$

if the solutions are coincident. These formulas are valid for any real value of λ_1 .

The above formulas can be generalized to cover the case of an n -th order difference equation. In the most general case of an n -th order difference equation, assuming that all roots are real, there will be $m < n$ distinct roots $\lambda_i, i = 1, 2, \dots, m$, each of order $n_i \geq 1$,

$$\sum_{i=1}^m n_i = n$$

and the general solution of the process will be

$$x_{2,t} = \sum_{i=0}^{\infty} ((\lambda_1 L)^i + i(\lambda_1 L)^i + \dots + i^{n_1-1}(\lambda_1 L)^i + \dots + (\lambda_m L)^i + i(\lambda_m L)^i + \dots + i^{n_m-1}(\lambda_m L)^i) y_t$$

if $|\lambda_i| < 1, i = 1, 2, \dots, m$, and

$$x_{2,t} = \sum_{i=0}^{t+m} ((\lambda_1 L)^i + i(\lambda_1 L)^i + \dots + i^{n_1-1}(\lambda_1 L)^i + \dots + (\lambda_m L)^i + i(\lambda_m L)^i + \dots + i^{n_m-1}(\lambda_m L)^i) y_t$$

if y_t starts at $t = -n$, that is, if $y_t = 0$ for $t = -(n+1), -(n+2), \dots$ for any real value of the λ_i .

Therefore, if the roots are all real, the general solution of a difference equation is a sum of exponentials. Figure 7 illustrates the case of the same difference equation as in Figure 3 with the same initial conditions $x_1 = 1, x_2 = 1.5$ but with an exogenous forcing sinusoidal variable:

$$(1 - 1.7L + 0.72L^2)x_t = 0.1 \times \sin(0.4 \times t)$$

The solution of the equation is the sum of $x_{1,t} = -7.5(0.8)^t + 7.7778(0.9)^t$ plus

$$x_{2,t} = \sum [((0.8)^i + (0.9)^i)0.1 \times \sin(0.4 \times (t - i))]$$

After the initial phase dominated by the solution of the homogeneous equation, the forcing term dictates the shape of the solution.

Complex Roots

Consider now the case of complex roots. For simplicity, consider initially a second-order difference equation:

$$A(L)x_t = (1 - a_1 L - a_2 L^2)x_t = y_t$$

Suppose that its characteristic equation,

$$A(z) = z^2 - a_1 z - a_2 = 0$$

admits the two complex conjugate roots,

$$\lambda_1 = a + ib, \quad \lambda_2 = a - ib$$

We write the two roots in polar notation:

$$\lambda_1 = r e^{i\omega}, \quad \lambda_2 = r e^{-i\omega} \\ r = \sqrt{a^2 + b^2}, \quad \omega = \arctan \frac{b}{a}$$

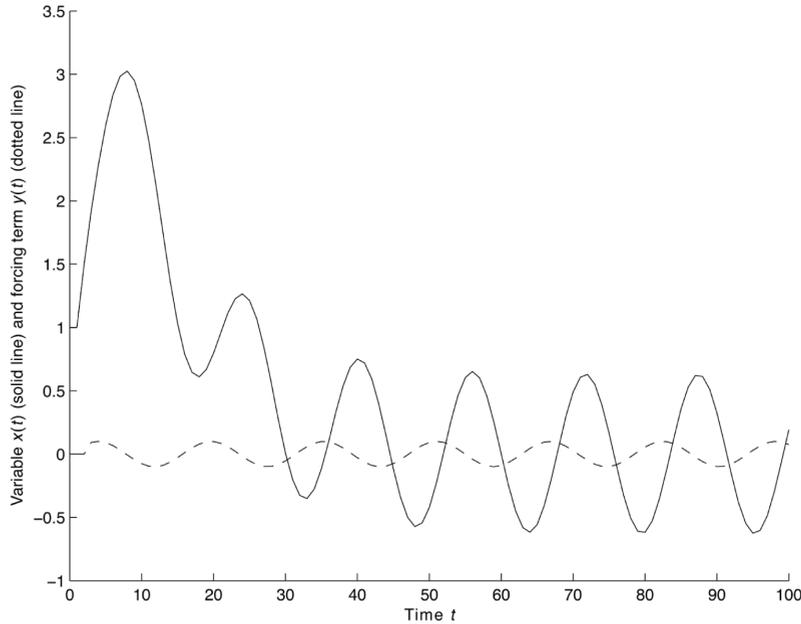

Figure 7 Solutions of the Equation $(1 - 1.7L + 0.72L^2)x_t = 0.1 \times \sin(0.4 \times t)$ with Initial Conditions $x_1 = 1, x_2 = 1.5$

It can be demonstrated that the general form of the $x_{2,t}$ of the above difference equation has the following form:

$$x_{2,t} = \sum_{i=1}^{\infty} (r^i (\cos(\omega i) + \sin(\omega i)) y_{t-i})$$

which is meaningful only if $|r| < 1$. If y_t starts at $t = -2$, that is, if $y_t = 0$ for $t = -3, -4, \dots, -n, \dots$ we can rewrite the previous formula as

$$x_{2,t} = \sum_{i=1}^{t+2} (r^i (\cos(\omega i) + \sin(\omega i)) y_{t-i})$$

This latter formula is meaningful for any real value of r . Note that the constant ω is determined by the structure of the model while the constants C_1, C_2 that appear in $x_{1,t}$ need to be determined in the function of initial conditions. If the imaginary part of the roots vanishes, then ω vanishes and $a = r$, the two complex conjugate roots become a real root, and we again find the expression $x_t = Cr^t$.

Figure 8 illustrates the case of the same difference equation as in Figure 7 with the same initial conditions $x_1 = 1, x_2 = 1.5$ but with an

exogenous forcing sinusoidal variable:

$$(1 - 1.2L + 1.0L^2)x_t = 0.5 \times \sin(0.4 \times t)$$

The solution of the equation is the sum of $x_{1,t} = -0.3\cos(0.9273t) + 1.475 \sin(0.9273t)$ plus

$$x_{2,t} = \sum_{i=0}^{t-1} [(\cos(0.9273i) + \sin(0.9273i))0.5 \sin(0.4 \times (t - i))]$$

After the initial phase dominated by the solution of the homogeneous equation, the forcing term dictates the shape of the solution. Note the model produces amplification and phase shift of the forcing term $0.1 \times \sin(0.4 \times t)$ represented by a dotted line.

SYSTEMS OF LINEAR DIFFERENCE EQUATIONS

In this section, we discuss *systems of linear difference equations* of the type

$$\begin{aligned} x_{1,t} &= a_{11}x_{1,t-1} + \dots + a_{1k}x_{k,t-1} + y_{1,t} \\ x_{k,t} &= a_{k1}x_{1,t-1} + \dots + a_{kk}x_{k,t-1} + y_{k,t} \end{aligned}$$

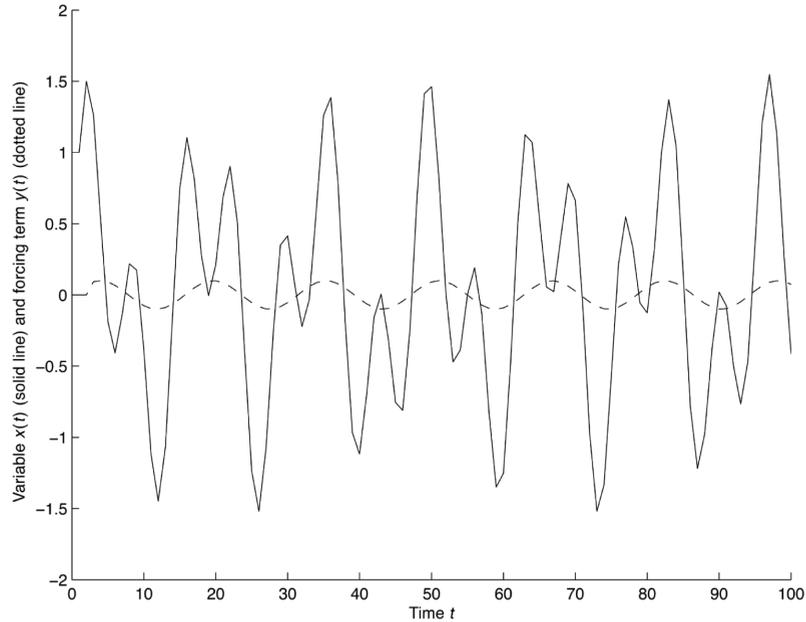

Figure 8 Solutions of the Equation $(1 - 1.2L + 1.0L^2)x_t = 0.5 \times \sin(0.4 \times t)$ with Initial Conditions $x_1 = 1, x_2 = 1.5$

or in vector notation:

$$\mathbf{x}_t = \mathbf{A}\mathbf{x}_{t-1} + \mathbf{y}_t$$

Observe that we need to consider only first-order systems, that is, systems with only one lag. In fact, a system of an arbitrary order can be transformed into a first-order system by adding one variable for each additional lag. For example, a second-order system of two difference equations,

$$\begin{aligned} x_{1,t} &= a_{11}x_{1,t-1} + a_{12}x_{2,t-1} + b_{11}x_{1,t-2} \\ &\quad + b_{12}x_{2,t-2} + y_{1,t} \\ x_{2,t} &= a_{21}x_{1,t-1} + a_{22}x_{2,t-1} + b_{21}x_{1,t-2} \\ &\quad + b_{22}x_{2,t-2} + y_{2,t} \end{aligned}$$

can be transformed in a first-order system adding two variables:

$$\begin{aligned} x_{1,t} &= a_{11}x_{1,t-1} + a_{12}x_{2,t-1} + b_{11}x_{1,t-1} \\ &\quad + b_{12}x_{2,t-1} + y_{1,t} \\ x_{2,t} &= a_{21}x_{1,t-1} + a_{22}x_{2,t-1} + b_{21}x_{1,t-1} \\ &\quad + b_{22}x_{2,t-1} + y_{2,t} \\ z_{1,t} &= x_{1,t-1} \\ z_{2,t} &= x_{2,t-1} \end{aligned}$$

Transformations of this type can be generalized to systems of any order and any number of equations.

A system of difference equations is called *homogeneous* if the exogenous variable \mathbf{y}_t is zero, that is, if it can be written as

$$\mathbf{x}_t = \mathbf{A}\mathbf{x}_{t-1}$$

while it is called *nonhomogeneous* if the exogenous term is present.

There are different ways to solve first-order systems of difference equations. One method consists in eliminating variables as in ordinary algebraic systems. In this way, the original first-order system in k equations is solved by solving a single difference equation of order k with the methods explained above. This observation implies that solutions of systems of linear difference equations are of the same nature as those of difference equations (i.e., sums of exponential and/or sinusoidal functions). In the following section we will show a direct method for solving systems of linear difference equations. This method could be used to solve equations of any order, as they are equivalent to first-order

systems. In addition, it gives a better insight into vector autoregressive processes.

SYSTEMS OF HOMOGENEOUS LINEAR DIFFERENCE EQUATIONS

Consider a homogeneous system of the following type:

$$\mathbf{x}(t) = \mathbf{A}\mathbf{x}(t - 1), \quad t = 0, 1, \dots, n, \dots$$

where \mathbf{A} is a $k \times k$, real-valued, nonsingular matrix of constant coefficients. Using the lag operator notation, we can also write the above systems in the following form:

$$(\mathbf{I} - \mathbf{A}L)\mathbf{x}_t = 0, \quad t = 1, \dots, n, \dots$$

If a vector of initial conditions $\mathbf{x}(0)$ is given, the above system is called an *initial value problem*.

Through recursive computation, that is, starting at $t = 0$ and computing forward, we can write

$$\begin{aligned} \mathbf{x}(1) &= \mathbf{A}\mathbf{x}(0) \\ \mathbf{x}(2) &= \mathbf{A}\mathbf{x}(1) = \mathbf{A}^2\mathbf{x}(0) \\ \mathbf{x}(t) &= \mathbf{A}^t\mathbf{x}(0) \end{aligned}$$

The following theorem can be demonstrated: Any homogeneous system of the type $\mathbf{x}(t) = \mathbf{A}\mathbf{x}(t - 1)$, where \mathbf{A} is a $k \times k$, real-valued, nonsingular matrix, coupled with given initial conditions $\mathbf{x}(0)$ admits one and only one solution.

A set of k solutions $\mathbf{x}_i(t), i = 1, \dots, k, t = 0, 1, 2, \dots$ are said to be linearly independent if

$$\sum_{i=1}^k c_i \mathbf{x}_i(t) = 0$$

$t = 0, 1, 2, \dots$ implies $c_i = 0, i = 1, \dots, k$. Suppose now that k linearly independent solutions $\mathbf{x}_i(t), i = 1, \dots, k$ are given. Consider the matrix

$$\Phi(t) = [\mathbf{x}_1(t) \cdots \mathbf{x}_k(t)]$$

The following matrix equation is clearly satisfied:

$$\Phi(t) = \mathbf{A}\Phi(t - 1)$$

The solutions $\mathbf{x}_i(t), i = 1, \dots, n$ are linearly independent if and only if the matrix $\Phi(t)$ is

nonsingular for every value $t \geq 0$, that is, if $\det[\Phi(t)] \neq 0, t = 0, 1, \dots$. Any nonsingular matrix $\Phi(t), t = 0, 1, \dots$ such that the matrix equation

$$\Phi(t) = \mathbf{A}\Phi(t - 1)$$

is satisfied is called a *fundamental matrix* of the system $\mathbf{x}(t) = \mathbf{A}\mathbf{x}(t - 1), t = 1, \dots, n, \dots$ and it satisfies the equation

$$\Phi(t) = \mathbf{A}^t\Phi(0)$$

In order to compute an explicit solution of this system, we need an efficient algorithm to compute the matrix sequence \mathbf{A}^t . We will discuss one algorithm for this computation.¹ Recall that an eigenvalue of the $k \times k$ real valued matrix $\mathbf{A} = (a_{ij})$ is a real or complex number λ that satisfies the matrix equation:

$$(\mathbf{A} - \lambda\mathbf{I})\xi = 0$$

where $\xi \in \mathbb{C}^k$ is a k -dimensional complex vector. The above equation has a nonzero solution if and only if

$$|(\mathbf{A} - \lambda\mathbf{I})| = 0$$

or

$$\det \begin{pmatrix} a_{11} - \lambda & \cdots & a_{1k} \\ \vdots & \ddots & \vdots \\ a_{k1} & \cdots & a_{kk} - \lambda \end{pmatrix} = 0$$

The above condition can be expressed by the following algebraic equation:

$$z^k + a_1z^{k-1} + \cdots + a_{k-1}z + a_k$$

which is called the characteristic equation of the matrix $\mathbf{A} = (a_{ij})$.

To see the relationship of this equation with the characteristic equations of single equations, consider the k -order equation:

$$\begin{aligned} (1 - a_1L - \cdots - a_kL^k)x(t) &= 0 \\ x_t &= a_1x(t - 1) + \cdots + a_kx(t - k) \end{aligned}$$

which is equivalent to the first-order system,

$$\begin{aligned} x_t &= a_1x_{t-1} + \cdots + a_kz_{t-1}^{k-1} \\ z_t^1 &= x_{t-1} \\ &\vdots \\ z_{t-1}^{k-1} &= x_{t-k} \end{aligned}$$

The matrix

$$\mathbf{A} = \begin{bmatrix} a_1 & a_2 & \cdots & a_{k-1} & a_k \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix}$$

is called the *companion matrix*. By induction, it can be demonstrated that the characteristic equation of the system $\mathbf{x}(t) = \mathbf{A}\mathbf{x}(t-1)$, $t = 1, \dots, n, \dots$ and of the k -order equation above coincide.

Given a system $\mathbf{x}(t) = \mathbf{A}\mathbf{x}(t-1)$, $t = 1, \dots, n, \dots$, we now consider separately two cases: (1) All, possibly complex, eigenvalues of the real-valued matrix \mathbf{A} are distinct, and (2) two or more eigenvalues coincide.

Recall that if λ is a complex eigenvalue with corresponding complex eigenvector ξ , the complex conjugate number $\bar{\lambda}$ is also an eigenvalue with corresponding complex eigenvector $\bar{\xi}$.

If the eigenvalues of the real-valued matrix \mathbf{A} are all distinct, then the matrix can be diagonalized. This means that \mathbf{A} is similar to a diagonal matrix, according to the matrix equation

$$\mathbf{A} = \Xi \begin{bmatrix} \lambda_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n \end{bmatrix} \Xi^{-1}$$

$$\Xi = [\xi_1 \cdots \xi_n]$$

and

$$\mathbf{A}^t = \Xi \begin{bmatrix} \lambda_1^t & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n^t \end{bmatrix} \Xi^{-1}$$

We can therefore write the general solution of the system $\mathbf{x}(t) = \mathbf{A}\mathbf{x}(t-1)$ as follows:

$$\mathbf{x}(t) = c_1 \lambda_1^t \xi_1 + \cdots + c_n \lambda_n^t \xi_n$$

The c_i are complex numbers that need to be determined for the solutions to be real and to satisfy initial conditions. We therefore see the parallel between the solutions of first-order systems of difference equations and the solutions of k -order difference equations that we have determined above. In particular, if solutions are all real they exhibit exponential decay if their modulus is less than 1 or exponential growth if their modulus is greater than 1. If the solutions of the characteristic equation are real, they can produce oscillating damped or undamped behavior with period equal to two time steps. If the solutions of the characteristic equation are complex, then solutions might exhibit damped or undamped oscillating behavior with any period.

To illustrate the above, consider the following second-order system:

$$x_{1,t} = 0.6x_{1,t-1} - 0.1x_{2,t-1} - 0.7x_{1,t-2} + 0.15x_{2,t-2}$$

$$x_{2,t} = -0.12x_{1,t-1} + 0.7x_{2,t-1} + 0.22x_{1,t-2} - 0.85x_{2,t-2}$$

This system can be transformed in the following first-order system:

$$x_{1,t} = 0.6x_{1,t-1} - 0.1x_{2,t-1} - 0.7x_{1,t-2} + 0.15x_{2,t-2}$$

$$x_{2,t} = -0.12x_{1,t-1} + 0.7x_{2,t-1} + 0.22x_{1,t-2} - 0.85x_{2,t-2}$$

$$z_{1,t} = x_{1,t-1}$$

$$z_{2,t} = x_{2,t-1}$$

with matrix

$$\mathbf{A} = \begin{bmatrix} 0.6 & -0.1 & -0.7 & 0.15 \\ -0.12 & 0.7 & 0.22 & -0.8 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}$$

The eigenvalues of the matrix \mathbf{A} are distinct and complex:

$$\lambda_1 = 0.2654 + 0.7011i, \quad \lambda_2 = \bar{\lambda}_1 = 0.2654 - 0.7011i$$

$$\lambda_3 = 0.3846 + 0.8887i, \quad \lambda_4 = \bar{\lambda}_3 = 0.3846 - 0.8887i$$

The corresponding eigenvector matrix Ξ is

$$\Xi = \begin{bmatrix} 0.1571 + 0.4150i & 0.1571 - 0.4150i & -0.1311 - 0.3436i & -0.1311 + 0.3436i \\ -0.0924 + 0.3928i & 0.0924 - 0.3928i & 0.2346 + 0.5419i & 0.2346 - 0.5419i \\ 0.5920 & 0.5920 & -0.3794 - 0.0167i & -0.3794 + 0.0167i \\ 0.5337 + 0.0702i & 0.5337 - 0.0702i & 0.6098 & 0.6098 \end{bmatrix}$$

Each column of the matrix is an eigenvector.
The solution of the system is given by

$$\begin{aligned}
 \mathbf{x}(t) &= c_1 \lambda_1^t \xi_1 + c_2 \overline{\lambda_1^t} \overline{\xi_1} + c_3 \lambda_3^t \xi_3 + c_4 \overline{\lambda_3^t} \overline{\xi_3} \\
 &= c_1 (0.2654 + 0.7011i)^t \begin{pmatrix} 0.1571 + 0.4150i \\ 0.0924 + 0.3928i \\ 0.5920 \\ 0.5337 + 0.0702i \end{pmatrix} \xi_1 \\
 &+ c_2 (0.2654 - 0.7011i)^t \begin{pmatrix} 0.1571 - 0.4150i \\ 0.0924 - 0.3928i \\ 0.5920 \\ 0.5337 - 0.0702i \end{pmatrix} \\
 &+ c_3 (0.3846 + 0.8887i)^t \begin{pmatrix} -0.1311 + 0.3436i \\ 0.2346 + 0.5419i \\ -0.3794 + 0.0167i \\ 0.6098 \end{pmatrix} \xi_3 \\
 &+ c_4 (0.3846 - 0.8887i)^t \begin{pmatrix} -0.1311 - 0.3436i \\ 0.2346 - 0.5419i \\ -0.3794 - 0.0167i \\ 0.6098 \end{pmatrix}
 \end{aligned}$$

The four constants c can be determined using the initial conditions: $x(1) = 1; x(2) = 1.2;$

$y(1) = 1.5; y(2) = -2.$ Figure 9 illustrates the behavior of solutions.

Now consider the case in which two or more solutions of the characteristic equation are coincident. In this case, it can be demonstrated that the matrix \mathbf{A} can be diagonalized only if it is normal, that is if

$$\mathbf{A}^T \mathbf{A} = \mathbf{A} \mathbf{A}^T$$

If the matrix \mathbf{A} is not normal, it cannot be diagonalized. However, it can be put in *Jordan canonical form*. In fact, it can be demonstrated that any nonsingular real-valued matrix \mathbf{A} is similar to a matrix in Jordan canonical form,

$$\mathbf{A} = \mathbf{P} \mathbf{J} \mathbf{P}^{-1}$$

where the matrix \mathbf{J} has the form $\mathbf{J} = \text{diag}[\mathbf{J}_1, \dots, \mathbf{J}_k]$, that is, it is formed by *Jordan diagonal blocks*:

$$\mathbf{J} = \begin{bmatrix} \mathbf{J}_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \mathbf{J}_k \end{bmatrix}$$

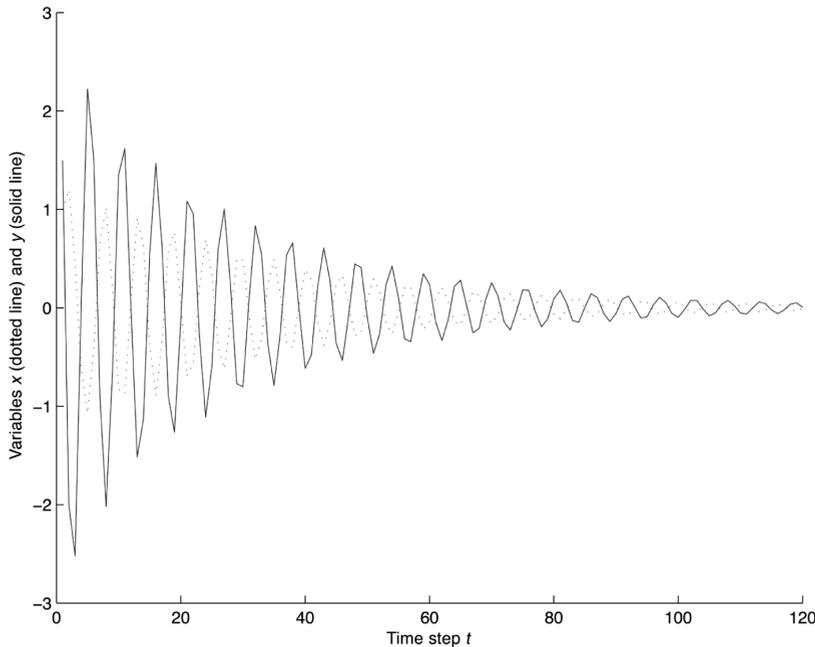

Figure 9 Solution of the System

$$\begin{aligned}
 x_{1,t} &= 0.6x_{1,t-1} - 0.1x_{2,t-1} - 0.7x_{1,t-2} + 0.15x_{2,t-2} \\
 x_{2,t} &= -0.12x_{1,t-1} + 0.7x_{2,t-1} + 0.22x_{1,t-2} - 0.85x_{2,t-2}
 \end{aligned}$$

where each Jordan block has the form

$$J_i = \begin{bmatrix} \lambda_1 & 1 & \cdots & 0 \\ 0 & \lambda_i & \cdots & \vdots \\ \vdots & \vdots & \ddots & 1 \\ 0 & 0 & \cdots & \lambda_i \end{bmatrix}$$

The Jordan canonical form is characterized by two sets of multiplicity parameters, the algebraic multiplicity and the geometric multiplicity. The geometric multiplicity of an eigenvalue is the number of Jordan blocks corresponding to that eigenvalue, while the algebraic multiplicity of an eigenvalue is the number of times the eigenvalue is repeated. An eigenvalue that is repeated s times can have from 1 to s Jordan blocks. For example, suppose a matrix has only one eigenvalue $\lambda = 5$ that is repeated three times. There are four possible matrices with the following Jordan representation:

$$\begin{pmatrix} 5 & 0 & 0 \\ 0 & 5 & 0 \\ 0 & 0 & 5 \end{pmatrix}, \begin{pmatrix} 5 & 1 & 0 \\ 0 & 5 & 0 \\ 0 & 0 & 5 \end{pmatrix}, \begin{pmatrix} 5 & 0 & 0 \\ 0 & 5 & 1 \\ 0 & 0 & 5 \end{pmatrix}, \begin{pmatrix} 5 & 1 & 0 \\ 0 & 5 & 1 \\ 0 & 0 & 5 \end{pmatrix}$$

These four matrices have all algebraic multiplicity 3 but geometric multiplicity from left to right 1, 2, 2, 3, respectively.

KEY POINTS

- Homogeneous difference equations are linear conditions that link the values of variables at different time lags.
- In the case of real roots, solutions are sums of exponentials. Any linear combination of solu-

tions of the homogeneous difference equation is another solution.

- When some of the roots are complex, the solutions of a homogeneous difference equation exhibit an oscillating behavior with a period that depends on the model coefficients.
- The general solution of a homogeneous difference equation that admits both real and complex roots with different multiplicities is a sum of the different types of solutions.
- A system of difference equations is called homogeneous if the system's exogenous variable is zero, and nonhomogeneous if the exogenous term is present.
- One method of solving first-order systems of difference equations is by eliminating variables as in ordinary algebraic systems; another way is a direct method that can be used to solve systems of linear difference equations of any order.

NOTE

1. This discussion of systems of difference equations draws on Elaydi (2002).

Abstract: In financial modeling, the goal is to be able to represent the problem at hand as a mathematical function. In a mathematical function, the dependent variable depends on one or more variables that are referred to as independent variables. In standard calculus, there are two basic operations with mathematical functions: differentiation and integration. The differentiation operation leads to derivatives. When a mathematical function has only one independent variable, then the derivative is referred to as an ordinary derivative. Typically in financial applications, the independent variable is time. The derivative of a mathematical function that has more than one independent variable (one of which is typically time) is called a partial derivative. A differential equation is an equation that contains derivatives. When it contains only an ordinary derivative, it is referred to as an ordinary differential equation; when the differential equation contains partial derivatives, the differential equation is called a partial differential equation.

In nontechnical terms, *differential equations* are equations that express a relationship between a function and one or more *derivatives* (or differentials) of that function. The highest order of derivatives included in a differential equation is referred to as its *order*. In financial modeling, differential equations are used to specify the laws governing the evolution of price distributions, deriving solutions to simple and complex options, and estimating term structure models. In most applications in finance, only first- and second-order differential equations are found.

Differential equations are classified as ordinary differential equations and partial differential equations depending on the type of

derivatives included in the differential equation. When there is only an ordinary derivative (i.e., a derivative of a mathematical function with only one independent variable), the differential equation is called an *ordinary differential equation*. For differential equations where there are partial derivatives (i.e., a derivative of a mathematical function with more than one independent variable), then the differential equation is called a *partial differential equation*. Typically in differential equations, one of the independent variables is time. A differential equation may have a derivative of a mathematical function where one or more of the independent variables is a random variable or a

stochastic process. In such instances, the differential equation is referred to as a *stochastic differential equation*.

The solutions to a differential equation or system of differential equations can be as simple as explicit formulas. When an explicit formula is not possible to obtain, various numerical methods can be used to approximate a solution. Even in the absence of an exact solution, properties of solutions of a differential equation can be determined. A large number of properties of differential equations have been established over the last three centuries. This entry provides only a brief introduction to the concept of differential equations and their properties, limiting our discussion to the principal concepts. We do not cover stochastic differential equations.

DIFFERENTIAL EQUATIONS DEFINED

A differential equation is a condition expressed as a functional link between one or more functions and their derivatives. It is expressed as an equation (that is, as an equality between two terms).

A solution of a differential equation is a function that satisfies the given condition. For example, the condition

$$Y''(x) + \alpha Y'(x) + \beta Y(x) - b(x) = 0$$

equates to zero a linear relationship between an unknown function $Y(x)$, its first and second derivatives $Y'(x), Y''(x)$, and a known function $b(x)$. (In some equations we will denote the first and second derivatives by a single and double prime, respectively.) The unknown function $Y(x)$ is the solution of the equation that is to be determined.

There are two broad types of differential equations: ordinary differential equations and partial differential equations. Ordinary differential equations are equations or systems of equations involving only one independent variable. Another way of saying this is that ordinary

differential equations involve only total derivatives. In contrast, partial differential equations are differential equations or systems of equations involving partial derivatives. That is, there is more than one independent variable.

ORDINARY DIFFERENTIAL EQUATIONS

In full generality, an ordinary differential equation (ODE) can be expressed as the following relationship:

$$F[x, Y(x), Y^1(x), \dots, Y^{(n)}(x)] = 0$$

where $Y^{(m)}(x)$ denotes the m -th derivative of an unknown function $Y(x)$. If the equation can be solved for the n -th derivative, it can be put in the form:

$$Y^{(n)}(x) = G[x, Y(x), Y^{(1)}(x), \dots, Y^{(n-1)}(x)]$$

Order and Degree of an ODE

A differential equation is classified in terms of its order and its degree. The order of a differential equation is the order of the highest derivative in the equation. For example, the above differential equation is of order n since the highest order derivative is $Y^{(n)}(x)$. The degree of a differential equation is determined by looking at the highest derivative in the differential equation. The degree is the power to which that derivative is raised.

For example, the following ordinary differential equations are first-degree differential equations of different orders:

$$Y^{(1)}(x) - 10Y(x) + 40 = 0 \quad (\text{order } 1)$$

$$4Y^{(3)}(x) + Y^{(2)}(x) + Y^{(1)}(x) - 0.5Y(x) + 100 = 0 \quad (\text{order } 3)$$

The following ordinary differential equations are of order 3 and fifth degree:

$$4[Y^{(3)}(x)]^5 + [Y^{(2)}(x)]^2 + Y^{(1)}(x) - 0.5Y(x) + 100 = 0$$

$$4[Y^{(3)}(x)]^5 + [Y^{(2)}(x)]^3 + Y^{(1)}(x) - 0.5Y(x) + 100 = 0$$

When an ordinary differential equation is of the first degree, it is said to be a *linear ordinary differential equation*.

Solution to an ODE

Let's return to the general ODE. A solution of this equation is any function $y(x)$ such that:

$$F[x, y(x), y^{(1)}(x), \dots, y^{(n)}(x)] = 0$$

In general there will be not one but an infinite family of solutions. For example, the equation

$$Y^{(1)}(x) = \alpha Y(x)$$

admits, as a solution, all the functions of the form

$$y(x) = C \exp(\alpha x)$$

To identify one specific solution among the possible infinite solutions that satisfy a differential equation, additional restrictions must be imposed. Restrictions that uniquely identify a solution to a differential equation can be of various types. For instance, one could impose that a solution of an n -th order differential equation passes through n given points. A common type of restriction—called an *initial condition*—is obtained by imposing that the solution and some of its derivatives assume given initial values at some initial point.

Given an ODE of order n , to ensure the uniqueness of solutions it will generally be necessary to specify a starting point and the initial value of $n-1$ derivatives. It can be demonstrated, given the differential equation

$$F[x, Y(x), Y^{(1)}(x), \dots, Y^{(n)}(x)] = 0$$

that if the function F is continuous and all of its partial derivatives up to order n are continuous in some region containing the values $y_0, \dots, y_0^{(n-1)}$, then there is a unique solution $y(x)$ of the equation in some interval $I = (M \leq x \leq L)$ such that $y_0 = Y(x_0), \dots, y_0^{(n-1)} = Y^{(n-1)}(x_0)$.¹ Note that this theorem states that there is an interval in which the solution exists. Existence and uniqueness of solutions in a given interval

is a more delicate matter and must be examined for different classes of equations.

The *general solution* of a differential equation of order n is a function of the form

$$y = \varphi(x, C_1, \dots, C_n)$$

that satisfies the following two conditions:

- *Condition 1.* The function $y = \varphi(x, C_1, \dots, C_n)$ satisfies the differential equation for any n -tuple of values (C_1, \dots, C_n) .
- *Condition 2.* Given a set of initial conditions $y(x_0) = y_0, \dots, y^{(n-1)}(x_0) = y_0^{(n-1)}$ that belong to the region where solutions of the equation exist, it is possible to determine n constants in such a way that the function $y = \varphi(x, C_1, \dots, C_n)$ satisfies these conditions.

The coupling of differential equations with initial conditions embodies the notion of universal determinism of classical physics. Given initial conditions, the future evolution of a system that obeys those equations is completely determined. This notion was forcefully expressed by Pierre-Simon Laplace in the eighteenth century: A supernatural mind who knows the laws of physics and the initial conditions of each atom could perfectly predict the future evolution of the universe with unlimited precision.

In the twentieth century, the notion of universal determinism was challenged twice in the physical sciences. First in the 1920s the development of quantum mechanics introduced the so-called indeterminacy principle which established explicit bounds to the precision of measurements. Later, in the 1970s, the development of *nonlinear dynamics* and chaos theory showed how arbitrarily small initial differences might become arbitrarily large: The flapping of a butterfly's wings in the southern hemisphere might cause a tornado in the northern hemisphere.

SYSTEMS OF ORDINARY DIFFERENTIAL EQUATIONS

Differential equations can be combined to form systems of differential equations. These are sets

of differential conditions that must be satisfied simultaneously. A *first-order system of differential equations* is a system of the following type:

$$\begin{cases} \frac{dy_1}{dx} = f_1(x, y_1, \dots, y_n) \\ \frac{dy_2}{dx} = f_2(x, y_1, \dots, y_n) \\ \cdot \\ \cdot \\ \frac{dy_n}{dx} = f_n(x, y_1, \dots, y_n) \end{cases}$$

Solving this system means finding a set of functions y_1, \dots, y_n that satisfy the system as well as the initial conditions:

$$y_1(x_0) = y_{10}, \dots, y_n(x_0) = y_{n0}$$

Systems of orders higher than one can be reduced to first-order systems in a straightforward way by adding new variables defined as the derivatives of existing variables. As a consequence, an n -th order differential equation can be transformed into a first-order system of n equations. Conversely, a system of first-order differential equations is equivalent to a single n -th order equation.

To illustrate this point, let's differentiate the first equation to obtain

$$\frac{d^2 y_1}{dx^2} = \frac{\partial f_1}{\partial x} + \frac{\partial f_1}{\partial y_1} \frac{dy_1}{dx} + \dots + \frac{\partial f_1}{\partial y_n} \frac{dy_n}{dx}$$

Replacing the derivatives

$$\frac{dy_1}{dx}, \dots, \frac{dy_n}{dx}$$

with their expressions f_1, \dots, f_n from the system's equations, we obtain

$$\frac{d^2 y_1}{dx^2} = F_2(x, y_1, \dots, y_n)$$

If we now reiterate this process, we arrive at the n -th order equation:

$$\frac{d^{(n)} y_1}{dx^{(n)}} = F_n(x, y_1, \dots, y_n)$$

We can thus write the following system:

$$\begin{cases} \frac{dy_1}{dx} = f_1(x, y_1, \dots, y_n) \\ \frac{d^2 y_1}{dx^2} = F_2(x, y_1, \dots, y_n) \\ \cdot \\ \cdot \\ \frac{d^{(n)} y_1}{dx^{(n)}} = F_n(x, y_1, \dots, y_n) \end{cases}$$

We can express y_2, \dots, y_n as functions of $x, y_1, y_1', \dots, y_1^{(n-1)}$ by solving, if possible, the system formed with the first $n-1$ equations:

$$\begin{cases} y_2 = \varphi_2(x, y_1, y_1', \dots, y_1^{(n-1)}) \\ y_3 = \varphi_3(x, y_1, y_1', \dots, y_1^{(n-1)}) \\ \cdot \\ \cdot \\ y_n = \varphi_n(x, y_1, y_1', \dots, y_1^{(n-1)}) \end{cases}$$

Substituting these expressions into the n -th equation of the previous system, we arrive at the single equation:

$$\frac{d^{(n)} y_1}{dx^{(n)}} = \Phi(x, y_1', \dots, y_1^{(n-1)})$$

Solving, if possible, this equation, we find the general solution

$$y_1 = y_1(x, C_1, \dots, C_n)$$

Substituting this expression for y_1 into the previous system, y_2, \dots, y_n can be computed.

CLOSED-FORM SOLUTIONS OF ORDINARY DIFFERENTIAL EQUATIONS

Let's now consider the methods for solving two types of common differential equations: equations with separable variables and equations of linear type. Let's start with equations with separable variables. Consider the equation

$$\frac{dy}{dx} = f(x)g(y)$$

This equation is said to have separable variables because it can be written as an equality between two sides, each depending on only y or only x . We can rewrite our equation in the following way:

$$\frac{dy}{g(y)} = f(x)dx$$

This equation can be regarded as an equality between two differentials in y and x respectively. Their indefinite integrals can differ only by a constant. Integrating the left side with respect to y and the right side with respect to x , we obtain the general solution of the equation:

$$\int \frac{dy}{g(y)} = \int f(x)dx + C$$

For example, if $g(y) \equiv y$, the previous equation becomes

$$\frac{dy}{y} = f(x)dx$$

whose solution is

$$\int \frac{dy}{y} = \int f(x)dx + C \Rightarrow \log y = \int f(x)dx + C \Rightarrow y = A \exp\left(\int f(x)dx\right)$$

where $A = \exp(C)$.

A differential equation of this type describes the continuous compounding of time-varying interest rates. Consider, for example, the growth of capital C deposited in a bank account that earns the variable but deterministic rate $r = f(t)$. When interest rates R_i are constant for discrete periods of time Δt_i , compounding is obtained by purely algebraic formulas as follows:

$$R_i \Delta t_i = \frac{C(t_i) - C(t_{i-\Delta t_i})}{C(t_{i-\Delta t_i})}$$

Solving for $C(t_i)$:

$$C(t_i) = (1 + R_i \Delta t_i)C(t_{i-\Delta t_i})$$

By recursive substitution we obtain

$$C(t_i) = (1 + R_i \Delta t_i)(1 + R_{i-1} \Delta t_{i-1}) \dots (1 + R_1 \Delta t_1)C(t_0)$$

However, market interest rates are subject to rapid change. In the limit of very short time intervals, the instantaneous rate $r(t)$ would be defined as the limit, if it exists, of the discrete interest rate:

$$r(t) = \lim_{\Delta t \rightarrow 0} \frac{C(t + \Delta t) - C(t)}{\Delta t C(t)}$$

The above expression can be rewritten as a simple first-order differential equation in C :

$$r(t)C(t) = \frac{dC(t)}{dt}$$

In a simple intuitive way, the above equation can be obtained considering that in the elementary time dt the bank account increments by the amount $dC = C(t)r(t)dt$. In this equation, variables are separable. It admits the family of solutions:

$$C = A \exp\left(\int r(t)dt\right)$$

where A is the initial capital.

Linear Differential Equation

Linear differential equations are equations of the following type:

$$a_n(x)y^{(n)} + a_{n-1}(x)y^{(n-1)} + \dots + a_1(x)y^{(1)} + a_0(x)y + b(x) = 0$$

If the function b is identically zero, the equation is said to be homogeneous.

In cases where the coefficients a 's are constant, *Laplace transforms* provide a powerful method for solving linear differential equations. (Laplace transforms are one of two popular integral transforms—the other being Fourier transforms—used in financial modeling. Integral transforms are operations that take any function into another function of a different variable through an improper integral.) Consider, without loss of generality, the following linear equation with constant coefficients:

$$a_n y^{(n)} + a_{n-1} y^{(n-1)} + \dots + a_1 y^{(1)} + a_0 y = b(x)$$

together with the initial conditions: $y(0) = y_0, \dots, y^{(n-1)}(0) = y_0^{(n-1)}$. In cases in which the initial point is not the origin, by a variable transformation we can shift the origin.

Laplace Transform

For one-sided Laplace transforms the following formulas hold:

$$\begin{aligned}\mathcal{L}\left(\frac{df(x)}{dx}\right) &= s\mathcal{L}[f(x)] - f(0) \\ \mathcal{L}\left(\frac{d^n f(x)}{dx^n}\right) &= s^n \mathcal{L}[f(x)] - s^{n-1} f(0) - \dots \\ &\quad - f^{(n-1)}(0)\end{aligned}$$

Suppose that a function $y = y(x)$ satisfies the previous linear equation with constant coefficients and that it admits a Laplace transform. Apply one-sided Laplace transform to both sides of the equation. If $Y(s) = \mathcal{L}[y(x)]$, the following relationships hold:

$$\begin{aligned}L(a_n y^{(n)} + a_{n-1} y^{(n-1)} + \dots + a_1 y^{(1)} + a_0 y) \\ &= L[b(x)] \\ a_n [s^n Y(s) - s^{n-1} y^{(1)}(0) - \dots - y^{(n-1)}(0)] \\ &\quad + a_{n-1} [s^{n-1} Y(s) - s^{n-2} y^{(1)}(0) - \dots - y^{(n-2)}(0)] \\ &\quad + \dots + a_0 Y(s) = B(s)\end{aligned}$$

Solving this equation for $Y(s)$, that is, $Y(s) = g[s, y^{(1)}(0), \dots, y^{(n-1)}(0)]$ the inverse Laplace transform $y(t) = \mathcal{L}^{-1}[Y(s)]$ uniquely determines the solution of the equation.

Because inverse Laplace transforms are integrals, with this method, when applicable, the solution of a differential equation is reduced to the determination of integrals. Laplace transforms and inverse Laplace transforms are known for large classes of functions. Because of the important role that Laplace transforms play in solving ordinary differential equations in engineering problems, there are published reference tables. Laplace transform methods also yield closed-form solutions of many ordinary differential equations of interest in economics and finance.

NUMERICAL SOLUTIONS OF ORDINARY DIFFERENTIAL EQUATIONS

Closed-form solutions are solutions that can be expressed in terms of known functions such as polynomials or exponential functions. Before the advent of fast digital computers, the search for closed-form solutions of differential equations was an important task. Today, thanks to the availability of high-performance computing, most problems are solved numerically. This section looks at methods for solving ordinary differential equations numerically.

The Finite Difference Method

Among the methods used to numerically solve ordinary differential equations subject to initial conditions, the most common is the finite difference method. The finite difference method is based on replacing derivatives with difference equations; differential equations are thereby transformed into recursive difference equations.

Key to this method of numerical solution is the fact that ODEs subject to initial conditions describe phenomena that evolve from some starting point. In this case, the differential equation can be approximated with a system of difference equations that compute the next point based on previous points. This would not be possible should we impose boundary conditions instead of initial conditions. In this latter case, we have to solve a system of linear equations.

To illustrate the finite difference method, consider the following simple ordinary differential equation and its solution in a finite interval:

$$\begin{aligned}f'(x) &= f(x) \\ \frac{df}{f} &= dx \\ \log f(x) &= x + C \\ f(x) &= \exp(x + C)\end{aligned}$$

As shown, the closed-form solution of the equation is obtained by separation of variables, that

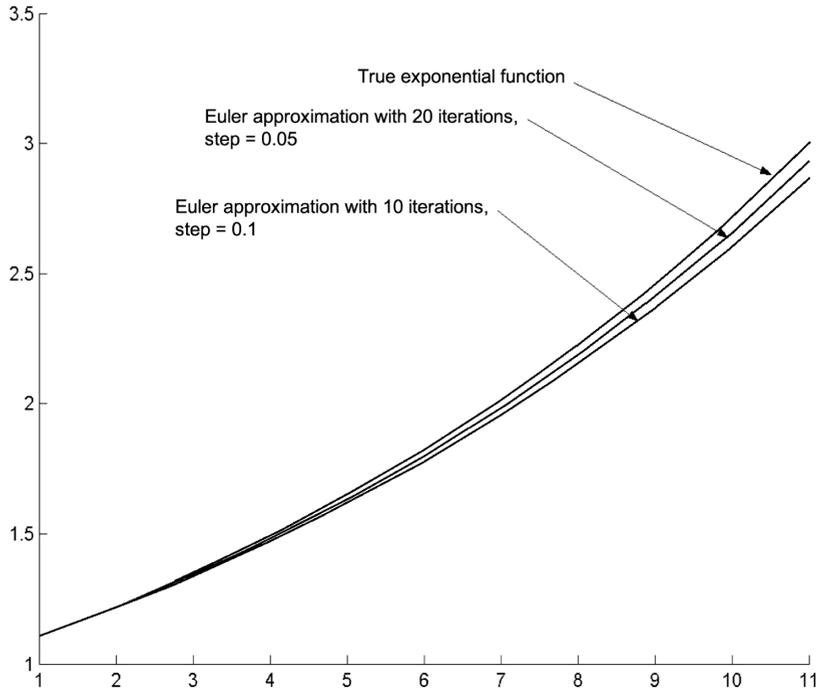

Figure 1 Numerical Solutions of the Equation $f' = f$ with the Euler Approximation for Different Step Sizes

is, by transforming the original equation into another equation where the function f appears only on the left side and the variable x only on the right side.

Suppose that we replace the derivative with its forward finite difference approximation and solve

$$\frac{f(x_{i+1}) - f(x_i)}{x_{i+1} - x_i} = f(x_i)$$

$$f(x_{i+1}) = [1 + (x_{i+1} - x_i)]f(x_i)$$

If we assume that the step size is constant for all i :

$$f(x_i) = [1 + \Delta x]^i f(x_0)$$

The replacement of derivatives with finite differences is often called the Euler approximation. The differential equation is replaced by a recursive formula based on approximating the derivative with a finite difference. The i -th value of the solution is computed from the $i-1$ -th value. Given the initial value of the func-

tion f , the solution of the differential equation can be arbitrarily approximated by choosing a sufficiently small interval. Figure 1 illustrates this computation for different values of Δx .

In the previous example of a first-order linear equation, only one initial condition was involved. Let's now consider a second-order equation:

$$f''(x) = kf(x) = 0$$

This equation describes oscillatory motion, such as the elongation of a pendulum or the displacement of a spring.

To approximate this equation we must approximate the second derivative. This could be done, for example, by combining difference quotients as follows:

$$f'(x) \approx \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

$$f'(x + \Delta x) \approx \frac{f(x + 2\Delta x) - f(x + \Delta x)}{\Delta x}$$

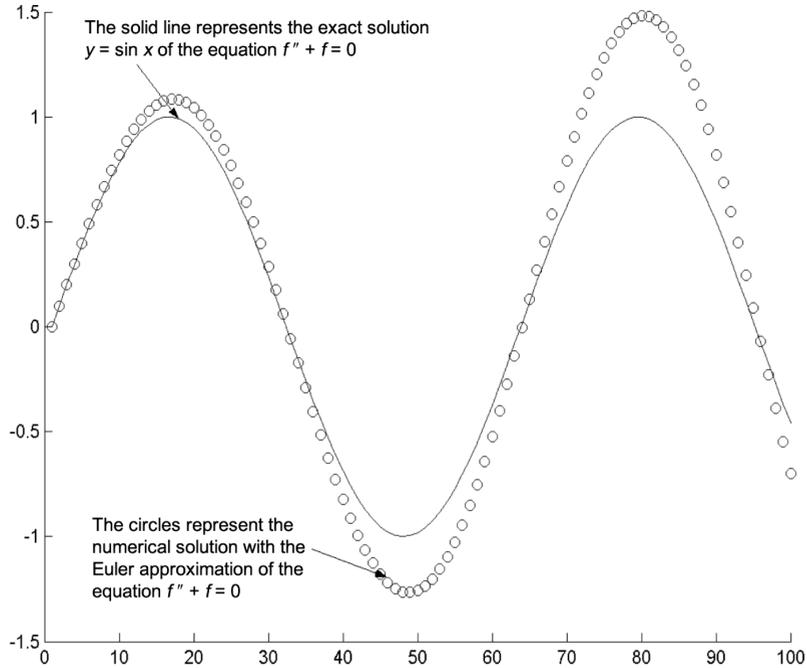

Figure 2 Numerical Solution of the Equation $f'' + f = 0$ with the Euler Approximation

$$\begin{aligned} f''(x) &\approx \frac{f'(x + \Delta x) - f'(x)}{\Delta x} \\ &= \frac{\frac{f(x + 2\Delta x) - f(x + \Delta x)}{\Delta x} - \frac{f(x + \Delta x) - f(x)}{\Delta x}}{\Delta x} \\ &= \frac{f(x + 2\Delta x) - 2f(x + \Delta x) + f(x)}{(\Delta x)^2} \end{aligned}$$

With this approximation, the original equation becomes

$$\begin{aligned} f''(x) + kf(x) &\approx \frac{f(x + 2\Delta x) - 2f(x + \Delta x) + f(x)}{(\Delta x)^2} + kf(x) = 0 \\ f(x + 2\Delta x) - 2f(x + \Delta x) + (1 + k(\Delta x)^2)f(x) &= 0 \end{aligned}$$

We can thus write the approximation scheme:

$$\begin{aligned} f(x + \Delta x) &= f(x) + \Delta x f'(x) \\ f(x + 2\Delta x) &= 2f(x + \Delta x) - (1 + k(\Delta x)^2)f(x) \end{aligned}$$

Given the increment Δx and the initial values $f(0), f'(0)$, using the above formulas we can recursively compute $f(0 + \Delta x), f(0 + 2\Delta x)$, and so on. Figure 2 illustrates this computation.

In practice, the Euler approximation scheme is often not sufficiently precise and more sophisticated approximation schemes are used. For example, a widely used approximation scheme is the *Runge-Kutta method*. We give an example of the Runge-Kutta method in the case of the equation $f'' + f = 0$ which is equivalent to the linear system:

$$\begin{aligned} x' &= y \\ y' &= -x \end{aligned}$$

In this case the Runge-Kutta approximation scheme is the following:

$$\begin{aligned} k_1 &= hy(i) \\ h_1 &= -hx(i) \\ k_2 &= h \left[y(i) + \frac{1}{2}h_1 \right] \\ h_2 &= -h \left[x(i) + \frac{1}{2}k_1 \right] \\ k_3 &= h \left[y(i) + \frac{1}{2}h_2 \right] \\ h_3 &= -h \left[x(i) + \frac{1}{2}k_2 \right] \end{aligned}$$

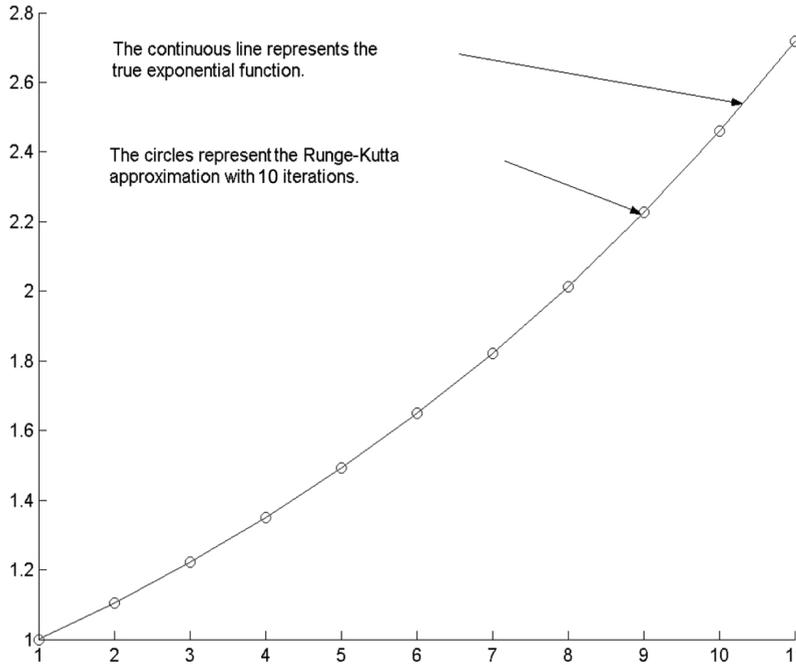

Figure 3 Numerical Solution of the Equation $f' = f$ with the Runge-Kutta Method After 10 Steps

$$\begin{aligned}
 k_4 &= h[y(i) + h_3] \\
 h_4 &= -h[x(i) + k_3] \\
 x(i + 1) &= x(i) + \frac{1}{6}(k_1 + 2k_2 + 2k_3 + k_4) \\
 y(i + 1) &= y(i) + \frac{1}{6}(h_1 + 2h_2 + 2h_3 + h_4)
 \end{aligned}$$

Figures 3 and 4 illustrate the results of this method in the two cases $f' = f$ and $f'' + f = 0$.

As mentioned above, this numerical method depends critically on our having as givens (1) the initial values of the solution, and (2) its first derivative. Suppose that instead of initial values two boundary values were given, for instance the initial value of the solution and its value 1,000 steps ahead, that is, $f(0) = f_0$, $f(0 + 1,000\Delta x) = f_{1000}$. Conditions like these are rarely used in the study of *dynamical systems* as they imply foresight, that is, knowledge of the future position of a system. However, they often appear in static systems and when trying to determine what initial conditions should be imposed to reach a given goal at a given date.

In the case of boundary conditions, one cannot write a direct recursive scheme; it's neces-

sary to solve a system of equations. For instance, we could introduce the derivative $f'(x) = \delta$ as an unknown quantity. The difference quotient that approximates the derivative becomes an unknown. We can now write a system of linear equations in the following way:

$$\begin{cases}
 f(\Delta x) = f_0 + \delta \Delta x \\
 f(2\Delta x) = 2f(\Delta x) - (1 + k(\Delta x)^2)f_0 \\
 f(3\Delta x) = 2f(2\Delta x) - (1 + k(\Delta x)^2)f(\Delta x) \\
 \vdots \\
 \vdots \\
 f_{1000} = 2f(999\Delta x) - (1 + k(\Delta x)^2)f(998\Delta x)
 \end{cases}$$

This is a system of 1,000 equations in 1,000 unknowns. Solving the system we compute the entire solution. In this system two equations, the first and the last, are linked to boundary values; all other equations are transfer equations that express the dynamics (or the law) of the system. This is a general feature of boundary value problems. We will encounter it again when discussing numerical solutions of partial differential equations.

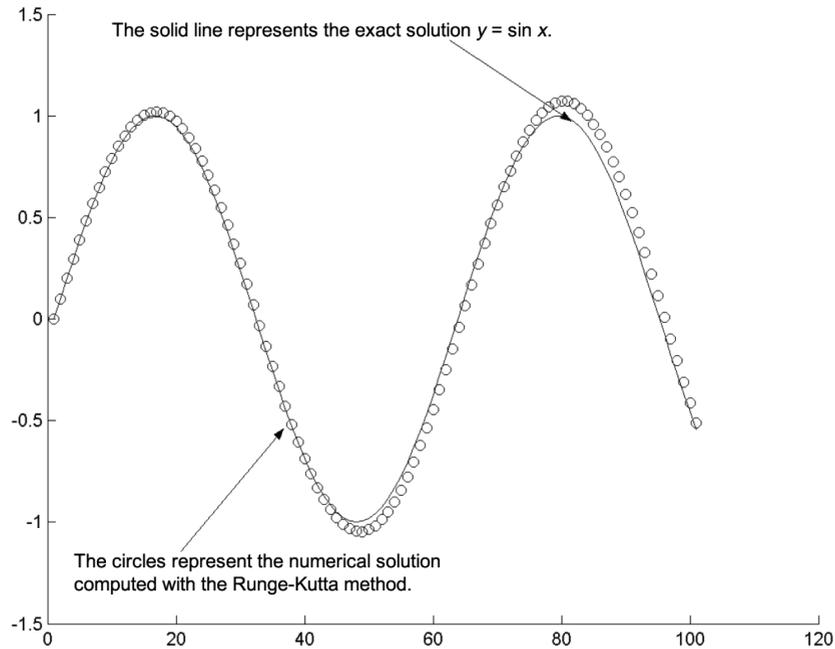

Figure 4 Numerical Solution of the Equation $f'' + f = 0$ with the Runge-Kutta Method

In the above example, we chose a forward scheme where the derivative is approximated with the forward difference quotient. One might use a different approximation scheme, computing the derivative in intervals centered around the point x . When derivatives of higher orders are involved, the choice of the approximation scheme becomes critical. Recall that when we approximated first and second derivatives using forward differences, we were required to evaluate the function at two points $(i, i + 1)$ and three points $(i, i + 1, i + 2)$ ahead respectively. If purely forward schemes are employed, computing higher-order derivatives requires many steps ahead. This fact might affect the precision and stability of numerical computations.

We saw in the examples that the accuracy of a finite difference scheme depends on the discretization interval. In general, a finite difference scheme works, that is, it is consistent and stable, if the numerical solution converges uniformly to the exact solution when the length of the discretization interval tends to zero. Suppose that the precision of an approximation

scheme depends on the length of the discretization interval Δx . Consider the difference $\delta f = \hat{f}(x) - f(x)$ between the approximate and the exact solutions. We say that $\delta f \rightarrow 0$ uniformly in the interval $[a, b]$ when $\Delta x \rightarrow 0$ if, given any ε arbitrarily small, it is possible to find a Δx such that $|\delta f| < \varepsilon$, $\forall x \in [a, b]$.

NONLINEAR DYNAMICS AND CHAOS

Systems of differential equations describe dynamical systems that evolve starting from initial conditions. A fundamental concept in the theory of dynamical systems is that of the *stability of solutions*. This topic has become of paramount importance with the development of nonlinear dynamics and with the discovery of chaotic phenomena. We can only give a brief introductory account of this subject whose role in economics is still the subject of debate.

Intuitively, a dynamical system is considered stable if its solutions do not change much when the system is only slightly perturbed.

There are different ways to perturb a system: changing parameters in its equations, changing the known functions of the system by a small amount, or changing the initial conditions.

Consider an equilibrium solution of a dynamical system, that is, a solution that is time invariant. If a stable system is perturbed when it is in a position of equilibrium, it tends to return to the equilibrium position or, in any case, not to diverge indefinitely from its equilibrium position. For example, a damped pendulum—if perturbed from a position of equilibrium—will tend to go back to an equilibrium position. If the pendulum is not damped it will continue to oscillate forever.

Consider a system of n equations of first order. (As noted above, systems of higher orders can always be reduced to first-order systems by enlarging the set of variables.) Suppose that we can write the system explicitly in the first derivatives as follows:

$$\left\{ \begin{array}{l} \frac{dy_1}{dx} = f_1(x, y_1, \dots, y_n) \\ \frac{dy_2}{dx} = f_2(x, y_1, \dots, y_n) \\ \cdot \\ \cdot \\ \cdot \\ \frac{dy_n}{dx} = f_n(x, y_1, \dots, y_n) \end{array} \right.$$

If the equations are all linear, a complete theory of stability has been developed. Essentially, linear dynamical systems are stable except possibly at singular points where solutions might diverge. In particular, a characteristic of linear systems is that they incur only small changes in the solution as a result of small changes in the initial conditions.

However, during the 1970s, it was discovered that nonlinear systems have a different behavior. Suppose that a nonlinear system has at least three degrees of freedom (that is, it has three independent nonlinear equations). The dynamics of such a system can then become chaotic in the sense that arbitrarily small changes in initial conditions might diverge. This sensitivity

to initial conditions is one of the signatures of *chaos*. Note that while discrete systems such as discrete maps can exhibit chaos in one dimension, continuous systems require at least three degrees of freedom (that is, three equations).

Sensitive dependence from initial conditions was first observed in 1960 by the meteorologist Edward Lorenz of the Massachusetts Institute of Technology. Lorenz remarked that computer simulations of weather forecasts starting, apparently, from the same meteorological data could yield very different results. He argued that the numerical solutions of extremely sensitive differential equations such as those he was using produced diverging results due to rounding-off errors made by the computer system. His discovery was published in a meteorological journal where it remained unnoticed for many years.

Fractals

While in principle deterministic chaotic systems are unpredictable because of their sensitivity to initial conditions, the statistics of their behavior can be studied. Consider, for example, the chaos laws that describe the evolution of weather: While the weather is basically unpredictable over long periods of time, long-run simulations are used to predict the statistics of weather.

It was discovered that probability distributions originating from chaotic systems exhibit *fat tails* in the sense that very large, extreme events have nonnegligible probabilities. (See Brock, Hsieh, and LeBaron [1991] and Hsieh [1991].) It was also discovered that chaotic systems exhibit complex unexpected behavior. The motion of chaotic systems is often associated with self-similarity and fractal shapes.

Fractals were introduced in the 1960s by Benoit Mandelbrot, a mathematician working at the IBM research center in Yorktown Heights, New York. Starting from the empirical observation that cotton price time-series are similar at different time scales, Mandelbrot developed a powerful theory of fractal geometrical objects.

Fractals are geometrical objects that are geometrically similar to part of themselves. Stock prices exhibit this property insofar as price time-series look the same at different time scales.

Chaotic systems are also sensitive to changes in their parameters. In a chaotic system, only some regions of the parameter space exhibit chaotic behavior. The change in behavior is abrupt and, in general, it cannot be predicted analytically. In addition, chaotic behavior appears in systems that are apparently very simple.

While the intuition that chaotic systems might exist is not new, the systematic exploration of chaotic systems started only in the 1970s. The discovery of the existence of nonlinear chaotic systems marked a conceptual crisis in the physical sciences: It challenges the very notion of the applicability of mathematics to the description of reality. Chaos laws are not testable on a large scale; their applicability cannot be predicted analytically. Nevertheless, the statistics of chaos theory might still prove to be meaningful.

The economy being a complex system, the expectation was that its apparently random behavior could be explained as a deterministic chaotic system of low dimensionality. Despite the fact that tests to detect low-dimensional chaos in the economy have produced a substantially negative response, it is easy to make macroeconomic and financial econometric models exhibit chaos. (See Brock, Dechert, Scheinkman, and LeBaron [1996] and Brock and Hommes [1997].) As a matter of fact, most macroeconomic models are nonlinear. Though chaos has not been detected in economic time-series, most economic dynamic models are nonlinear in more than three dimensions and thus potentially chaotic. At this stage of the research, we might conclude that if chaos exists in economics it is not of the low-dimensional type.

PARTIAL DIFFERENTIAL EQUATIONS

To illustrate the notion of a partial differential equation (PDE), let's start with equations in two

dimensions. An n -order PDE in two dimensions x, y is an equation of the form

$$F\left(x, y, \frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}, \dots, \frac{\partial^{(i)} f}{\partial^{(k)} x \partial^{(i-k)} y}\right) = 0, 0 \leq k \leq i, 0 \leq i \leq n$$

A solution of the previous equation will be any function that satisfies the equation.

In the case of PDEs, the notion of initial conditions must be replaced with the notion of boundary conditions or initial plus boundary conditions. Solutions will be defined in a multidimensional domain. To identify a solution uniquely, the value of the solution on some subdomain must be specified. In general, this subdomain will coincide with the boundary (or some portion of the boundary) of the domain.

Diffusion Equation

Different equations will require and admit different types of boundary and initial conditions. The question of the existence and uniqueness of solutions of PDEs is a delicate mathematical problem. We can only give a brief account by way of an example.

Let's consider the *diffusion equation*. This equation describes the propagation of the probability density of stock prices under the random-walk hypothesis:

$$\frac{\partial f}{\partial t} = a^2 \frac{\partial^2 f}{\partial x^2}$$

The *Black-Scholes equation*, which describes the evolution of option prices, can be reduced to the diffusion equation.

The diffusion equation describes propagating phenomena. Call $f(t, x)$ the probability density that prices have value x at time t . In finance theory, the diffusion equation describes the time-evolution of the probability density function $f(t, x)$ of stock prices that follow a random walk.² It is therefore natural to impose initial and boundary conditions on the distribution of prices.

In general, we distinguish two different problems related to the diffusion equation: the first

boundary value problem and the Cauchy initial value problem, named after the French mathematician Augustin Cauchy who first formulated it. The two problems refer to the same diffusion equation but consider different domains and different initial and boundary conditions. It can be demonstrated that both problems admit a unique solution.

The first boundary value problem seeks to find in the rectangle $0 \leq x \leq l$, $0 \leq t \leq T$ a continuous function $f(t, x)$ that satisfies the diffusion equation in the interior Q of the rectangle plus the following initial condition,

$$f(0, x) = \phi(x), \quad 0 \leq x \leq l$$

and boundary conditions,

$$f(t, 0) = f_1(t), \quad f(t, l) = f_2(t), \quad 0 \leq t \leq T$$

The functions f_1, f_2 are assumed to be continuous and $f_1(0) = \phi(0), f_2(0) = \phi(l)$.

The Cauchy problem is related to an infinite half plane instead of a finite rectangle. It is formulated as follows. The objective is to find for any x and for $t \geq 0$ a continuous and bounded function $f(t, x)$ that satisfies the diffusion equation and which, for $t = 0$, is equal to a continuous and bounded function $f(0, x) = \phi(x), \forall x$.

Solution of the Diffusion Equation

The first boundary value problem of the diffusion equation can be solved exactly. We illustrate here a widely used method based on the separation of variables, which is applicable if the boundary conditions on the vertical sides vanish (that is, if $f_1(t) = f_2(t) = 0$). The method involves looking for a tentative solution in the form of a product of two functions, one that depends only on t and the other that depends only on x : $f(t, x) = h(t)g(x)$.

If we substitute the previous tentative solution in the diffusion equation

$$\frac{\partial f}{\partial t} = a^2 \frac{\partial^2 f}{\partial x^2}$$

we obtain an equation where the left side depends only on t while the right side depends

only on x :

$$\begin{aligned} \frac{dh(t)}{dt} g(x) &= a^2 h(t) \frac{d^2 g(x)}{dx^2} \\ \frac{dh(t)}{dt} \frac{1}{h(t)} &= a^2 \frac{d^2 g(x)}{dx^2} \frac{1}{g(x)} \end{aligned}$$

This condition can be satisfied only if the two sides are equal to a constant. The original diffusion equation is therefore transformed into two ordinary differential equations:

$$\begin{aligned} \frac{1}{a^2} \frac{dh(t)}{dt} &= bh(t) \\ \frac{d^2 g(x)}{dx^2} &= bg(x) \end{aligned}$$

with boundary conditions $g(0) = g(l) = 0$. From the above equations and boundary conditions, it can be seen that b can assume only the negative values,

$$b = -\frac{k^2 \pi^2}{l^2}, \quad k = 1, 2, \dots$$

while the functions g can only be of the form

$$g(x) = B_k \sin \frac{k\pi}{l} x$$

Substituting for h , we obtain

$$h(t) = B'_k \exp\left(-\frac{a^2 k^2 \pi^2}{l^2} t\right)$$

Therefore, we can see that there are denumerably infinite solutions of the diffusion equation of the form

$$f_x(t, x) = C_k \exp\left(-\frac{a^2 k^2 \pi^2}{l^2} t\right) \sin \frac{k\pi}{l} x$$

All these solutions satisfy the boundary conditions $f(t, 0) = f(t, l) = 0$. By linearity, we know that the infinite sum

$$\begin{aligned} f(t, x) &= \sum_{k=1}^{\infty} f_k(t, x) \\ &= \sum_{k=1}^{\infty} C_k \exp\left(-\frac{a^2 k^2 \pi^2}{l^2} t\right) \sin \frac{k\pi}{l} x \end{aligned}$$

will satisfy the diffusion equation. Clearly $f(t, x)$ satisfies the boundary conditions $f(t, 0) = f(t, l) = 0$. In order to satisfy the initial condition, given that $\phi(x)$ is bounded and continuous and

that $\phi(0) = \phi(l) = 0$, it can be demonstrated that the coefficients C_k can be uniquely determined through the following integrals, which are called the Fourier integrals:

$$C_k = \frac{2}{L} \int_0^L \phi(\xi) \sin\left(\frac{\pi k}{L} \xi\right) d\xi$$

The previous method applies to the first boundary value problem but cannot be applied to the Cauchy problem, which admits only an initial condition. It can be demonstrated that the solution of the Cauchy problem can be expressed in terms of a convolution with a Green's function. In particular, it can be demonstrated that the solution of the Cauchy problem can be written in closed form as follows:

$$f(t, x) = \frac{1}{2\sqrt{\pi t}} \int_{-\infty}^{\infty} \frac{\phi(\xi)}{\sqrt{t}} \exp\left\{-\frac{(x-\xi)^2}{4t}\right\} d\xi$$

for $t > 0$ and $f(0, x) = \phi(x)$. It can be demonstrated that the Black-Scholes equation, which

is an equation of the form

$$\frac{\partial f}{\partial t} + \frac{1}{2}\sigma^2 x^2 \frac{\partial^2 f}{\partial x^2} + rx \frac{\partial f}{\partial x} - rf = 0$$

can be reduced through transformation of variables to the standard diffusion equation to be solved with the Green's function approach.

Numerical Solution of PDEs

There are different methods for the numerical solution of PDEs. We illustrate the finite difference methods, which are based on approximating derivatives with finite differences. Other discretization schemes such as finite elements and spectral methods are possible but, being more complex, they go beyond the scope of this book.

Finite difference methods result in a set of recursive equations when applied to initial conditions. When finite difference methods are applied to boundary problems, they require the solution of systems of simultaneous linear equations. PDEs might exhibit boundary conditions, initial conditions, or a mix of the two.

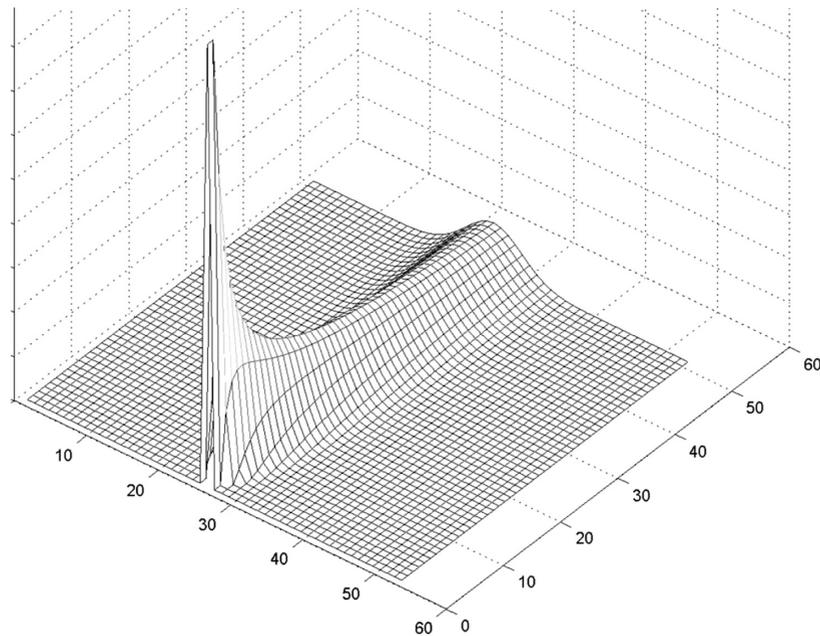

Figure 5 Solution of the Cauchy Problem by the Finite Difference Method

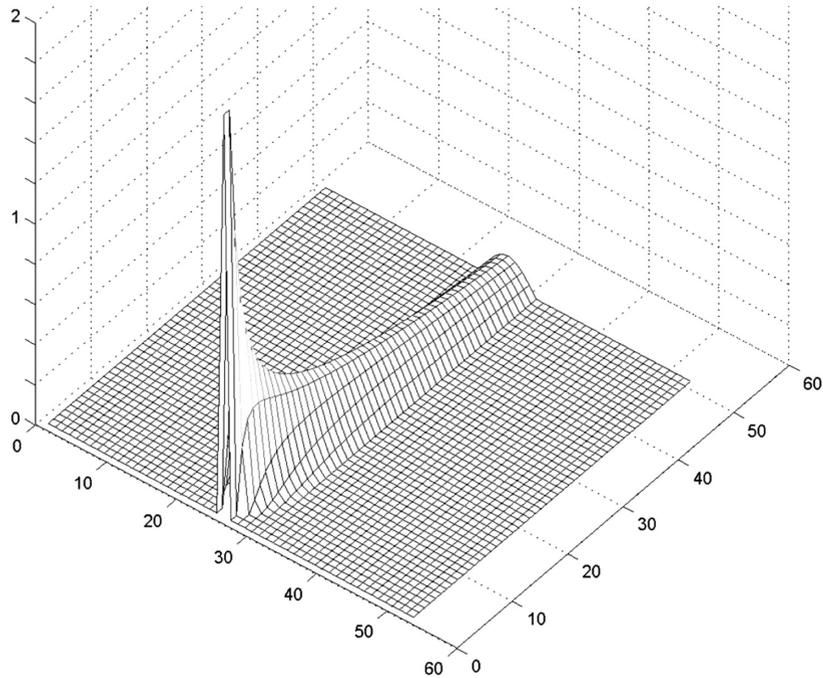

Figure 6 Solution of the First Boundary Problem by the Finite Difference Method

The Cauchy problem of the diffusion equation is an example of initial conditions. The simplest discretization scheme for the diffusion equation replaces derivatives with their difference quotients. As for ordinary differential equations, the discretization scheme can be written as follows:

$$\frac{\partial f}{\partial t} \approx \frac{f(t + \Delta t, x) - f(t, x)}{\Delta t}$$

$$\frac{\partial^2 f}{\partial x^2} \approx \frac{f(t, x + \Delta x) - 2f(t, x) + f(t, x - \Delta x)}{(\Delta x)^2}$$

In the case of the Cauchy problem, this approximation scheme defines the forward recursive algorithm. It can be proved that the algorithm is stable only if the Courant-Friedrichs-Lewy (CFL) conditions

$$\Delta t < \frac{(\Delta x)^2}{2a^2}$$

are satisfied.

Different approximation schemes can be used. In particular, the forward approximation to the derivative used above could be replaced by centered approximations. Figure 5 illustrates the solution of a Cauchy problem for initial conditions that vanish outside of a finite interval. The simulation shows that solutions diffuse in the entire half space.

Applying the same discretization to a first boundary problem would require the solution of a system of linear equations at every step. Figure 6 illustrates this case.

KEY POINTS

- Basically, differential equations are equations that express a relationship between a function and one or more derivatives (or differentials) of that function.
- The two classifications of differential equations are ordinary differential equations and partial differential equations. The classification depends on the type of derivatives

included in the differential equation: ordinary differential equation when there is only an ordinary derivative and partial differential equation where there are partial derivatives.

- Typically in differential equations, one of the independent variables is time.
- The term stochastic differential equation refers to a differential equation in which a derivative of one or more of the independent variables is a random variable or a stochastic process.
- Differential equations are conditions that must be satisfied by their solutions. Differential equations generally admit infinite solutions. Initial or boundary conditions are needed to identify solutions uniquely.
- Differential equations are the key mathematical tools for the development of modern science; in finance they are used in arbitrage pricing, to define stochastic processes, and to compute the time evolution of averages.
- Differential equations can be solved in closed form or with numerical methods. Finite difference methods approximate derivatives with difference quotients. Initial conditions yield recursive algorithms.
- Boundary conditions require the solution of linear equations.

NOTES

1. The condition of existence and continuity of derivatives is stronger than necessary. The Lipschitz condition, which requires that the incremental ratio be uniformly bounded in a given interval, would suffice.
2. In physics, the diffusion equation describes phenomena such as the diffusion of particles suspended in some fluid. In this case, the diffusion equation describes the density of particles at a given moment at a given point.

Abstract: Partial differential equations are useful in finance in various contexts, in particular for the pricing of European and American options, for stochastic portfolio optimization, and for calibration. They can be used for simple options as well as for more exotic ones, such as Asian or lookback options. They are particularly useful for nonlinear models. They allow for the numerical computations of several spot prices at the same time. Numerical aspects, discretization methods, algorithms, and analysis of the numerical schemes have been under constant development during the last three decades. Finite difference methods are the simplest and most basic approaches. Finite element methods allow the use of nonuniform meshes and refinement procedures can then be applied and improve accuracy near a region of interest. Deterministic approaches based on partial differential equation formulations can also be used for calibration of various volatility models (such as local, stochastic, or Levy-driven volatility models) and by making use of Dupire's formula. Current research directions include the development of discretization methods for high-dimensional problems.

Numerical methods based on *partial differential equations (PDEs) in finance* are not very popular. Indeed, the models are usually derived from probabilistic arguments and Monte Carlo methods are therefore much more natural. Stochastic methods are also often simpler to implement than the algorithms used for solving the related PDEs. However, when it is possible to efficiently discretize the PDE (which

is not always the case, the typical counterexample being high-dimensional problems), deterministic methods are usually more efficient than stochastic ones. Moreover, the solution to the partial differential equation gives more information. In the context of option pricing, one obtains, for example, the price of the option for all values of the maturity and for all spot prices, while the probabilistic formulation

typically gives the value of the option for a fixed maturity and a fixed spot price. In particular, this is useful for computing derivatives of the option's price with respect to some parameters of the model (the so-called "Greeks").

The PDEs obtained in finance have several characteristics. First, they are posed on a bounded domain in time $(0, T)$, with typically a singular final condition at the maturity $t = T$, and very often in an unbounded domain in the spot variable, which requires to impose suitable "boundary conditions" at infinity to get well-posed problems and to use appropriate numerical approximations (truncation to a bounded domain and artificial boundary conditions). These PDEs are usually of parabolic type, but often with degenerate diffusions. Because of operational constraints, the numerical methods used for the discretization of the PDE must be sufficiently fast and accurate to be useful in practice. These peculiarities of PDEs in finance explain the need for up-to-date and sometimes involved numerical methods.

In this entry we focus on numerical issues and try to review the main numerical methods used for solving PDEs in finance. This presentation heavily relies on Achdou and Pironneau (2005), as well as Lamberton and Lapeyre (1997), Karatzas and Shreve (1991), and Wilmott, Dewynne, and Howison (1993).

PARTIAL DIFFERENTIAL EQUATIONS FOR OPTION PRICING

In this section, we present the main arguments to derive a PDE for the price of various European and American options.

A Primer: The Black and Scholes Model for European Options

The aim of this section is to recall the basic tools needed to derive a PDE in the context of option pricing, without providing all the detailed assumptions required on the data to perform

this derivation. Karatzas and Shreve (1991) and Lamberton and Lapeyre (1997), for example, provide more details on the mathematical aspects. We adopt the standard *Black and Scholes* model (Black and Scholes, 1973; Merton, 1973) with a risky asset whose price at time t is S_t and a risk-free asset whose price at time t is S_t^0 , such that:

$$dS_t = S_t(\mu dt + \sigma dB_t), \quad dS_t^0 = rS_t^0 dt$$

The process B_t is a standard Brownian motion defined on a probability space $(\Omega, \mathcal{F}, \mathcal{F}_t, \mathbb{Q})$, and μ (the mean rate of return), r (the interest rate), and $\sigma > 0$ (the volatility) are three constants. However, the following can be generalized to the case where μ , r , and $\sigma > 0$ are functions of t and S (under suitable smoothness assumptions).

We introduce the stochastic process $W_t = B_t + \frac{\mu-r}{\sigma}t$. Under the so-called risk-neutral probability \mathbb{P} defined by its Radon-Nikodym derivative with respect to \mathbb{Q} by

$$\frac{d\mathbb{P}}{d\mathbb{Q}} \Big|_{\mathcal{F}_t} = \exp \left(\int_0^t \frac{r-\mu}{\sigma} dB_s - \frac{1}{2} \int_0^t \left(\frac{r-\mu}{\sigma} \right)^2 ds \right)$$

W_t is a Brownian motion and S_t/S_t^0 is a martingale. This is one of the fundamental properties of the stochastic process needed in the following. The process S_t satisfies the following stochastic differential equation (SDE) under \mathbb{P} :

$$dS_t = S_t(r dt + \sigma dW_t) \quad (1)$$

Let us now consider a portfolio with H_t risky assets and H_t^0 no-risk assets. Its value at time t is:

$$P_t = H_t S_t + H_t^0 S_t^0 \quad (2)$$

We suppose that this portfolio is self-financing (any manipulation on this portfolio, i.e., any change of the values of H_t or H_t^0 , is done without any inflows or outflows of money), which translates into

$$dP_t = H_t dS_t + H_t^0 dS_t^0 \quad (3)$$

The value of a self-financing portfolio changes if and only if the price of the risky asset changes.

Using (3), it is possible to show that P_t/S_t^0 is also a martingale.

We consider the following problem: For a given function ϕ (the payoff function) and a given time $T > 0$ (the maturity), is it possible to build a self-financing portfolio such that $P_T = \phi(S_T)$? Classical examples of function ϕ are $\phi(S) = (S - K)_+$ (vanilla call) or $\phi(S) = (S - K)_-$ (vanilla put), where, for any real x , $x_+ = \max(x, 0)$ and $x_- = \max(-x, 0)$. The answer is positive (this is typically based on a martingale representation theorem, the fact that P_t/S_t^0 is a martingale, and the fact that the payoff $\phi(S_T)$ is \mathcal{F}_T -measurable), and it is then possible to show that such a portfolio has the following value at time t :

$$P_t = \mathbb{E} \left(\exp \left(- \int_t^T r \, ds \right) \phi(S_T) \middle| \mathcal{F}_t \right) \quad (4)$$

where here and in the following, \mathbb{E} denotes an expectation with respect to the risk-neutral probability \mathbb{P} . By the so-called arbitrage-free principle, P_t is actually the “fair price” at time t of the option, which enables its owner to get the payoff $\phi(S_T)$ at time T . In the particular context of vanilla options, the solution is analytically known, at least if r and σ are constant: This is the celebrated Black and Scholes formula. However, in the case when r and σ are functions of t and S , (4) cannot be estimated without a numerical method. We are interested in deterministic numerical methods, based on a PDE related to (4).

The second fundamental property of the stochastic process S_t required to obtain a PDE formulation of this problem is a Markov property. Roughly speaking, it states that the expectation of any function of $(S_t)_{0 \leq t \leq T}$ conditionally to \mathcal{F}_t is actually a function of the price S_t of the risky asset at time t . In our context, this property shows that P_t writes

$$P_t = p(t, S_t) \quad (5)$$

where p is a function of $t \in [0, T]$ and $S \in [0, \infty)$, called the pricing function of the option. Notice that even if (5) only involves the value of p at

point (t, S_t) , the pricing function p is a deterministic function defined for all values of $t \geq 0$ and $S \geq 0$. By the Markov property of S_t , we also have the following representation formula for p :

$$p(t, x) = \mathbb{E} \left(\exp \left(- \int_t^T r \, ds \right) \phi(S_T^{t,x}) \right) \quad (6)$$

where $(S_\theta^{t,x})_{t \leq \theta \leq T}$ denotes the process solution to (1) starting from x at time t

$$\begin{cases} dS_\theta^{t,x} = S_\theta^{t,x} (r \, d\theta + \sigma \, dW_\theta), & \theta \geq t, \\ S_t^{t,x} = x \end{cases} \quad (7)$$

By using Ito’s calculus and the fact that P_t/S_t^0 is a martingale, we then obtain that p should satisfy the following backward-in-time PDE:

$$\begin{cases} \frac{\partial p}{\partial t} + rS \frac{\partial p}{\partial S} + \frac{\sigma^2 S^2}{2} \frac{\partial^2 p}{\partial S^2} - rp = 0, \\ p(T, S) = \phi(S) \end{cases} \quad (8)$$

Conversely, it is possible (using again a martingale representation theorem) to show that if p satisfies (8), then $p(t, S_t)$ is the value of a self-financing portfolio with value $\phi(S_T)$ at time T . Moreover, one can check that $\frac{\partial p}{\partial S}(t, S_t) = H_t$, which shows that obtaining an accurate approximation of $\frac{\partial p}{\partial S}$ is important in order to estimate the quantity of risky asset H_t needed at time t to build the portfolio with value P_t (this is the hedging strategy). Collectively, equations (4)–(5) and (8) provide an example of so-called Feynman-Kac formulas, which are used in many other contexts (quantum chemistry or transport equations, for example) either to give a probabilistic interpretation to a PDE, or to recast the computation of an expectation into a PDE problem.

For problem (8) to be well posed (i.e., for one and only one solution to exist), one needs to supply the system with “boundary conditions” when $S = 0$ or $S \rightarrow \infty$. More precisely, one needs to make precise in which functional space the function p is looked for. This will be explained in the next section.

From the PDE (8) and the so-called maximum principle, it is possible to derive many qualitative properties and a priori bounds on the price p (like the call-put parity, for example; see Achdou and Pironneau, 2005). Roughly speaking, the maximum principle states that if the data (initial condition, boundary conditions, right-hand side) for the PDE (8) are positive, then the solution is positive. This property is definitely necessary to hold for a price. It is also an important property to check on the numerical schemes (which is then called a discrete maximum principle as discussed below).

It is also possible to obtain the PDE without introducing the risk-neutral probability (see Wilmott, Dewynne, and Howison, 1993) by considering a portfolio containing some options and some risky assets and by using an arbitrage-free argument.

It is important to recall that the Black and Scholes model for the evolution of the risky asset (1) badly compares with experimental data. We discuss later in this entry some possible refinements that have been introduced in order to better fit the observations (see the discussion on calibration below). However, this model remains very important in practice because it is used as a prototypical description of the evolution of the asset. Moreover, for a given observed price of a derivative, there exists a constant volatility σ (called the implied volatility; see the section on calibration below) for which the Black-Scholes price is the observed price. The implied volatility is a major quantity used in practice to compare derivatives.

Other Options

The argument presented for the Black-Scholes model is prototypical. In particular, the derivation of a PDE satisfied by the pricing function of an option always relies on the two fundamental properties stressed above: the martingale and the Markov properties of a suitable stochastic process. In this section, we present PDEs for the prices of various options without providing all the details of the derivation.

Basket Options

In many cases, the payoff of the option depends on the values of more than one asset, which typically do not evolve independently. Let us, for example, consider the case of two assets, which evolve following the following SDE under the neutral risk probability

$$\begin{cases} dS_t^1 = S_t^1 (r dt + \sigma_1 dW_t^1) \\ dS_t^2 = S_t^2 (r dt + \sigma_2 dW_t^2) \end{cases}$$

where W_t^1 and W_t^2 are possibly correlated standard Brownian motions. We call ρ the correlation of W_t^1 and W_t^2 : $d\langle W_1, W_2 \rangle_t = \rho dt$. We suppose that the maturity is $T > 0$ and the payoff is $\phi(S_T^1, S_T^2)$, where ϕ is a given function. It is then possible to show that the price of the option at time t is $p(t, S_t^1, S_t^2)$ where p satisfies

$$\begin{cases} \frac{\partial p}{\partial t} + rS_1 \frac{\partial p}{\partial S_1} + rS_2 \frac{\partial p}{\partial S_2} + \frac{\sigma_1^2 S_1^2}{2} \frac{\partial^2 p}{\partial S_1^2} \\ \quad + \frac{\sigma_2^2 S_2^2}{2} \frac{\partial^2 p}{\partial S_2^2} + \rho\sigma_1\sigma_2 S_1 S_2 \frac{\partial^2 p}{\partial S_1 \partial S_2} - rp = 0, \\ p(T, S_1, S_2) = \phi(S_1, S_2) \end{cases} \quad (9)$$

Here again, r , σ_1 , and σ_2 may be functions of t and (S_1, S_2) . It is possible to solve such PDEs by standard numerical methods up to dimension 3 or 4. As discussed later, to derive appropriate discretization for higher dimensions is not an easy task and is still the subject of current research.

Barrier Options

Again, let us consider an option on a single asset. For some options, the payoff becomes 0 if there exists a time $t \in [0, T]$ such that S_t goes below a or above b , where a and b are two given values, $0 < a < b$ (the case $a = 0$ or $b = \infty$ can be treated similarly). Mathematically, the payoff is $1_{\forall t \in [0, T], S_t \in [a, b]} \phi(S_T)$ where, for any event $A \subset \Omega$, 1_A denotes the characteristic function of A , and S_t satisfies (1). In this case, the relevant stochastic process for deriving the PDE is $S_{t \wedge \tau}$, where $\tau = \inf\{t \in [0, T], S_t \geq b \text{ or } S_t \leq a\}$ is a stopping time, and, for any real x and y ,

$x \wedge y = \inf(x, y)$. It can be checked that $S_{t \wedge \tau}$ is a Markov process, and that $S_{t \wedge \tau} / S_{t \wedge \tau}^0$ is a martingale. It is then possible to show that the price of the option at time t is $p(t \wedge \tau, S_{t \wedge \tau})$ where p is defined for $t \in [0, T]$ and $S \in [a, b]$ and satisfies:

$$\begin{cases} \frac{\partial p}{\partial t} + rS \frac{\partial p}{\partial S} + \frac{\sigma^2 S^2}{2} \frac{\partial^2 p}{\partial S^2} - rp = 0, \\ p(T, S) = \phi(S), \\ p(t, a) = p(t, b) = 0 \end{cases} \quad (10)$$

Here again, r and σ may be functions of t and S . Moreover, the generalization to basket options is straightforward, as explained above. In this case, it is possible to consider more general *barriers*, namely a payoff of the form $1_{\forall t \in [0, T], (S_t^1, S_t^2, \dots, S_t^d) \in \mathcal{D}} \phi(S_T)$, where d denotes the number of underlying assets and \mathcal{D} is any simple connected domain of \mathbb{R}^d . The appropriate discretization for general domains \mathcal{D} is the finite element method that will be discussed later on.

Options on the Maximum

For some options (the so-called *lookback options*), the payoff involves the maximum of the risky asset. For example, it writes $\phi(S_T, M_T)$ where $M_t = \max_{0 \leq r \leq t} S_r$ and S_t satisfies (1). One can check that (S_t, M_t) is a Markov process. It is then possible to show that the price of the option at time t is $p(t, S_t, M_t)$ where p is defined for $t \in [0, T]$ and $(S, M) \in \{(S, M) \in \mathbb{R}^2, 0 \leq S \leq M\}$ and satisfies:

$$\begin{cases} \frac{\partial p}{\partial t} + \frac{\sigma^2}{2} S^2 \frac{\partial^2 p}{\partial S^2} + rS \frac{\partial p}{\partial S} - rp = 0, \\ p(T, S, M) = \phi(S, M), \\ \frac{\partial p}{\partial M}(t, S, S) = 0 \end{cases} \quad (11)$$

If the payoff is of the form $\phi(S, M) = M\tilde{\phi}(S/M)$, it is possible to reduce the problem to a two-dimensional one (including the time variable). Indeed, one can check by straightforward computations that $p(t, S, M) = Mw(t, S/M)$ where w is a function of $t \in [0, T]$ and $\xi \in [0, 1]$, which

satisfies:

$$\begin{cases} \frac{\partial w}{\partial t} + \frac{\sigma^2}{2} \xi^2 \frac{\partial^2 w}{\partial \xi^2} + r\xi \frac{\partial w}{\partial \xi} - rw = 0, \\ w(T, \xi) = \tilde{\phi}(\xi), \\ \frac{\partial w}{\partial \xi}(t, 1) = w(t, 1) \end{cases} \quad (12)$$

Notice that this reduction is not generally possible for (t, S, M) -dependent interest rate and volatility (except for very peculiar dependencies).

Options on the Average

Some options (the so-called *Asian options*) involve the average of the risky asset. More precisely, the payoff writes $\phi(S_T, A_T)$ where $A_t = \frac{1}{t} \int_0^t S_r dr$ and S_t satisfies (1). One can check that (S_t, A_t) is a Markov process. Using this property, it is possible to show that the price of the option at time t is $p(t, S_t, A_t)$ where p is defined for $t \in [0, T]$ and $(S, A) \in [0, \infty)^2$, and p satisfies:

$$\begin{cases} \frac{\partial p}{\partial t} + \frac{\sigma^2 S^2}{2} \frac{\partial^2 p}{\partial S^2} + rS \frac{\partial p}{\partial S} \\ + \frac{1}{t}(S - A) \frac{\partial p}{\partial A} - rV = 0, \\ p(T, S, A) = \phi(S, A) \end{cases} \quad (13)$$

In some cases (see Rogers and Shi, 1995), it is possible to reduce this problem to a one-dimensional PDE. More precisely, for fixed strike call ($\phi(S, A) = (A - K)_+$) or fixed strike put ($\phi(S, A) = (K - A)_+$), we have $p(t, S, A) = Sf(t, \frac{K-tA/T}{S})$ where f satisfies

$$\begin{cases} \frac{\partial f}{\partial t} + \frac{\sigma^2 \xi^2}{2} \frac{\partial^2 f}{\partial \xi^2} - \left(\frac{1}{T} + r\xi\right) \frac{\partial f}{\partial \xi} = 0, \\ f(T, \xi) = \tilde{\phi}(\xi) \end{cases} \quad (14)$$

and $\tilde{\phi}(\xi) = \xi_-$ (resp. $\tilde{\phi}(\xi) = \xi_+$). This reduction of (13) to (14) is also possible for floating strike call ($\phi(S, A) = (S - A)_+$) (resp. for floating strike put ($\phi(S, A) = (A - S)_+$)) by setting $p(t, S, A) = Sf(t, -\frac{tA}{TS})$ and $\tilde{\phi}(\xi) = (1 + \xi)_+$ (resp. $\tilde{\phi}(\xi) = (1 + \xi)_-$). However, this reduction

is generally not possible for general payoff function or (t, S, A) -dependent interest rate and volatility (except for very peculiar dependencies).

Bermudean Options

As a transition between European and American options, we would like to mention that it is very easy to price Bermudean options with the PDE approach. For such options, the contract can be exercised only at certain days between the present time and the maturity. Mathematically, for an option on a single asset (the spot price is called S) and if ϕ denotes the payoff, the pricing function satisfies $p(t_i^+, S) = \max(p(t_i^-, S), \phi(S))$, at each exercising time t_i , and (8) between the exercising times; see Duffie (1992, p. 211).

The Case of American Options

We have so far presented so-called *European options*, that is, some options that enable their owners to get $\phi(S_T)$ at a fixed time T . On the other hand, *American options* can be exercised at any time up to the maturity. Hence the price of an American option of payoff ϕ and maturity T will be the maximum of all possible expectations such as (6) for stopping times τ between t and T , that is, for $t \in [0, T]$ and $x \geq 0$,

$$p(t, x) = \sup_{\tau \in \mathcal{T}_{[t, T]}} \mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t, x}) \right) \quad (15)$$

where $\mathcal{T}_{[t, T]}$ denotes the set of stopping times τ of the filtration \mathcal{F}_t , with values in $[t, T]$.

The PDE for American Options

We now present the main arguments to derive a PDE on p defined by (15) (or more precisely a system of partial differential inequalities).

Notice first that taking $\tau = t$ in (15) yields the inequality

$$p(t, x) \geq \phi(x) \quad (16)$$

Moreover, we clearly have from (15) $p(T, x) = \phi(x)$.

Let t and δt be such that $0 \leq t \leq t + \delta t \leq T$. From (15) we have:

$$\begin{aligned} & e^{-\int_0^{t+\delta t} r ds} p(t + \delta t, S_{t+\delta t}^{t, x}) \\ &= \sup_{\tau \in \mathcal{T}_{[t+\delta t, T]}} \mathbb{E} \left(e^{-\int_0^\tau r ds} \phi \left(S_\tau^{t+\delta t, S_{t+\delta t}^{t, x}} \right) \right), \\ &\leq \sup_{\tau \in \mathcal{T}_{[t, T]}} \mathbb{E} \left(e^{-\int_0^\tau r ds} \phi \left(S_\tau^{t, x} \right) \right), \\ &\leq e^{-\int_0^t r ds} p(t, x) \end{aligned}$$

where we have used the fact that: $S_\tau^{t+\delta t, S_{t+\delta t}^{t, x}} = S_\tau^{t, x}$. By Ito's calculus (taking the limit $\delta t \rightarrow 0$), we thus obtain

$$-\frac{\partial p}{\partial t} + \mathcal{A}p \geq 0 \quad (17)$$

where we have introduced the linear PDE operator

$$\mathcal{A}p = -rS \frac{\partial p}{\partial S} - \frac{\sigma^2 S^2}{2} \frac{\partial^2 p}{\partial S^2} + rp \quad (18)$$

Combined with (16), we then obtain

$$\min \left(-\frac{\partial p}{\partial t} + \mathcal{A}p, p - \phi \right) \geq 0 \quad (19)$$

Our aim is now to show that the inequality in (19) is actually an equality. This is done in several steps, and requires us to identify an optimal stopping time τ^* for which the supremum in (15) is obtained. For a fixed (t, x) , let us introduce the stopping time $\tau^* \in \mathcal{T}_{[t, T]}$ defined by

$$\tau^* = \inf \{ \theta \geq t, p(\theta, S_\theta^{t, x}) = \phi(S_\theta^{t, x}) \}, \text{ a.s.} \quad (20)$$

(notice that $\tau^* \leq T$ since $p(T, x) = \phi(x)$). It can be shown (see Appendix) that

$$\begin{aligned} p(t, x) &= \mathbb{E} \left(e^{-\int_t^{\tau^*} r ds} \phi \left(S_{\tau^*}^{t, x} \right) \right) \\ &= \mathbb{E} \left(e^{-\int_t^{\tau^*} r ds} p(\tau^*, S_{\tau^*}^{t, x}) \right) \end{aligned} \quad (21)$$

Using a decreasing property (65) proved in the Appendix, one then obtains that for any $\delta t > 0$,

$$\begin{aligned} p(t, x) &= \mathbb{E} \left(e^{-\int_t^{\tau_{\delta t}^*} r ds} p \left(\tau_{\delta t}^*, S_{\tau_{\delta t}^*}^{t, x} \right) \right), \\ &\text{where } \tau_{\delta t}^* = (t + \delta t) \wedge \tau^* \end{aligned} \quad (22)$$

This can be seen as a dynamic programming principle (or Bellman’s principle). For a European option we would have more simply

$$p(t, x) = \mathbb{E} \left(e^{-\int_t^{t+\delta t} r ds} p(t + \delta t, S_{t+\delta t}^{t,x}) \right)$$

Now if we suppose that $p(t, x) > \phi(x)$, then for any $\delta t > 0$ we have $\mathbb{P}(\tau_{\delta t}^* > t) = 1$. Considering Ito’s formula in (22), and by (17), we obtain $(-\frac{\partial p}{\partial t} + \mathcal{A}p)(\theta, S_{\theta}^{t,x}) = 0$ for $t \leq \theta \leq \tau_{\delta t}^*$, thus leading to $(-\frac{\partial p}{\partial t} + \mathcal{A}p)(t, x) = 0$. This shows that the inequality in (19) is actually an equality.

Hence the PDE for the American option is

$$\begin{cases} \min \left(-\frac{\partial p}{\partial t} + \mathcal{A}p, p - \phi \right) = 0, \\ t \in [0, T], x \geq 0, \\ p(T, x) = \phi(x), \quad x \geq 0 \end{cases} \quad (23)$$

where \mathcal{A} is defined by (18). The major difference between the PDE (23) for American options and the PDE (8) for European options is that (23) is a nonlinear equation. This makes the theory of existence and uniqueness as well as the numerical approximation more difficult than for European options.

In the presentation above, we have used Ito’s formula, which requires that p is C^1 in time and C^2 in the spot variable. This is not true in general. It is however possible, following the same lines, to prove that p is a weak solution to (23) in the viscosity sense. For a historical derivation of this PDE, see Bensoussan and Lions (1978) or El Karoui (1981) where a variational formulation of (23) is derived (see (52) below). We also refer to Oksendal and Rekvam (1998) for an infinite horizon-related problem, Crandall, Ishii, and Lions (1992) for general results, Pham (1998) for an approach of optimal stopping including jump diffusion processes, and to Barles (1994) for the case of a discontinuous payoff ϕ .

PRICING EUROPEAN OPTIONS WITH PDEs

The aim of this section is to present two classes of methods for solving partial differential equa-

tions with some applications to the PDEs derived previously. We first introduce the *finite difference method*, which is based on approximation of the differential operators by Taylor expansions, and then the *finite element methods*, which belong to the wider class of Galerkin methods and are based on a variational formulation of the PDE. We try to stress the most important aspects of the numerical methods and refer, for example, to Achdou and Pironneau (2005 and 2009) for a more comprehensive presentation.

The Finite Difference Method for European Options

We first present the simplest approach to discretize a PDE: the finite difference method.

Basic Schemes

Let us introduce the finite difference method on the simple PDE (8). Let us first concentrate on the discretization of (8) with respect to the variable S . The principle is to divide the interval $[0, S_{\max}]$ into I intervals of length $\delta S = S_{\max}/I$ (where S_{\max} has to be chosen large enough, see below), and to approximate the derivatives by finite differences. A possible semidiscretization of (8) is: for $i \in \{0, 1, \dots, I\}$,

$$\begin{cases} \frac{\partial P_i}{\partial t} + rS_i \frac{P_{i+1} - P_{i-1}}{2\delta S} \\ + \frac{\sigma^2 S_i^2}{2} \frac{P_{i+1} - 2P_i + P_{i-1}}{\delta S^2} - rP_i = 0, \\ P_i(T) = \phi(S_i) \end{cases} \quad (24)$$

where $S_i = i\delta S$ denotes the i -th discretization point, and $P_i(t)$ is intended to be an approximation of $p(t, S_i)$. Now, (24) is a system of coupled ordinary differential equations (ODEs). The generalization to the case of a time and spot dependent r or σ is straightforward.

Notice that for $S = 0$, P_0 can be solved independently (since $S_0 = 0$): $P_0(t) = \phi(0) \exp(-\int_t^T r ds)$. In order to obtain a solution of the whole system of ODEs, one needs to define an appropriate boundary condition at

$S = S_{\max}$. Indeed, (24) taken at $i = I$ involves P_{I+1} which is a priori not defined. There are basically two methods to deal with this issue. The first one consists of using some a priori knowledge on the values of $p(t, S)$ when S is large and making some approximations of $p(t, S_{\max})$. In this case, the value of P_I is given as a data (this is a so-called Dirichlet boundary condition), and the unknowns are $(P_i)_{0 \leq i \leq I-1}$. For example, in the case of a put ($\phi(S) = (S - K)_-$) (resp. a call ($\phi(S) = (S - K)_+$)), it is known that $\lim_{S \rightarrow \infty} p(t, S) = 0$ (resp., in the limit $S \rightarrow \infty$, $p(t, S) \sim S - K \exp(-\int_t^T r ds)$), so that one can set $P_I(t) = 0$ (resp. $P_I(t) = S_{\max} - K \exp(-\int_t^T r ds)$). The error introduced by these artificial boundary conditions can be estimated. Another method is based on some knowledge on the asymptotic behavior of the derivatives of p . For example, in the case of the put, one can use the so-called homogeneous Neumann boundary condition, which writes $\partial p / \partial S(t, S_{\max}) = 0$ at the continuous level and $\frac{P_{I+1}(t) - P_I(t)}{\delta S} = 0$ at the discrete level. In this case, the unknowns are $(P_i)_{0 \leq i \leq I}$. For both methods, S_{\max} should be chosen sufficiently large. In practice, the quality of the method may be assessed by measuring how sensitive the result is to the value of S_{\max} .

Let us now consider the time discretization. Here again, the idea is to divide the time interval $[0, T]$ into N intervals of length $\delta t = T/N$ and to replace the time derivative by a finite difference. Three numerical methods are classically used:

$$\left\{ \begin{array}{l} \frac{P_i^{n+1} - P_i^n}{\delta t} + rS_i \frac{P_{i+1}^{n+1} - P_{i-1}^{n+1}}{2\delta S} \\ + \frac{\sigma^2 S_i^2}{2} \frac{P_{i+1}^{n+1} - 2P_i^{n+1} + P_{i-1}^{n+1}}{\delta S^2} - rP_i^{n+1} = 0, \\ P_i^N = \phi(S_i) \end{array} \right. \quad (25)$$

$$\left\{ \begin{array}{l} \frac{P_i^{n+1} - P_i^n}{\delta t} + rS_i \frac{P_{i+1}^n - P_{i-1}^n}{2\delta S} \\ + \frac{\sigma^2 S_i^2}{2} \frac{P_{i+1}^n - 2P_i^n + P_{i-1}^n}{\delta S^2} - rP_i^n = 0, \\ P_i^N = \phi(S_i) \end{array} \right. \quad (26)$$

or

$$\left\{ \begin{array}{l} \frac{P_i^{n+1} - P_i^n}{\delta t} + \frac{1}{2} \left(rS_i \frac{P_{i+1}^{n+1} - P_{i-1}^{n+1}}{2\delta S} \right. \\ + \frac{\sigma^2 S_i^2}{2} \frac{P_{i+1}^{n+1} - 2P_i^{n+1} + P_{i-1}^{n+1}}{\delta S^2} - rP_i^{n+1} \\ + rS_i \frac{P_{i+1}^n - P_{i-1}^n}{2\delta S} + \frac{\sigma^2 S_i^2}{2} \frac{P_{i+1}^n - 2P_i^n + P_{i-1}^n}{\delta S^2} \\ \left. - rP_i^n \right) = 0, \\ P_i^N = \phi(S_i) \end{array} \right. \quad (27)$$

where P_i^n is intended to be an approximation of $p(t_n, S_i)$, with $t_n = n\delta t$. Notice that using the discretization scheme (25) (the so-called explicit Euler scheme), the values of $(P_i^n)_{0 \leq i \leq I}$ are explicitly obtained from the values of $(P_i^{n+1})_{0 \leq i \leq I}$. On the contrary, in the two other schemes (26) (implicit Euler scheme) or (27) (Crank-Nicolson scheme), the values of $(P_i^n)_{0 \leq i \leq I}$ are obtained from the values of $(P_i^{n+1})_{0 \leq i \leq I}$ through the resolution of a linear system, which is more demanding from the computational viewpoint. Various numerical methods can be used for solving this linear system; here, we cannot describe them in detail. Let us simply mention that basically, there exist two classes of methods: the direct methods, which are based on Gaussian elimination, and the iterative methods, which consist of computing the solution as the limit of a sequence of approximations and which only require matrix-vector multiplications. The method of choice depends on the characteristics of the problem.

Notions of Stability and Consistency

In order to analyze the convergence of the three discretization schemes (25), (26), and (27), and to understand the differences between these schemes, we need to introduce two important notions. The first notion is the consistency. A numerical method is said to be consistent if, when the exact solution is plugged into the numerical scheme, the error tends to zero when the discretization parameters tend to zero. In our context, it consists of replacing P_i^n in (25),

(26), or (27) by $p(t_n, S_i)$, where p satisfies (8), and to check that the remaining terms tend to zero when δt and δS tend to zero. By using Taylor expansions, one can check that for (25) and (26) (resp. for (27)), the remaining terms are bounded from above by $C(\delta t + \delta S^2)$ (resp. by $C(\delta t^2 + \delta S^2)$), where C denotes a constant, which depends on some norms of the derivatives of p . Therefore (25) and (26) (resp. (27)) are consistent discretization schemes of order 2 in the spot variable, and of order 1 (resp. 2) in time. The second important notion is the stability. A numerical method is said to be stable if the norm of the solution to the numerical scheme is bounded from above by a constant (independent of the discretization parameters) multiplied by the norm of the data (initial condition, boundary conditions, right-hand side). This property is clearly satisfied if the numerical method is convergent, that is, if the numerical approximation converges to the solution of the PDE when the discretization parameters tend to zero. A general result states that, conversely, a consistent and stable discretization scheme is indeed convergent. The estimate of convergence is given by the estimate of consistency error. For example, if p is smooth enough, the error for the EI scheme is bounded from above by $C(\delta t + \delta S^2)$. Notice that the constant C in these estimates depends on the solution p . Higher order schemes will lead to better error estimates as soon as the solution of the continuous problem is smooth enough: The higher the order, the more regular p must be in order to take full advantage of the scheme. For example, for some parameters, it may happen that the results obtained with the CN scheme around $t = T$ are not better than those obtained with an order one scheme (IE or EE) since the solution is not sufficiently regular in time around $t = T$.

To give a precise meaning to all these results would require us to specify the norms used to measure the errors and to prove the stability. Let us simply mention that two norms are used in practice: The stability in L^∞ -norm (the supremum of the absolute values of the components) is related to a discrete maximum prin-

ciple (see below); and the stability in L^2 -norm (the Euclidean norm of the vector) is related to an energy estimate on the variational formulation. We refer, for example, to Achdou and Pironneau (2005) for more details.

The discrete maximum principle is the counterpart at the discrete level of the maximum principle at the continuous level mentioned above. It states that if the data for the numerical schemes are positive, then the solution is positive. Such schemes are by construction stable in L^∞ -norm. There exist deterministic numerical methods based on a probabilistic representation of the stock evolution on a binomial or a trinomial tree. Such methods can be interpreted as explicit finite difference methods to solve the PDE (8) and naturally satisfy a discrete maximum principle.

Convergence Analysis

Let us now discuss the properties of the three discretization schemes. We already mentioned that they are all consistent. On the other hand, it can be shown that the explicit scheme (25) is stable under an additional assumption (a so-called CFL condition; see Courant, Friedrichs, and Lewy, 1967) of the form $\delta t \leq C\delta S^2$, where C denotes a positive constant. The other two schemes (26) and (27) are unconditionally stable (in L^2 -norm). In conclusion, with the explicit scheme, the values of $(P_i^n)_{0 \leq i \leq I}$ can be very rapidly obtained from the values of $(P_i^{n+1})_{0 \leq i \leq I}$, but the time step must be sufficiently small with respect to the spot step to guarantee stability and hence convergence. On the other hand, the implicit schemes (26) and (27) require the resolution of a linear system at each time-step, but converge without any restriction on the time-step. This situation is very general for the parabolic PDEs obtained in finance. In terms of computational costs, the balance is generally in favor of the implicit schemes, since the CFL condition appears to be very stringent in practice. Concerning the stability in L^∞ -norm, let us just mention that the implicit schemes above do not satisfy the discrete maximum

Table 1 Error on the Value of a Call in Function of the Number of Intervals I in the Variable S , for the Implicit Euler (IE) Scheme

$N = 1000$	$I = 150$	$I = 300$	$I = 600$	$I = 1200$
IE	0.165	0.0356	0.00103	0.000452

principle and are not L^∞ -stable as such. These properties are, however, satisfied after a small modification of the discretization of the advection term $rS \frac{\partial p}{\partial S}$ (this is a so-called upwinding technique), which amounts to adding a diffusion term of order δS , which implies that this modified scheme becomes only of order 1 in the spot variable. Thus, the price to pay to get L^∞ -stability is a loss of one order of convergence.

In Tables 1 and 2, we illustrate this analysis by computing the error on the price of a call with $r = 0.1, \sigma = 0.01, K = 100, T = 1, S_0 = 100$, and $S_{\max} = 300$ for the three discretization schemes (25), (26), and (27), and various values of the numerical parameters I and N . The reference value ($P = 9.51625$) is obtained by the analytic Black and Scholes formula. In particular, one can check that the rates of convergence with respect to δt and δS are indeed those predicted by the analysis.

Before presenting an extension of this discretization method to Asian options, we mention the interest of a classical change of variable for the spot variable. It is indeed well known that by a change of variable $x = \ln S$, it is possible to get rid of the dependency in S of the advection and diffusion terms in (8). It is not better to discretize the PDE after this change of

variable, since it corresponds to taking a grid refined near $S = 0$, which is useless in this case. As we will see below, what actually matters is to refine the grid around the singularity of p (i.e., around $S = K$). A finite element approach is better suited in order to implement these refinements.

Application to Asian Options

We now present a less easy implementation of a finite difference method for pricing Asian options (see Dubois and Lelièvre, 2005). More precisely, we focus on computing numerical solutions to (14) for a fixed strike call:

$$\tilde{\phi}(\xi) = \xi_- \quad (28)$$

We have seen in the previous section that a simple finite difference scheme leads to very satisfactory results when computing the solution of the classical Black-Scholes equation (8). On the other hand, when one uses a simple finite difference scheme on (14), very bad results are obtained, especially when the volatility σ is small (see Table 1 in Dubois and Lelièvre, 2005). These bad results are due to the fact that when ξ is close to zero, the advection term ($\frac{1}{T} + r\xi$) is much larger than the diffusion term $\sigma^2 \xi^2 / 2$ in (14). This is known to deteriorate the stability of the numerical scheme, particularly with respect to the L^∞ -norm. In practice, the numerical solution exhibits some oscillations and does not satisfy the discrete maximum principle. Moreover, the finite difference method introduces numerical diffusion, which leads to unsatisfactory results for purely advective equations.

Table 2 Error on the Value of a Call in Function of the Number of Time-Steps N

$I = 500$	$N = 5$	$N = 10$	$N = 20$	$N = 40$	$N = 80$	$N = 160$
EE	28.53	0.386	0.398	0.0739	0.0162	0.00714
IE	0.0892	0.0449	0.0225	0.0113	0.00554	0.00226
CN	0.0299	0.00758	0.00103	0.00169	0.00169	0.00168

Note: We observe that the Euler explicit (EE) scheme is unstable for $N = 5$. The convergence in time of the Crank-Nicolson (CN) scheme is much faster than for the implicit Euler (IE) scheme. The remaining error when N is large is due to the discretization with respect to the variable S .

One way to handle this problem is to use a characteristic method (based on the solution of $d\xi/dt = -1/T$) in order to get rid of the term $1/T$. This means that the following change of variable is introduced:

$$g(t, x) = f(t, x - t/T) \tag{29}$$

One can easily show that g is solution of:¹

$$\begin{cases} \frac{\partial g}{\partial t} + \frac{\sigma^2(x - t/T)^2}{2} \frac{\partial^2 g}{\partial x^2} - r(x - t/T) \frac{\partial g}{\partial x} = 0, \\ g(T, x) = \tilde{\phi}(x - 1) = (1 - x)_+ \end{cases} \tag{30}$$

The PDE (30) satisfied by g is such that when the advection term $r(x - t/T)$ is small, the diffusion term $\frac{\sigma^2(x - t/T)^2}{2}$ is also small. As shown below, a finite difference scheme applied to (30) will indeed lead to satisfactory results.

An important property of the solution to (30) for $\tilde{\phi}(\xi) = \xi_-$ is that (see Rogers and Shi, 1995) $\forall \xi \leq 0$,

$$f(t, \xi) = \frac{1}{rT}(1 - e^{-r(T-t)}) - \xi e^{-r(T-t)} \tag{31}$$

and therefore, $\forall x \leq t/T$,

$$g(t, x) = \frac{1}{rT}(1 - e^{-r(T-t)}) - (x - t/T)e^{-r(T-t)} \tag{32}$$

To prove (31), one can notice that f given by (31) is the solution to (14) with $\phi(\xi) = -\xi$, and that, due to the fact that the diffusion term is null for $\xi = 0$ and that the advection term is negative, the solution to (14) for $\phi(\xi) = \xi_-$ on $\xi \leq 0$ is the same as the solution to (14) for $\phi(\xi) = -\xi$ on $\xi \leq 0$.

To discretize (30), a Crank-Nicolson time scheme is used, with a uniform time step $\delta t = T/N$. In order to use the fact that g is analytically known on $x \leq t/T$ (see (32)), a mesh that properly discretizes the boundary $x = t/T$ is used. Therefore, the space interval $(0, 1)$ is also discretized with N space steps of length $\delta x = 1/N$ (see Figure 1). The mesh is completed by adding J intervals on the right-hand side of $x = 1$, so that $x \in (0, x_{max})$ with $x_{max} = (N + J)\delta x$. The value $J = N/2$ has been found to be sufficient

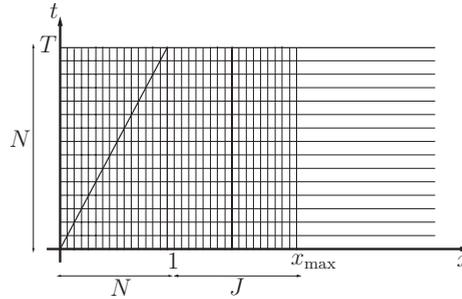

Figure 1 The Mesh and the Computational Domain for the Finite Difference Scheme Used to Discretize (30)

to guarantee the independence of the results on the position of x_{max} .

Notice that at time $t_n = n\delta t$, the number of unknowns is $(N + J - n)$. This means that the dimension of the linear system to solve depends on the time-step.

As far as boundary conditions are concerned, we use a Dirichlet boundary condition on $x = t/T$ (using (32)) and an artificial zero Neumann boundary condition on $x = x_{max}$.

Let us now give some numerical results. In Table 3, a few comparisons of the results obtained with the characteristic method and other methods are given. The characteristic method appears to be accurate for both small and large volatilities. For any values of the parameters, at least 5 digits of precision are obtained in less than one second. Notice that the Thompson bounds and the characteristic method are implemented in Premia.²

The Finite Element Method for European Options

We would like now to introduce the finite element method. This technique is more flexible than the finite difference method. In particular, it allows for local refinements of the spot grid (even in dimensions greater than one), and possibly based on local error estimators that are mentioned below. This is particularly important for American options, because the pricing function is singular near the exercise boundary, and

Table 3 Comparisons of the Prices for an Asian Fixed Call Obtained with Various *Finite Difference* Methods: Characteristic Method, Zvan et al. (1998), Večeř (2001), and Thompson (1999)

σ	K	Charact. Method	N:	Zvan et al.	Večeř	Thompson (low)	Thompson (up)
0.05	95	11.09409	(300)	11.094	11.094	11.094094	11.094096
	100	6.7943	(1000)	6.793	6.795	6.794354	6.794465
	105	2.7444	(3000)	2.748	2.744	2.744406	2.744581
0.30	90	16.512	(300)	16.514	16.516	16.512024	16.523720
	100	10.209	(300)	10.210	10.215	10.208724	10.214085
	110	5.730	(1000)	5.729	5.736	5.728161	5.735488

Note: Values of parameters: $T = 1$, $r = 0.15$, $S_0 = 100$, $J = N/2$. For the characteristic method, the number of time-steps $N \geq 300$ needed to obtain at least 5 digits of precision is given.

this curve is not known a priori. Let us emphasize that the use of a refined mesh around the singularities of the solution (for example, for vanilla option pricing problems, around $t = T$ and $S = K$) is very important in practice to rapidly obtain accurate results. The finite element method can also be used in a flexible way when the geometry of the computational domain becomes complex, which may be of interest for barrier options in dimensions greater than one. Finally, finite element methods are interesting since they are naturally stable (in L^2 -norm) and optimal error bounds (in L^2 -norm) can be derived.

In the following, we first present the finite element method on a simple example, namely equation (8). We then show how to treat more complex European options.

Variational Formulation and Finite Element Space

The conforming finite element method is based on two ingredients: a so-called variational formulation of the PDE on a functional space V and the choice of an appropriate sequence of finite dimensional spaces $V_h \subset V$, which tends to V when h (which is the typical diameter of the cells of the space mesh) tends to 0. Let us illustrate this on (8).

To derive a variational formulation of (8), the principle is to multiply the equation by a test function of the spot variable and to integrate by parts. For these computations to be

well defined, the functions need to be sufficiently smooth. We thus introduce the functional spaces $H = L^2(\mathbb{R}_+) = \{q : [0, \infty) \rightarrow \mathbb{R}, \int_0^\infty q^2 < \infty\}$, and $V = \{q \in L^2(\mathbb{R}_+), S(\partial q / \partial S) \in L^2(\mathbb{R}_+)\}$. Assuming that ϕ is square integrable, a variational formulation of (8) is then (for an S -dependent volatility σ): Find $p \in L^2((0, T), V) \cap C^0([0, T], H)$ such that for all $q \in V$,

$$\begin{cases} \frac{d}{dt} \int_0^\infty pq - \int_0^\infty \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial S} \frac{\partial q}{\partial S} \\ + \int_0^\infty \left(r - \sigma^2 - S\sigma \frac{\partial \sigma}{\partial S} \right) S \frac{\partial p}{\partial S} q \\ - r \int_0^\infty pq = 0, \\ p(T, S) = \phi(S) \end{cases} \quad (33)$$

All the integrals are with respect to $S \in [0, \infty)$. This rewrites: Find $p \in L^2((0, T), V) \cap C^0([0, T], H)$ such that for all $q \in V$,

$$\begin{cases} \frac{d}{dt} \int_0^\infty pq - a(p, q) = 0, \\ p(T, S) = \phi(S) \end{cases} \quad (34)$$

where a is the bilinear form

$$\begin{aligned} a(p, q) &= \int_0^\infty \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial S} \frac{\partial q}{\partial S} \\ &- \int_0^\infty \left(r - \sigma^2 - S\sigma \frac{\partial \sigma}{\partial S} \right) S \frac{\partial p}{\partial S} q \\ &+ r \int_0^\infty pq \end{aligned} \quad (35)$$

Under suitable assumptions on the data ($r, \sigma,$ and ϕ), it is possible to prove that this variational problem is well posed (see Achdou and Pironneau, 2005).

The second step is to introduce a sequence of meshes in the spot variable indexed by the maximal step h and related finite dimensional functional spaces $V_h \subset V$. In the case of (33), the problem is posed on an infinite domain, and one needs to first localize the PDE in a finite domain $[0, S_{\max}]$ by using artificial boundary condition at $S = S_{\max}$, as already explained for finite difference discretizations. We consider, for example, a zero Neumann boundary condition on $S = S_{\max}$: $\frac{\partial p}{\partial S}(t, S_{\max}) = 0$. Then, a mesh of $[0, S_{\max}]$ consists of a finite number of intervals (S_i, S_{i+1}) with $S_0 = 0$ and $S_I = S_{\max}$. We set $h = \max_{0 \leq i \leq I-1} (S_{i+1} - S_i)$. The intervals (S_i, S_{i+1}) are called elements. We then need to define a functional space V_h associated with the mesh. A classical example is the $P1$ finite element space, which contains continuous and piecewise affine functions, namely, continuous functions, which are affine on each interval (S_i, S_{i+1}) , for $0 \leq i \leq I - 1$. In this case, a basis of the vector space V_h is given by the so-called hat functions $q_i \in V_h$ such that for $0 \leq i, j \leq I$, $q_i(S_j) = \delta_{i,j} = \begin{cases} 0 & \text{if } i \neq j \\ 1 & \text{if } i = j \end{cases}$ ($\delta_{i,j}$ is the Kronecker symbol). Notice that higher order finite element methods may be easily obtained by taking continuous and element-wise polynomial functions of degree $k > 1$.

The discretization in the spot price variable now simply consists in replacing the functional space V by the finite dimensional space V_h in (33) or (34) (this is the principle of Galerkin methods): Find $p_h \in C^0([0, T], V_h)$ such that for all $q_h \in V_h$,

$$\begin{cases} \frac{d}{dt} \int_0^{S_{\max}} p_h q_h - a(p_h, q_h) = 0, \\ p_h(T, S) = \phi_h(S) \end{cases} \quad (36)$$

where ϕ_h is an approximation of ϕ in the space V_h , and where the integrals in the bilinear form

a are here for $S \in [0, S_{\max}]$ (see (35)). One can take, for example, ϕ_h such that $\int_0^{S_{\max}} (\phi - \phi_h) q_h = 0$ for all $q_h \in V_h$ (ϕ_h is then the L^2 projection of ϕ onto V_h). Problem (36) is a finite-dimensional problem in space of the form $M_h dp_h/dt = A_h P_h$, where $P_h(t)$ is a vector of dimension I containing the values of p_h at the nodes of the mesh ($p_h(t, x) = \sum_{j=0}^I P_{h,j}(t) q_j(x)$) and M_h, A_h are $I \times I$ matrices. The matrix M_h (resp. A_h), with (i, j) -th component $\int_0^{S_{\max}} q_i q_j$ (resp. $a(q_j, q_i)$) is classically called the mass (resp. stiffness) matrix, because the finite element method was originally popularized by the mechanical engineering community. When using the nodal basis (hat functions), these matrices are very sparse (tridiagonal for one-dimensional problems). Problem (36) is somewhat similar to (24) obtained by the finite difference method; the two problems (24) and (36) are actually equivalent if a mesh with uniform space steps is used, and if M_h is replaced by a close diagonal matrix (mass-lumping).

A fundamental result (the Cea's lemma) states that the norm of $(p - p_h)$ (the discretization error) is bounded from above by a constant times the infimum of the norm of $(p - q_h)$, over all $q_h \in V_h$ (the best fit error). Using this result, if V_h gets closer to V when h tends to 0, that is, if the best fit error tends to 0 when h tends to zero, so does the discretization error. In particular, the finite element discretization is thus naturally stable in this norm. A precise meaning for this statement requires us to define the norm and study the best fit error. Let us simply mention that the norms used in this context are related to the L^2 -norm introduced for finite difference schemes. We refer to Achdou and Pironneau (2005) or Quarteroni and Valli (1997) for the details. In our specific example, it is possible to prove that, if the payoff function is regular enough, then

$$\|p - p_h\|_{L^\infty([0,T],H)} + \|p - p_h\|_{L^2([0,T],V)} \leq Ch$$

and that

$$\|p - p_h\|_{L^2([0,T],H)} \leq Ch^2$$

For the discretization in time, the situation is exactly the same as for the finite difference method: One can use the explicit Euler scheme, implicit Euler scheme, or Crank-Nicolson scheme, and the rate of convergence is $O(\delta t)$ for the Euler schemes and $O(\delta t^2)$ for the Crank-Nicolson scheme.

Finite Element Methods for Other Options

We have introduced the finite element method in a very simple case. The aim of this section is to explain how it applies for other options.

Let us first consider basket options, or basket options with barriers, in dimension 2 and 3. The derivation of a variational formulation for (9) is very similar to the one-dimensional case. However, the construction of the mesh is much more complicated in dimension 2 and 3, than in dimension 1. It consists of partitioning the domain into non-overlapping cells (elements) whose shapes are simple and fixed (for example, triangles or quadrilaterals in dimension 2, or tetrahedra or hexahedra in dimension 3). The functional spaces V_h can then be constructed as in dimension 1, for example, by considering continuous piecewise affine functions. One interest of the finite element method in this context is that it is possible to mesh any domain \mathcal{D} for barrier options. In the finite difference method, to mesh nonquadrilateral (or nonhexahedral) domains is complicated.

Let us now consider the case of lookback options whose prices satisfy (11). This is a natural variational formulation of (11) (written here for a constant volatility σ): Find $p : \mathcal{D} \rightarrow \mathbb{R}$ such that, for all $q : \mathcal{D} \rightarrow \mathbb{R}$,

$$\begin{aligned} & \frac{d}{dt} \int_{\mathcal{D}} pq - \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial S} \frac{\partial q}{\partial S} - \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial S} \frac{\partial q}{\partial M} \\ & + \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial M} \frac{\partial q}{\partial S} + \int_{\mathcal{D}} \sigma^2 S \frac{\partial p}{\partial M} q \\ & + \int_{\mathcal{D}} (r - \sigma^2) S \frac{\partial p}{\partial S} q - r \int_{\mathcal{D}} pq = 0, \\ & p(T, S, M) = \phi(S, M) \end{aligned} \tag{37}$$

where $\mathcal{D} = \{(S, M) \in \mathbb{R}^2, 0 \leq S \leq M\}$. The boundary condition $\partial p / \partial M(t, S, S) = 0$ is naturally contained in this variational formulation since, by integration by parts over \mathcal{D} :

$$\begin{aligned} & - \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial S} \frac{\partial q}{\partial S} - \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial S} \frac{\partial q}{\partial M} \\ & + \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial M} \frac{\partial q}{\partial S} + \int_{\mathcal{D}} \sigma^2 S \frac{\partial p}{\partial M} q \\ & - \int_{\mathcal{D}} \sigma^2 S \frac{\partial p}{\partial S} q = \int_{\mathcal{D}} \frac{\sigma^2 S^2}{2} \frac{\partial^2 p}{\partial S^2} q \\ & + \frac{1}{\sqrt{2}} \int_{\{S=M\}} \frac{\sigma^2 S^2}{2} \frac{\partial p}{\partial M} q \end{aligned}$$

The first term corresponds to the diffusion term in (11). The second term is an integral over the boundary $\{S = M\}$ of \mathcal{D} and naturally enforces the boundary condition $\partial p / \partial M(t, S, S) = 0$. In Figure 2, we represent the price of a fixed strike call obtained using the formulation (11), an implicit Euler scheme, and $P1$ finite elements. The computations are made with FreeFem++.³

A Posteriori Error Estimates

A frequently mentioned advantage of the Monte Carlo methods is that they naturally provide a posteriori error bounds through a confidence interval, typically built upon the central limit theorem. It is also possible to obtain such a posteriori error estimates in the framework of the finite element method (this is one additional advantage of this method compared to finite difference methods). Moreover, these a posteriori estimates have two very important features:

- They depend on local error indicators.
- They can be proved to be reliable and efficient, that is, the actual error is bounded above and below by some fixed constants times the a posteriori error, and these estimates can be made local.

Therefore, in the finite element method, the a posteriori error estimates enable us to refine the mesh in space and time adaptively. We will

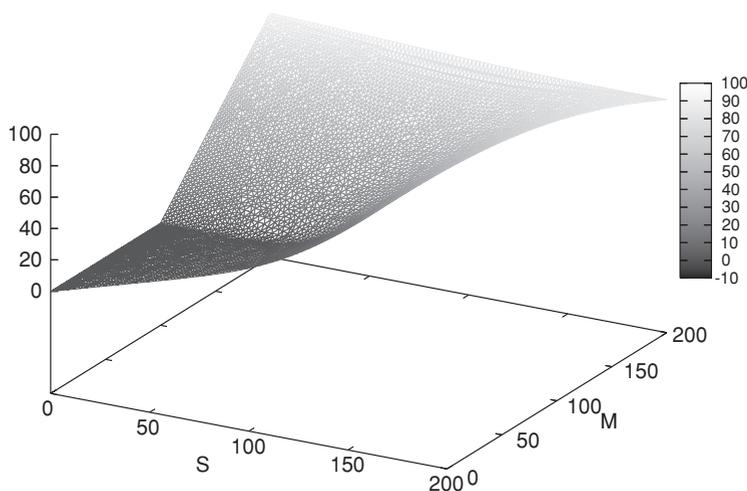

Figure 2 Price of a Lookback Option for a Fixed Strike Call: $\phi(S, M) = (M - K)_+$
Note: The parameters are: $\sigma = 0.3$, $r = 0.1$, $K = 100$, $T = 1$.

give a numerical illustration for American options and refer to Ern, Villeneuve, and Zanette (2004), Achdou and Pironneau (2005 and 2009), or Achdou, Hecht, and Pommier (2008) for more details.

High-Dimensional Problems

In practical problems, options often involve more than three assets. In this case, the PDE is posed in a space of dimension larger than 4, and the finite element or difference methods cannot be used, since the number of unknowns typically grows exponentially with respect to the problem's dimension. This is the so-called curse of dimensionality. Let us mention that such high-dimensional problems also appear in other scientific fields, quantum chemistry, for example, and that it is still a subject of current research to build appropriate discretizations for high-dimensional PDEs. Roughly speaking, the problem is to find an appropriate sequence of functional spaces V_h (whose basis is called a Galerkin basis), such that their dimensions do not grow too rapidly with the dimension of the problem. One approach is the sparse tensor product (see Bungartz and Griebel, 2004; Petersdoff and Schwab, 2004). The main difficulty when using this approach is actually

to project the initial condition on V_h . Another approach used in other contexts for solving high-dimensional problems by deterministic methods is the low separation rank method (see Beylkin and Mohlenkamp, 2002) and the related greedy algorithms (see Ammar et al., 2002; Temlyakov, 2008; Le Bris, Lelièvre, and Maday, 2009; and Nouy, 2009). Let us finally mention that another possible approach for building an appropriate Galerkin basis would be the reduced basis method, where some solutions for a given set of parameters are used to approximate the solution for other values of the parameters. Such methods are currently actively investigated (see, for example, Boyaval, Le Bris, Lelièvre, Maday, Nguyen, and Patera, 2010).

The Uncertain Volatility Model: An Example of a Nonlinear PDE

One major interest of the PDE approach is that it can be applied for nonlinear models. This will be the case for American options, see below, but we would like to give here another example of such a situation. The principle of the uncertain volatility model introduced by Avellaneda, Levy, and Paras (1995) is to give a price for a European option, when the volatility is only supposed to be in an interval $[\sigma_{\min}, \sigma_{\max}]$. The

principle is the following. For a European option with convex payoff, it is easy to check that the price should be the Black-Scholes price obtained with the maximum volatility σ_{\max} . In this case, the profit and loss for the hedging strategy is indeed zero if the realized volatility is constant equal to σ_{\max} . A similar reasoning holds for concave payoffs: In this case, one should consider the Black-Scholes price with the minimum volatility σ_{\min} . For a general payoff, it is thus natural (and it can be checked that this is indeed an approach that leads to a very good hedging strategy, with small profit and loss, and thus cheap price) to consider the solution p to the PDE:

$$\begin{cases} \frac{\partial p}{\partial t} + rS \frac{\partial p}{\partial S} + \\ \frac{1}{2} \left(\sigma_{\max}^2 \mathbf{1}_{\frac{\partial^2 p}{\partial S^2} \geq 0} + \sigma_{\min}^2 \mathbf{1}_{\frac{\partial^2 p}{\partial S^2} < 0} \right) S^2 \frac{\partial^2 p}{\partial S^2} - rp = 0, \\ p(T, S) = \phi(S) \end{cases} \quad (38)$$

In other words, σ_{\max} (resp. σ_{\min}) is used where the price is convex (resp. concave), as a function of the spot. This PDE can be solved using extensions of the discretization techniques presented above; see, for instance, section 2.4 in van der Pijl and Oosterlee (2011).

PRICING AMERICAN OPTIONS WITH PDES

This section is devoted to the discretization of the system (23) for the price of an American option. Notice that no closed formulas such as the Black-Scholes formula are available for American put, or for American call with a dividend rate, so that efficient discretization of this system is needed even for these simple payoffs.

The Finite Difference Approach for American Options

We first present the extension of the finite difference approach presented above for European options to American options.

Some Finite Difference Schemes

We consider a regular mesh discretization $S_i = i\delta S$ and a time discretization $t_n = n\delta t$ with $\delta t = \frac{T}{N}$. As in the European case, it is natural to consider the following three iterative numerical schemes for P_i^n , an approximation of $p(t_n, S_i)$. In all cases, the scheme is initialized by $P_i^N = \phi(S_i)$. Let A be the matrix such that

$$(AP^{n+1})_i = -rS_i \frac{P_{i+1}^{n+1} - P_{i-1}^{n+1}}{2\delta S} - \frac{\sigma^2 S_i^2}{2} \frac{P_{i+1}^{n+1} - 2P_i^{n+1} + P_{i-1}^{n+1}}{\delta S^2} + rP_i^{n+1} \quad (39)$$

The explicit Euler (EE) scheme for (23) is, for $n = N - 1, N - 2, \dots, 0$,

$$\min \left(-\frac{P_i^{n+1} - P_i^n}{\delta t} + (AP^{n+1})_i, P_i^n - \phi(S_i) \right) = 0 \quad (40)$$

The scheme computes $P^n = (P_i^n)_{i=0, \dots, I-1}$ from the knowledge of $P^{n+1} = (P_i^{n+1})_{i=0, \dots, I-1}$. Similarly, we can propose an implicit Euler (IE) scheme:

$$\min \left(-\frac{P_i^{n+1} - P_i^n}{\delta t} + (AP^n)_i, P_i^n - \phi(S_i) \right) = 0 \quad (41)$$

and an (implicit) Crank-Nicolson (CN) scheme

$$\min \left(-\frac{P_i^{n+1} - P_i^n}{\delta t} + \frac{1}{2}((AP^n)_i + (AP^{n+1})_i), P_i^n - \phi(S_i) \right) = 0 \quad (42)$$

In the case of the EE scheme, it is easy to see that we have the equivalent formulation

$$P_i^n = \max \left(((I_d - \delta t A)P^{n+1})_i, \phi(S_i) \right) \quad (43)$$

where I_d denotes the identity matrix.

We now have two new difficulties compared to the European case: First, the well-posedness of the schemes (41) or (42) is not immediate (for European options, we obtained a linear system, but this is no longer true for American options), and second, studying the convergence is more difficult.

One way to circumvent the first difficulty is to introduce a splitting method (see Barles and Souganidis, 1991; Barles, Daher, and Romano, 1995; and Lions and Mercier, 1979). For (23), it writes (a similar modification of (42) could also be considered, yielding a Crank Nicolson-splitting (CN-S) scheme):

$$\text{compute } P^{n,1} \text{ s.t. } -\frac{P_i^{n+1} - P_i^{n,1}}{\delta t} + (AP^{n,1})_i = 0 \tag{44a}$$

$$\text{and then compute } P_i^n = \max(P_i^{n,1}, \phi(S_i)) \tag{44b}$$

Hereafter, (44) will be referred to as the implicit Euler-splitting (IE-S) scheme. The first step (44a) consists of solving a linear system, as in the European case. The second step is a projection on the set $\{v = (v_i), v_i \geq \phi(S_i), \forall i\}$, as for the EE scheme (43).

Notice that as for European options, we set the equation on a truncated domain $(0, S_{\max})$ and use artificial boundary conditions on $S = S_{\max}$. We refer to Barles, Daher, and Romano (1995) for error estimates between the truncated problem on $(0, S_{\max})$ and the exact problem.

An Abstract Convergence Result

Assuming for the moment that the schemes are well posed, it is possible to study the convergence in the general framework of finite different schemes for Hamilton-Jacobi equations. Possibly under some restrictions on the mesh sizes δt and δS , we can obtain convergence to the viscosity solution of the PDE (23). We refer to Barles (1994) or Barles, Daher, and Romano (1995) for a short introduction, and Crandall, Ishii, and Lions (1992) for a more detailed overview. To give a rough idea of the convergence results for such schemes, we consider a general Hamilton-Jacobi equation of the form

$$H\left(t, S, p, \frac{\partial p}{\partial t}, \frac{\partial p}{\partial S}, \frac{\partial^2 p}{\partial S^2}\right) = 0 \tag{45}$$

with a terminal condition on $p(T, \cdot)$, where H is assumed to be Lipschitz continuous and

“backward parabolic” in the sense that

$$\begin{aligned} \text{if } \psi_1 \leq \psi_2 \text{ then } H(t, S, p, u, v, \psi_1) \\ \geq H(t, S, p, u, v, \psi_2) \end{aligned} \tag{46a}$$

$$\begin{aligned} \text{and if } u_1 \leq u_2 \text{ then } H(t, S, p, u_1, v, \psi) \\ \geq H(t, S, p, u_2, v, \psi) \end{aligned} \tag{46b}$$

Equation (23) is indeed of the form of (45) with, for $(t, S) \in (0, T) \times (0, S_{\max})$, $H(t, S, p, u, v, \psi) = \min(-u - rSv - \frac{1}{2}\sigma^2 S^2 \psi + rp, p - \phi(S))$, which obviously satisfies (46).

First convergence results were given in the fundamental work of Crandall and Lions (1984) for Lipschitz continuous final condition ϕ (and without $\frac{\partial^2 p}{\partial S^2}$ dependence in (45)).

An abstract and general convergence result is given by Barles and Souganidis (1991), and we now give a simplified presentation of this result.

We first assume that H satisfies a comparison principle, which can be seen as an extension of the maximum principle to some nonlinear equations. The comparison principle is roughly the following (see Crandall, Ishii, and Lions, 1992; Barles, 1994; or Pham, 1998): Assume that u (resp. v) is a subsolution (resp. supersolution) of (45), that is,

$$\begin{aligned} H\left(t, x, u, \frac{\partial u}{\partial t}, \frac{\partial u}{\partial x}, \frac{\partial^2 u}{\partial x^2}\right) \leq 0 \\ \left(\text{resp. } H\left(t, x, v, \frac{\partial v}{\partial t}, \frac{\partial v}{\partial x}, \frac{\partial^2 v}{\partial x^2}\right) \geq 0\right) \end{aligned}$$

for $(t, S) \in (0, T) \times (0, S_{\max})$, and that $u \leq v$ on the boundaries $S = S_{\max}$ and $t = T$, then $u \leq v$ everywhere.

Now, suppose that we can write the scheme in the abstract form: $\forall i \in \{0, \dots, I\}, \forall n \in \{0, \dots, N\}$,

$$S_\rho(t_n, S_i, P_i^n, [P]) = 0 \tag{47}$$

where $\rho = (\delta t, \delta S)$, and $[P]$ stands for a continuous function that takes values $(P_j^k)_{0 \leq k \leq N, 0 \leq j \leq I}$ on the corresponding grid points (t_k, S_j) .⁴ We suppose that (47) admits at least one solution denoted P_ρ . Then, in the limit when ρ goes to

zero, P_ρ converges to p solution to (45) if the following conditions are satisfied:

- (i) A stability condition, which reads $\max_{0 \leq n \leq N, 0 \leq i \leq I} |P_i^n| \leq C$, for some constant C independent of N and I (i.e., independent of ρ).
- (ii) A consistency condition: for any regular function ψ ,

$$\begin{aligned} & \lim_{\xi \rightarrow 0, \rho \rightarrow 0, t_n \rightarrow t, S_i \rightarrow S} \mathcal{S}_\rho(t_n, S_i, \psi(t_n, S_i) + \xi, \psi + \xi) \\ &= H\left(t, S, \psi, \frac{\partial \psi}{\partial t}, \frac{\partial \psi}{\partial S}, \frac{\partial^2 \psi}{\partial S^2}\right)(t, S) \end{aligned}$$

For a weaker statement see Barles and Souganidis (1991).

- (iii) A monotonicity condition, which reads

$$\varphi \leq \psi \Rightarrow \mathcal{S}_\rho((t, S), P, \varphi) \geq \mathcal{S}_\rho((t, S), P, \psi)$$

For most standard financial options, a comparison principle holds. The stability and consistency conditions are close to the stability and consistency conditions already introduced in the case of the schemes for European options. Hence the new condition to check is the monotonicity assumption (which is related to the property (46a) satisfied by H). It is actually related to a discrete maximum principle.

Error estimates can also be obtained for the finite difference schemes (40)–(41)–(42). For example, for the EE scheme, an error estimate of order $\delta S^{1/2}$ in L^∞ -norm can be proved under a CFL condition and for Lipschitz initial data (see Jackobsen, 2003). In the context of the finite element method (see below) an error estimate of order δS^2 can be proved, but in the weaker L^2 -norm.

Implementation and Convergence of the Finite Difference Schemes

It is easy to see, in view of (43), that the EE scheme is stable and monotone if the components of the matrix $(I_d - \delta t A)$ are nonnegative. This is exactly what is needed to prove a discrete maximum principle in the European case.

This property holds under a CFL condition of the form $\delta t \leq C \delta S^2$, C constant, and with an appropriate discretization of the advection term. The CN scheme is also stable and monotone under a CFL-like condition. On the other hand, it can be shown that the IE-S scheme as well as the IE scheme are stable and monotone without any CFL condition.

Now let us explain how to solve the implicit schemes (41) or (42) in practice. Let us consider the IE scheme (41). At each time step, setting $b = P^{n+1}$, $B = I_d + \delta t A$ and $g = (\phi(S_i))_i$, the problem is equivalent to finding $x = P^n$ such that

$$\min((Bx - b)_i, (x - g)_i) = 0, \quad \forall i \quad (48)$$

The Howard algorithm (see Howard, 1960; also called the policy iteration algorithm) is the method of choice to solve (48). To present this algorithm, we rewrite (48) in the following form: Find x such that,

$$\min_{\alpha \in \{0,1\}^I} ((B(\alpha)x - b(\alpha))_i) = 0, \quad \forall i \quad (49)$$

where $B_{i,j}(\alpha) = \begin{cases} B_{i,j} & \text{if } \alpha_i = 0 \\ \delta_{i,j} & \text{if } \alpha_i = 1 \end{cases}$ (where $\delta_{i,j}$ is again the Kronecker symbol, i.e., the (i, j) -th component of I_d) and $b_i(\alpha) = \begin{cases} b_i & \text{if } \alpha_i = 0 \\ g_i & \text{if } \alpha_i = 1 \end{cases}$. The i -th component of $B(\alpha)x - b(\alpha)$ only depends on the i -th component of α , so that the minimum for the i -th component in (49) is indeed taken with respect to the i -th component of α . Thus, for a given x and α realizing the minimum in (49), the component α_i is equal to 0 (resp. to 1) if, at the i -th node, the minimum in (48) is $(Bx - b)_i$ (resp. $(x - g)_i$). For an initial value $\alpha^0 \in \{0, 1\}^I$, the algorithm is written as follows: Iterate for $k \geq 0$,

- (i) Compute x^k such that $B(\alpha^k)x^k = b(\alpha^k)$
- (ii) $\alpha_i^{k+1} = \arg \min_{\alpha_i \in \{0,1\}} (B(\alpha)x^k - b(\alpha))_i$

Santos and Rust (2004) and Bokanowski, Maroso, and Zidani (2009) provide some convergence results. Under suitable assumptions

on the matrix B (which are satisfied for the schemes considered above, which satisfy the monotonicity condition), it can be proved that this method converges in at most I iterations. In practice, only a few iterations are needed for solving (41).

This algorithm can also be seen as:

- A Newton’s method on the function F defined by $F_i(x) = \min((Bx - b)_i, (x - g)_i)$. More precisely, it is a semismooth Newton’s method applied to the slantly differentiable function⁶ F .
- A primal-dual algorithm to implement the fully implicit Euler scheme (41) as introduced in Hintermüller, Ito, and Kunisch (2002).

Another well-known method for solving (48) is the projected successive over relaxation (PSOR) method, which is a modification of the successive over relaxation (SOR) method to solve iteratively systems of linear equations (see Saad, 2003). In its simplest form, it consists of decomposing $B = L + U$ where L is a lower triangular matrix and U is an upper triangular matrix with zero coefficients on the diagonal. The algorithm consists of choosing an initial guess x^0 and then computing iteratively for $n \geq 1$, for $i = 1, \dots, I$, $x_i^n = \arg \min \{(Lx^{n-1} - (b - Ux^{n-1}))_i, (x^{n-1} - g)_i\}$. This method converges only if B is a diagonal dominant matrix, and the convergence is rather slow in practice. However, it leads to a highly efficient method for the finite element method discussed below, when combined with a suitable splitting scheme.

For the specific case of an American put option on a single asset, a fast algorithm was proposed by Brennan and Schwartz (1977) for solving (41) and proved to converge in Jaillet, Lamberton, and Lapeyre (1990) in the finite element setting (see also Bokanowski, Maroso, and Zidani [2009] in the finite difference setting). Also in this case it can be proved that the region of exercise (namely $\Gamma_t = \{x \in \mathbb{R}_+, p(t, x) > \phi(x)\}$) is of the form $\Gamma_t = [\gamma(t), \infty[$ where γ is continuous under some regularity assumption

Table 4 Error on the Value of an American Put in Function of the Number I of Intervals in the Variable S (and for $N = 1000$)

$(N = 1000)$	$I = 100$	$I = 200$	$I = 400$	$I = 800$	$I = 1600$
IE-S	0.00267	0.0361	0.00180	0.00210	0.00210
IE	0.00379	0.0146	0.00011	0.00024	0.00018

of the data. Then the Howard algorithm takes a simple form, which is known as the front-tracking algorithm (see, for instance, Achdou and Pironneau, 2005). However, these algorithms are very specific to the one-dimensional case and do not apply for general payoff functions.

Numerical Results for the American Put Option

In Table 4, we give numerical results obtained with the IE-S and IE schemes for an American put option with $r = 0.1$, $\sigma = 0.1$, $K = 100$, $T = 1$, $S = 100$, and $S_{\max} = 150$. We have computed all error values by taking the reference value $P = 1.63380$ (obtained with a Cox-Ross-Rubinstein algorithm with $N = 10^5$, CPU-time = 1750 s.; see Cox, Ross, and Rubinstein [1979] and Lamberton and Lapeyre [1997]). In this example, the IE scheme is one digit more accurate than the IE-S scheme. With these numerical parameters, the EE scheme would yield bad results since the CFL condition is not respected. The IE scheme has been implemented using the Howard algorithm. The remaining error when I is large is due to the time discretization.

In Table 5, we compare the EE, IE-S and IE schemes. Since the error is of order of $O(\delta t) + O(\delta S^2)$, we have used parameters N and I such that $\delta t \simeq \delta S^2$ (i.e., $N \simeq I^2$), and such that the CFL condition is satisfied. We remark that the EE scheme gives satisfactory results in less than a few seconds. The IE is more accurate but more costly than IE-S. Hence in view of the CPU-time it is more advantageous here to use simply the EE or the IE-S scheme. This conclusion holds for a finite difference discretization, but may be

different for a finite element discretization, or for another set of parameters.

Markov Chains Approximations

There exist related discretization schemes for American options based on Markov chain approximations. Markov chain schemes (see Kushner and Dupuis, 2001) are based on the approximation of the dynamic programming principle between times t and $t + \delta t$ and on the use of a spatial interpolation over a mesh (S_j). This leads to another class of schemes that are also in finite difference form. Their convergence can be established by showing the convergence to the dynamic programming equation, or by using the Barles-Souganidis theorem (see Barles and Souganidis, 1991). Finite difference schemes enter this framework as well as semi-Lagrangian schemes (Capuzzo-Dolcetta and Falcone, 1989; Falcone and Ferretti, 1994). An inversed CFL condition, typically of the form $\delta S^2 / \delta t \xrightarrow{\delta t, \delta S \rightarrow 0} 0$ can then be needed. Notice that the Cox-Ross-Rubinstein algorithm (Cox, Ross, and Rubinstein, 1979) can also be seen as a discrete Markov chain approximation scheme using a very particular spatial mesh such that no interpolation appears at the end.

Portfolio Optimization

The techniques developed above for pricing American options can be used in the context of portfolio optimization. A portfolio op-

timization problem (or stochastic optimization problem) is typically of the form

$$p(t, x) = \max_{\alpha \in L^\infty([t, T], K)} \mathbb{E} \left(\int_t^T e^{-\int_t^u r(s) ds} \times f(u, X_u^{t, x, \alpha}, \alpha(u)) du + e^{-\int_t^T r(s) ds} \phi(X_T^{t, x, \alpha}) \right) \quad (50)$$

where K is compact, α is a progressively measurable function with values in K , and with

$$\begin{cases} dX_u^{t, x, \alpha} = b(u, X_u^{t, x, \alpha}, \alpha(u)) du \\ \quad + \sigma(u, X_u^{t, x, \alpha}, \alpha(u)) dW_u, \quad u \geq t, \\ X_t^{t, x, \alpha} = x \end{cases}$$

The corresponding PDE can be shown to be

$$\min_{\alpha \in K} \left(-\frac{\partial p}{\partial t} - \frac{1}{2} \sigma^2(t, S, \alpha) \frac{\partial^2 p}{\partial S^2} - b(t, S, \alpha) \frac{\partial p}{\partial S} + rp - f(t, S, \alpha) \right) = 0$$

in the viscosity sense (see Pham, 2006). Finite difference schemes similar to those presented above for American options can be applied. Implicit schemes, if considered, can be solved by the Howard algorithm. This can also be generalized to an optimal stopping time problem, adding in (50) a supremum over stopping times with values in $[t, T]$ (as in (15)). For such general HJB equations, a discretization by a finite element approach is not always possible because an appropriate variational formulation cannot always be obtained; see Bensoussan and Lions (1978).

The Finite Element Approach for American Options

As in the European case, the finite element approach requires a variational formulation of the PDE (23). Let us consider the case of the American put option. Let V be the functional space used for the variational formulation, and

$$K = \{q \in V, q \geq \phi\}$$

We first notice that (23) is equivalent to the set of inequalities⁷ (together with $p(T, S) = \phi(S)$)

$$\begin{cases} p - \phi \geq 0, \\ -\frac{\partial p}{\partial t} + \mathcal{A}p \geq 0, \\ \left(-\frac{\partial p}{\partial t} + \mathcal{A}p\right)(p - \phi) = 0 \end{cases} \quad (51)$$

We can check that this is equivalent (for sufficiently smooth function p) to the following variational formulation for (23): find $p \in L^2([0, T], K) \cap C^0([0, T], L^2(\mathbb{R}_+))$ such that for all $t \in [0, T)$,

$$\forall q \in K, -\int \frac{\partial p}{\partial t}(q - p) + a(p, q - p) \geq 0 \quad (52)$$

where a is the bilinear form (35) defined above (recall that for compactly supported functions p and q , $a(p, q) = \int \mathcal{A}p q$), with the final condition

$$p(T, S) = \phi(S)$$

Indeed, by writing $q - p = (q - \phi) - (p - \phi)$, it is clear that (51) implies (52). Conversely, choosing a sufficiently large $q \in K$ in (52), we obtain that $-\frac{\partial p}{\partial t} + \mathcal{A}p \geq 0$. Taking then $q = \phi$ in (52), we obtain that $\langle -\frac{\partial p}{\partial t} + \mathcal{A}p, \phi - p \rangle \geq 0$, but this inequality is actually an equality since $-\frac{\partial p}{\partial t} + \mathcal{A}p \geq 0$ and $\phi - p \leq 0$.

Notice that if we take $K = V$ in (52), we recover the variational formulation (34) for the European option. Precise existence and uniqueness results for such variational inequalities can be found in Bensoussan and Lions (1978). For results and applications in the finance context,

we refer to Achdou and Pironneau (2005 and 2009).

Now, as in the case of the finite element method for European options, we introduce a sequence of finite dimensional functional spaces $V_h \subset V$, such that the functions in V are better and better approximated by functions in V_h as h goes to 0. One can, for example, consider a P1 finite element space on a mesh $(S_i)_{0 \leq i \leq I}$. Remember that a basis of V_h is given by a set of functions $(q_i)_{0 \leq i \leq I}$. The finite element approximation of (52) is obtained by replacing V by V_h : Find $p_h \in C^0([0, T], K \cap V_h)$ such that for all $t \in [0, T)$,

$$\forall q_h \in K \cap V_h, -\int \frac{\partial p_h}{\partial t}(q_h - p_h) + a(p_h, q_h - p_h) \geq 0 \quad (53)$$

with the final condition $p_h(T) = \phi_h$, where $\phi_h \in V_h$ is an approximation of ϕ .

For time discretization, one can again use the schemes we have introduced in the case of the discretization of European options. For example, the implicit Euler scheme applied to (53) is naturally defined as follows: Find $p_h^N, p_h^{N-1}, \dots, p_h^0$ in $V_h \cap K$ such that $p_h^N = \phi_h$ (initialization) and, for $n = N - 1, \dots, 0$:

$$\forall q_h \in V_h \cap K, -\int \frac{p_h^{n+1} - p_h^n}{\delta t}(q_h - p_h^n) + a(p_h^n, q_h - p_h^n) \geq 0 \quad (54)$$

One can easily check that

$$q_h \in V_h \cap K \Leftrightarrow q_h \in V_h \text{ and } q_h(S_i) \geq \phi(S_i), \forall i$$

Denoting A_h and M_h the mass and stiffness matrices as in the case of the finite element method for European options, and reasoning as for the equivalence between (23), (51), and (52), it can be checked that (54) is equivalent to solve in \mathbb{R}^I :

$$\min \left(\left(-M_h \frac{P^{n+1} - P^n}{\delta t} + A_h P^n\right)_i, (P^n - g)_i \right) = 0, \quad \forall i$$

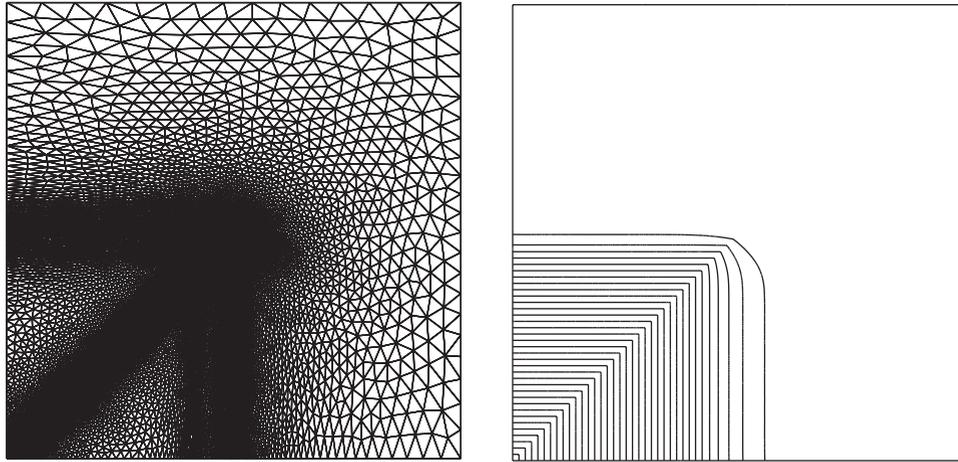

Figure 3 The Adapted Mesh and the Contours of P One Year to Maturity. $\sigma_1 = 0.2, \sigma_2 = 0.1, \rho = -0.6$.

where $g_i = \phi(S_i)$ and $P_i^n = p_h^n(S_i)$. Equivalently, the problem is to find P^n such that

$$\min \left((M_h + \delta t A_h) P^n - M_h P^{n+1} \right)_i, (P^n - g)_i = 0, \quad \forall i$$

This is a similar problem as for the IE finite difference scheme (see (48)) where the matrix $(I_d + \delta t A)$ is now replaced by $(M_h + \delta t A_h)$. It can be solved by the Howard algorithm previously presented. For the particular American put problem under some assumptions on the mesh steps δt and h , it can also be solved by the Brennan and Schwartz algorithm or the front-tracking algorithm mentioned above.

Notice that a Crank-Nicolson scheme can be derived in a similar way. The expected error (in L^2 -norm) is (as in the European case) $O(h^2) + O(\delta t)$ for the IE scheme and $O(h^2) + O(\delta t^2)$ for the CN scheme.

We conclude this section by a numerical illustration of the mesh refinement procedure (that can be implemented by using a posteriori error estimates) applied to the pricing of an American option on two assets. Such an automatic refinement procedure is particularly useful for American options because the pricing function is not smooth at any given time $t \in [0, T]$. Figures 3 and 4 illustrate such a mesh refinement for a typical two-assets American option with

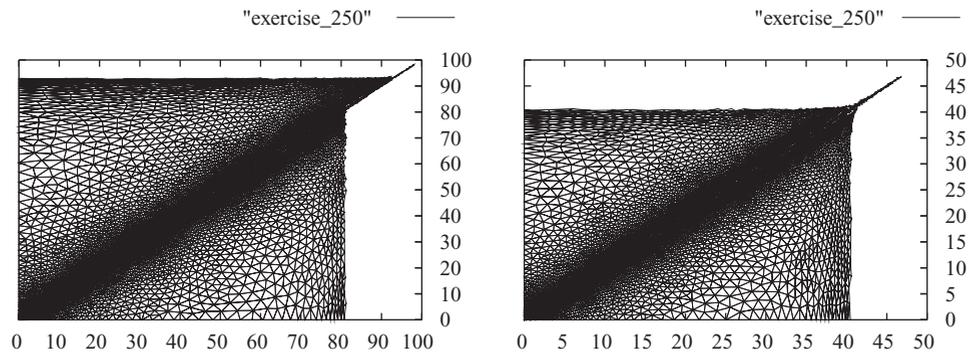

Figure 4 The Exercise Region One Year to Maturity. Left: $K = 100, \sigma_1 = 0.2, \sigma_2 = 0.1, \rho = -0.6$. Right: $K = 50, \sigma_1 = \sigma_2 = 0.2, \rho = 0$.

payoff $\phi(S_1, S_2) = (K - \max(S_1, S_2))_+$. The artificial boundary Γ_0 is $\{\max(S_1, S_2) = \bar{S} = 200\}$. Homogeneous Dirichlet conditions are imposed on Γ_0 . We have chosen two examples. In the first example, the parameters are $\sigma_1 = 0.2$, $\sigma_2 = 0.1$, $r = 0.05$, $\rho = -0.6$, and $K = 100$. In the second example, the parameters are $\sigma_1 = \sigma_2 = 0.2$, $r = 0.05$, $\rho = 0$, and $K = 50$. The implicit Euler scheme has been used with a uniform time step of $1/250$ year. For the variables S_1 and S_2 , we have used adaptive finite elements. For solving the linear complementarity problems, we have used the Howard algorithm. Mesh adaption in the (S_1, S_2) variable has been performed every $1/10$ year. In Figure 3, we have plotted the adapted mesh (left) and the contours of the pricing function (right) one year to maturity for the first example. Note that the contours exhibit right angles in the exercise region. In Figure 4, we plot the exercise region one year to maturity for the first example (left) and for the second example (right). One sees that the exercise boundary has singularities. It is also visible that the mesh has been adapted near the exercise boundary.

CALIBRATION

Let us now discuss the question of the determination of the parameters that appear in the models we introduced, with an emphasis on the *calibration* of the *local volatility*.

Limitation of the Black-Scholes Model: The Need for Calibration

Consider a European-style option on a given stock with a maturity T and a payoff function ϕ , and assume that this option is on the market. Call p its present price. Also, assume the risk-free interest rate is the constant r . One may associate with p the so-called implied volatility, that is, the volatility σ_{imp} such that the price given by formula (4) at time $t = 0$ with $\sigma = \sigma_{imp}$ coincides with p . If the Black-Scholes model was sharp, then the implied volatility would not depend on the payoff function ϕ . Unfortunately,

for vanilla European puts or calls, for example, it is often observed that the implied volatility is far from constant. Rather, it is often a convex function of the strike price. This phenomenon is known as the volatility smile. A possible explanation for the volatility smile is that the deeply out-of-the-money options are less liquid, thus relatively more expensive than the options in-the-money.

This shows that the critical parameter in the Black-Scholes model is the volatility σ . Assuming σ constant and using (8) often leads to poor predictions of the options' prices. The volatility smile is the price paid for the too great simplicity of Black-Scholes' assumptions.

Let us now discuss some of the possible enrichments of the Black-Scholes model:

- Local volatility models: The volatility is a function of time and of the spot price, that is, $\sigma_t = \sigma(t, S_t)$. With suitable assumptions on the regularity and the behavior at infinity of the function σ , (4) holds, and $P_t = p(t, S_t)$, where p satisfies the final value problem (8), in which σ varies with t and S . Calibrating the model consists of tuning the function σ in such a way that the prices computed, for example, with the PDE coincide with the observed prices. This will be discussed in detail below.
- Stochastic volatility models: One assumes that $\sigma_t = f(y_t)$, where y_t is a continuous time stochastic process, correlated or not to the process driving S_t ; see Fouque, Papanicolaou, and Sircar (2000) for a nice presentation. Several models have been proposed, among which are the following:

1. Hull-White model (see Hull and White, 1987): $f(y) = \sqrt{y}$ and y_t is a lognormal process.
2. Scott model: $f(y) = \sqrt{y}$ and y_t is a mean-reverting Ornstein-Uhlenbeck process:

$$dy_t = \alpha(m - y_t)dt + \beta dZ_t \quad (55)$$

where α and β are positive constants, Z_t is a Brownian motion.

3. Heston model (see Heston, 1993): $f(y) = \sqrt{y}$ and y_t is a Cox-Ingersoll-Ross process,

$$dy_t = \kappa(m - y_t)dt + \lambda\sqrt{y_t}dZ_t \quad (56)$$

where κ , m , and λ are positive constants.

4. Stein-Stein model (see Stein and Stein, 1991): $f(y) = \sqrt{y}$ and y_t is a mean-reverting Ornstein-Uhlenbeck process.

There are two risk factors, one for the stock price and the other for the volatility. If the two driving processes are not completely correlated, it is not possible to construct a hedged portfolio containing simply one option and shares of the underlying asset. One says that the market is incomplete. Nevertheless, if one fixes the contribution of the second source of randomness dZ_t to the risk premium, that is, the market price of the volatility risk or the risk premium factor as a function of t , S_t and y_t , then it is possible to prove that the option's price is of the form $P_t = p(t, S_t, y_t)$, where the pricing function satisfies a PDE in the variables (t, S, y) . The PDE may be degenerate for the values of y corresponding to volatility cancellation. Calibrating the model consists of tuning the parameters of the process y_t and the function f in order to match the observed prices.

- Lévy-driven spot price: One may generalize the Black-Scholes model by assuming that the spot price is driven by a more general stochastic process, for example, a Lévy process (see Cont and Tankov, 2003; Merton, 1976; and Carr, Geman, and Yor, 2002). Lévy processes are processes with stationary and independent increments which are continuous in probability. For a Lévy process X_t on a filtered probability space with probability \mathbb{P}^* , the Lévy-Khintchine formula says that there exists a function $\chi : \mathbb{R} \rightarrow \mathbb{C}$ such that

$$\begin{aligned} \mathbb{E}^*(e^{iuX_t}) &= e^{-\tau\chi(u)}, \\ \chi(u) &= \frac{\sigma^2 u^2}{2} - i\beta u - \int_{|z|<1} (e^{iuz} - 1 - iuz)v(dz) \\ &\quad - \int_{|z|>1} (e^{iuz} - 1)v(dz) \end{aligned}$$

for $\sigma \geq 0$, $\beta \in \mathbb{R}$ and a positive measure ν on $\mathbb{R} \setminus \{0\}$ such that $\int_{\mathbb{R}} \min(1, z^2)\nu(dz) < +\infty$. The measure ν is called the Lévy measure of X . We focus on the Lévy measure with a density, $\nu(dz) = k(z)dz$. It is assumed that the discounted price of the risky asset is a square integrable martingale under \mathbb{P}^* , and that it is represented as the exponential of a Lévy process:

$$e^{-r\tau} S_\tau = S_0 e^{X_\tau}$$

The martingale property is that $\mathbb{E}^*(e^{X_\tau}) = 1$, i.e.

$$\begin{aligned} \int_{|z|>1} e^z \nu(dz) < \infty, \quad \text{and} \\ \beta &= -\frac{\sigma^2}{2} - \int_{\mathbb{R}} (e^z - 1 - z1_{|z|\leq 1})k(z)(dz) \end{aligned}$$

and the square integrability comes from the condition $\int_{|z|>1} e^{2z}k(z)dz < \infty$.

With such models, the pricing function for a European option is obtained by solving a partial integrodifferential equation (PIDE), with a nonlocal term. Calibrating the model consists of tuning σ and the function k in such a way that the prices computed with the PIDE, for example, match the observed prices (see Cont and Tankov, 2004).

Local Volatility and Dupire's Formula

We consider a local volatility model and call $(t, S) \mapsto C(t, S, \tau, x)$ the pricing function for a vanilla European call with maturity τ and strike x . It satisfies the final value problem: for $t \in [0, \tau)$ and $x \in \mathbb{R}_+$,

$$\begin{aligned} \frac{\partial C}{\partial t} + \frac{\sigma^2(t, S)S^2}{2} \frac{\partial^2 C}{\partial S^2} + (r - q)S \frac{\partial C}{\partial S} - rC &= 0 \\ C(\tau, S) &= (S - x)_+ \end{aligned} \quad (57)$$

where we have supposed that the underlying asset yields a distributed dividend, $qS_t dt$. By reasoning directly on (4) or by using PDE arguments, it can be proved that the function $(\tau, x) \mapsto C(t, S, \tau, x)$ (now t and S are fixed)

satisfies the forward parabolic PDE:

$$\frac{\partial C}{\partial \tau} - \frac{1}{2}\sigma^2(\tau, x)x^2\frac{\partial^2 C}{\partial x^2} + (r - q)x\frac{\partial C}{\partial x} + qC = 0 \tag{58}$$

for $\tau > t$ and $x \in \mathbb{R}_+$. This observation was first made by Dupire (1994), and the proof of (58) by PDE arguments can be found in Achdou and Pironneau (2005) or Pironneau (2007). We also mention that similar partial differential equations can be derived for other options, like binary options, *barrier options*, options on Lévy-driven assets, or basket options (see Pironneau, 2007).

Using (58) is useful for two reasons. First, consider a family of calls on the same stock with different maturities and strikes (τ_i, x_i) , $I \in I$, where I is a finite set. Assume that the spot price is known, that is, $S = S_0$. In order to numerically compute the prices of the calls, that is, $C(0, S_0, \tau_i, x_i)$, $i \in I$, one may solve (58) for $\max_{i \in I} \tau_i > \tau > 0$ and initial data $C(\tau = 0, x) = (S_0 - x)_+$ with, for example, a finite difference or a finite element method. Only one initial value problem is needed. On the contrary, using (8) would necessitate solving $\#I$ initial value problems. We see that (58) may save a lot of work.

Second, (58) may be used for local volatility calibration. Indeed, if all the possible vanilla options were on the market, the local volatility in (57) could be computed:

$$\sigma^2(\tau, x) = 2 \frac{\frac{\partial C}{\partial \tau}(\tau, x) + (r - q)x\frac{\partial C}{\partial x}(\tau, x) + qC(\tau, x)}{x^2\frac{\partial^2 C}{\partial x^2}(\tau, x)} \tag{59}$$

This is known as *Dupire's formula* for the local volatility. In practice, (59) cannot be used directly because only a finite number of options are on the market.

Assume that the observations are the prices $(\tilde{C}_i)_{i \in I}$ of a family of calls with maturity/strike $(\tau_i, x_i)_{i \in I}$. Finding a function $(\tau, x) \mapsto \sigma(\tau, x)$ such that the solution of (58) with $C(0, x) = (S_0 - x)_+$ takes the value \tilde{C}_i at (τ_i, x_i) , $i \in I$ is called an inverse problem.

A natural idea is to somehow interpolate the observed prices by a sufficiently smooth function $\tilde{C} : [0, \max_{i \in I} \tau_i] \rightarrow \mathbb{R}_+$, then use (59) with $C = \tilde{C}$. For example, bicubic splines may be used. This approach has several serious drawbacks:

- It is difficult to design an interpolation process such that $\frac{\partial^2 \tilde{C}}{\partial x^2}$ does not take the value 0, and such that the right-hand side of (59) is nonnegative.
- There is an infinity of possible interpolations of \tilde{C}_i at (τ_i, x_i) , $i \in I$, and for two possible choices, the volatility obtained by (59) may differ considerably.

We see that financially relevant additional information has to be added to the interpolation process.

Least-Square Methods

Here, we show how (58) can be used for calibration. The first idea is to use *least squares*, that is, to minimize a functional $J : \sigma \mapsto \sum_{i \in I} \omega_i |\tilde{C}_i - C(\tau_i, x_i)|^2$ for σ in a suitable function set Σ , where ω_i are positive weights, and the pricing function C is the solution of (58) with $C(0, x) = (S_0 - x)_+$. The evaluation of J requires the solution of an initial value problem. The set Σ where the volatility is to be found must be chosen in order to ensure that from a minimizing sequence one can extract at least a subsequence that converges in Σ , and that its limit is indeed a solution of the least square problem. For example, Σ may be a compact subset of a Hilbert space W (in principle W could be a more general Banach space but it is easier to work in Hilbert spaces if gradients are needed) such that the mapping J is continuous in W . In practice, W has a finite dimension and is compactly embedded in the space of bounded and continuous functions σ such that $x\partial_x\sigma$ is bounded. Thus, the existence of a solution to the minimization problem is most often guaranteed. What is more difficult to guarantee is uniqueness and stability: Is there a unique solution to the least square problem? If yes, is the solution

insensitive to small variations of the data? The answer to these questions is no in general, and we say that the problem is ill-posed.

As a possible cure to ill-posedness, one usually modifies the problem by minimizing the functional $\sigma \mapsto J(\sigma) + J_R(\sigma)$ instead of J , where J_R is a sufficiently large strongly convex functional defined on W and containing some financially relevant information. For example, one may choose $J_R(\sigma) = \omega \|\sigma - \bar{\sigma}\|^2$, where ω is some positive weight, $\|\cdot\|$ is a norm in W , and $\bar{\sigma}$ is a prior local volatility, which may come from historical knowledge. The difficulty is that ω must not be too large not to perturb the inverse problem too much, but not too small to guarantee some stability. The art of the practitioner lies in the choice of J_R .

Once the least square problem is chosen, we are left with proposing a strategy for the construction of minimizing sequences. If J and J_R are C^1 functional, then gradient methods may be used. The drawbacks and advantages of such methods are well known: On the one hand, they do not guarantee convergence to the global minimum if the functional is not convex, because the iterates can be trapped near a local minimum. On the other hand, they are fast and accurate when the initial guess is close enough to the minimum. For these reasons, gradient methods are often combined with techniques that permit us to localize the global minimum but that are slow, like simulated annealing or evolutionary algorithms.

Anyhow, gradient methods require the evaluation of the functional's gradient. Since J_R explicitly depends on σ , its gradient is easily computed. The gradient of J is more difficult to evaluate, because the prices $C(\tau_i, x_i)$ depend on σ in an indirect way: One needs to evaluate the variations of $C(\tau_i, x_i)$ caused by a small variation of σ ; calling $\delta\sigma$ the variation of σ and δC the induced variation of C , one sees by differentiating (58) that $\delta C(\tau = 0, \cdot) = 0$ and

$$\begin{aligned} \partial_\tau \delta C - \frac{\sigma^2(\tau, x)x^2}{2} \partial_{xx}^2 \delta C + (r - q)x \partial_x \delta C + q \delta C \\ = \sigma \delta \sigma x^2 \partial_{xx}^2 C \end{aligned} \quad (60)$$

To express δJ in terms of $\delta\sigma$, an adjoint state function P is introduced as the solution to the adjoint problem: Find the function P such that $P(\bar{\tau}, \cdot) = 0$ and for $\tau < \bar{\tau}$,

$$\begin{aligned} \partial_\tau P + \partial_{xx}^2 \left(\frac{\sigma^2 x^2}{2} P \right) - \partial_x (P(r - q)x) - qP \\ = 2 \sum_{i \in I} \omega_i (C(\tau_i, x_i) - \bar{C}_i) \delta_{\tau_i, x_i} \end{aligned} \quad (61)$$

where $\bar{\tau}$ is an arbitrary time greater than $\max_{i \in I} \tau_i$ and in the right-hand side, the δ_{τ_i, x_i} denote Dirac functions in time and strike at (τ_i, x_i) . The meaning of (61) is the following:

$$\begin{aligned} - \int_Q \left(\partial_\tau v - \frac{\sigma^2 x^2}{2} \partial_{xx}^2 v + (r - q)x \partial_x v + qv \right) P \\ = 2 \sum_{i \in I} \omega_i (C(\tau_i, x_i) - \bar{C}_i) v(\tau_i, x_i) \end{aligned} \quad (62)$$

where $Q = (0, \bar{\tau}) \times \mathbb{R}_+$, and v is any function such that $v \in L^2((0, \bar{\tau}), V)$ with $\partial_\tau v \in L^2(Q)$ and $x^2 \partial_{xx}^2 v \in L^2(Q)$. Taking $v = \delta C$ in (62) and using (60), one finds

$$\begin{aligned} 2 \sum_{i \in I} \omega_i (C(\tau_i, x_i) - \bar{C}_i) \delta C(\tau_i, x_i) \\ = 2 \sum_{i \in I} \omega_i (C(\tau_i, x_i) - c_i) (\delta_{\tau_i, x_i}, \delta C) \\ = - \int_Q \left(\partial_\tau \delta C - \frac{\sigma x^2}{2} \partial_{xx}^2 \delta C + (r - q)x \partial_x \delta C + q \delta C \right) P \\ = - \int_Q \sigma \delta \sigma x^2 P \partial_{xx}^2 C \end{aligned}$$

We have worked in a formal way, but all the integrations above can be justified. This leads to the estimate

$$\left| \delta J + \int_Q \sigma \delta \sigma x^2 P \partial_{xx}^2 C \right| \leq c \|\delta \sigma\|_{L^\infty(Q)}^2$$

which implies that J is differentiable, and that its differential at point σ is given by

$$DJ(\sigma) : \eta \mapsto - \int_Q \sigma \eta x^2 P(\sigma) \partial_{xx}^2 C(\sigma)$$

where $P(\sigma)$ satisfies (61), and $C(\sigma)$ satisfies (58). We see that the gradient of J can be evaluated. When (58) is discretized with, for example, finite elements, all that has been done can be repeated with a discrete adjoint problem, and the gradient of the functional can be evaluated in the same way. Let us stress that the gradient

$DJ(\sigma)$ is computed exactly, which would not be the case with, for example, a finite difference method.

Local volatility can also be calibrated with American options, but it is not possible to find the analogue of Dupire’s equation. Thus, in the context of a least square approach, the evaluation of the cost function requires the solution of #1 variational inequalities, which is computationally expensive (see Achdou and Pironneau, 2005). In this case, it is also possible to find the necessary optimality conditions involving an adjoint state (see Achdou, 2005).

Appendix: Proof of (21)

First, from the definition (15) of p we have, for any stopping time $\rho \in \mathcal{T}_{[t,T]}$,

$$\begin{aligned} & e^{-\int_t^\rho r ds} p(\rho, S_\rho^{t,x}) \\ &= \text{ess sup}_{\tau \in \mathcal{T}_{[\rho,T]}} \mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x}) \mid \mathcal{F}_\rho \right), \text{ a.s.} \end{aligned} \tag{63}$$

where $\mathcal{T}_{[\rho,T]}$ denotes the set of stopping times τ such that $\rho \leq \tau \leq T$. Then it is possible to show that (see, for instance, Karatzas and Shreve, 2010, Eq. (D.7)), for any stopping time $\rho \in \mathcal{T}_{[t,T]}$,

$$\begin{aligned} & \mathbb{E} \left(e^{-\int_t^\rho r ds} p(\rho, S_\rho^{t,x}) \right) \\ &= \sup_{\tau \in \mathcal{T}_{[\rho,T]}} \mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x}) \right) \end{aligned} \tag{64}$$

We obtain from (64) the decreasing property: For all stopping times $\rho_1, \rho_2 \in \mathcal{T}_{[t,T]}$, such that $\rho_1 \geq \rho_2$,

$$\begin{aligned} & \mathbb{E} \left(e^{-\int_t^{\rho_1} r ds} p(\rho_1, S_{\rho_1}^{t,x}) \right) \\ & \leq \mathbb{E} \left(e^{-\int_t^{\rho_2} r ds} p(\rho_2, S_{\rho_2}^{t,x}) \right) \end{aligned} \tag{65}$$

We deduce from (63) that, for any $\tau \in \mathcal{T}_{[\tau^*,T]}$,

$$\begin{aligned} & \mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x}) \mid \mathcal{F}_{\tau^*} \right) \leq e^{-\int_t^{\tau^*} r ds} p(\tau^*, S_{\tau^*}^{t,x}) \\ &= e^{-\int_t^{\tau^*} r ds} \phi(S_{\tau^*}^{t,x}) \end{aligned} \tag{66}$$

where the last identity comes from the definition (20) of τ^* . Then, for any stopping time

$\tau \in \mathcal{T}_{[t,T]}$, we have (by decomposing on the events $\{\tau < \tau^*\}$ and $\{\tau \geq \tau^*\}$), and using (66) for $\tau \geq \tau^*$):

$$\mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x}) \right) \leq \mathbb{E} \left(e^{-\int_t^{\tau \wedge \tau^*} r ds} \phi(S_{\tau \wedge \tau^*}^{t,x}) \right)$$

Hence, by taking the supremum over all the stopping times $\tau \in \mathcal{T}_{[t,T]}$,

$$\begin{aligned} p(t, x) & \leq \sup_{\tau \in \mathcal{T}_{[t,T]}} \mathbb{E} \left(e^{-\int_t^{\tau \wedge \tau^*} r ds} \phi(S_{\tau \wedge \tau^*}^{t,x}) \right) \\ &= \sup_{\tau \leq \tau^*, \tau \in \mathcal{T}_{[t,T]}} \mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x}) \right) \end{aligned} \tag{67}$$

By (15), the right-hand side of (67) is bounded from above by $p(t,x)$, and thus we obtain the equality

$$p(t, x) = \sup_{\tau \leq \tau^*, \tau \in \mathcal{T}_{[t,T]}} \mathbb{E} \left(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x}) \right) \tag{68}$$

In fact the supremum in (68) is reached only for $\tau = \tau^*$ a.s.. Indeed, for $\tau \in \mathcal{T}_{[t,T]}$, if $\tau \leq \tau^*$ and $\mathbb{P}(\tau < \tau^*) > 0$, we have, by the definition of τ^* , $\mathbb{E}(e^{-\int_t^\tau r ds} \phi(S_\tau^{t,x})) < \mathbb{E}(e^{-\int_t^{\tau^*} r ds} p(\tau, S_\tau^{t,x})) \leq p(t, x)$. This concludes the proof of (21).

KEY POINTS

- When a deterministic method is available to price an option, it is generally more efficient than a brute force Monte Carlo algorithm.
- Deterministic techniques are usually more involved to implement than stochastic approaches and typically require specific developments for each targeted pricing problem.
- Deterministic approaches are particularly useful for nonlinear problems (including the pricing of American options and portfolio optimization) and for calibration.
- Future research subjects for such approaches include the development of efficient discretization methods for high-dimensional problems, and the combination of deterministic and stochastic approaches to take advantage of both techniques (using variance-reduction techniques or predictor-corrector methods, for example).

NOTES

1. Notice that the same equation has been considered by Vecer (2001) using some financial arguments.
2. <http://www-rocq.inria.fr/mathfi/Premia/index.html>
3. <http://www.freefem.org/>
4. More precisely, the interpolating operator should also satisfy $[P] \leq [Q]$ everywhere as soon as $P_j^k \leq Q_j^k$ for all k, j .
5. A good initial guess is indeed the vector α obtained at the previous time iteration.
6. F is slantly differentiable if there exist $C > 0$ and a matrix $G(x)$ such that $\forall x, \|G(x)^{-1}\|_\infty < C$ and $F(x+h) = F(x) + G(x)h + o(h)$ as $h \rightarrow 0$. Here $G(x)$ can be defined by $G(x)_{ij} = B_{ij}$ if $(Bx - b)_i \leq (x - g)_i$, and $G(x)_{ij} = \delta_{ij}$ otherwise.
7. Such a problem is called a linear complementarity problem.

Model Risk and Selection

Model Risk

KEVIN DOWD, PhD

Partner, Cobden Partners, London

Abstract: Model risk is the risk of error in pricing or risk-forecasting (such as value at risk, or VaR) models. It arises in part because any model involves simplification and calibration, and both of these require subjective judgments that are inevitably open to error. Model risk can also arise where a model is used inappropriately. Model risk is therefore an inescapable consequence of model use, and there is abundant anecdotal and other evidence that it is a major problem, especially for VaR models. However, there are also many ways in which risk managers and financial institutions can manage this problem.

This entry examines the subject of model risk. Loosely speaking, *model risk* is the risk of error in the valuations produced by a pricing model or in the estimated risk measures produced by a risk model. The nature of model risk and its diverse causes and manifestations are examined. The entry also briefly addresses the scale of the problem and the dangers it entails, and then goes on to discuss ways in which model risk can be managed.

MODELS AND MODEL RISK

A *model* can be defined as “a simplified description of reality that is at least potentially useful in decision-making” (Geweke, 2005, p. 7). A model attempts to identify the key features of whatever it is meant to represent and is, by its very nature, a highly simplified structure. We should therefore not expect any model to give a perfect answer: Some degree of error is to be expected, and we can think of this risk of error as a form of model risk.

However, the term *model risk* is more subtle than it looks, and not all output errors are due to model inadequacy. For example, simulation methods generally produce errors due to sampling variation, so even the best simulation-based model will produce results affected by random noise. Conversely, models that are theoretically inappropriate can sometimes provide good results. The most obvious cases in point are the well-known “holes in Black-Scholes”: Simple option pricing models often work well even when some of the assumptions on which they are based are known to be invalid. They work well not because they are accurate, but because those who use them are aware of their limitations and use them discerningly.

In finance, we are concerned with both *pricing* (or valuation) *models* and risk (or VaR) *models*. The former are models that enable us to price a financial instrument, and with these model risk boils down to the risk of mispricing. These models are typically used on a stand-alone basis and it is often very important that

they give precise answers: Mispricing can lead to rapid and large arbitrage losses. Their exposure to this risk depends on such factors as the complexity of the position, the presence or otherwise of unobserved variables (e.g., such as volatilities), interactions between risk factors, the use of numerical approximations, and so on.

Risk models are models that forecast financial risks or probabilities. These models are exposed to many of the same problems as pricing models, but all are often also affected by the difficulties of trying to integrate risks across different positions or business units, and this raises a host of issues (e.g., aggregation problems, potential inconsistencies across constituent positions or models, etc.) that do not (typically) arise in stand-alone pricing models. So risk models are exposed to more sources of model risk than pricing models typically are. However, with risk models there is far less need for accuracy: Errors in risk estimates do not lead directly to arbitrage losses, and the old engineering principle applies that the end output is only as good as the weakest link in the system. With risk models, we therefore want to be approximate and right, and efforts to achieve high levels of precision would be pointless because any reported precision would be spurious.

We are particularly concerned in this entry with how models can go wrong, and to appreciate these problems it helps to understand how our models are constructed in the first place. To get to know our models we should:

- Understand the securities involved and the markets in which they are traded.
- Isolate the most important variables and separate out the causal variables (or exogenous variables) from the caused (or endogenous) variables.
- Decide which exogenous variables are deterministic and which are stochastic or random, decide how the exogenous variables are to be modeled, and decide how the exogenous variables affect the endogenous ones.
- Decide which variables are observable or measurable and which are not; decide how the former are measured, and consider whether and how the unobservable variables can be proxied or implicitly solved from other variables.
- Try to ensure that the model captures all key features of the problem at hand, but also has no unnecessary complexity.
- Consider how the model can be solved and look for the simplest possible solutions. We should also consider the possible benefits and drawbacks of using approximations instead of exact solutions.
- Program the model, taking account of programming considerations, computational time, and so on.
- Calibrate the model using suitable methods: For example, we might estimate parameters using maximum likelihood methods and then adjust them using subjective judgments about factors such as changing market conditions that might not be fully reflected in our data set.
- Test the model using data not used to calibrate the model.
- Implement the model, regularly evaluate its performance, and identify its strengths and weaknesses.
- Keep a log of all these activities and their outcomes.

SOURCES OF MODEL RISK

Incorrect Model Specification

One of the most important sources of model risk is incorrect model specification, and this can manifest itself in many ways:

- **Stochastic processes might be misspecified.** We might assume that a stochastic process follows a geometric Brownian motion when it is in fact heavy-tailed, we might fit a symmetric distribution to skewed data, and so forth. It is very easy to misspecify stochastic processes, because the “true” stochastic

process is very difficult to identify and it is impossible in practice to distinguish between a “true” process and a similar but false alternative. The misspecification of stochastic processes can lead to major errors in estimates of risk measures: The classic example is where we incorrectly assume normality in the presence of heavy tails, an error that can lead to major underestimates of VaR and other risk measures.

- **Incorrect calibration of parameters.** Even if we do manage to identify the “true” model, the model might be calibrated with incorrect parameter values. Parameters might be estimated with error, not kept up to date, estimated over inappropriate sample periods, and so forth. This problem is often referred to as *parameter risk*, and it arises everywhere in risk management because it is practically impossible to determine “true” parameter values. Besides leading to major errors in risk estimates, incorrect calibration can also lead to major losses if the models are used to price traded instruments. A good example was the £90 million loss made by the NatWest Bank from 1995 to 1997, where a trader had fed his own (artificially high) estimates of volatility into a model used to price long-dated over-the-counter (OTC) interest rate options. We can also get problems when correlations unexpectedly polarize in a crisis: In such cases, the portfolio loses much of its effective diversification, and the “true” risks taken can be much greater than estimates based on earlier correlations might suggest.
- **Missing risk factors and misspecified relationships.** We might ignore stochastic volatility or fail to consider enough points across the term structure of interest rates, ignore background risk factors such as macroeconomic ones, or we might misspecify important relationships (e.g., by ignoring correlations).
- **Ignoring of transactions costs, liquidity, and crisis factors.** Many models ignore transactions costs and assume that markets are perfectly liquid. Such assumptions are very

convenient for modelling purposes, but can lead to major errors where transactions costs are significant, where market liquidity is limited, or where a crisis occurs. These sorts of problems were highlighted by the difficulties experienced by portfolio insurance strategies in the October 1987 crash—where strategies predicated on dynamic hedging were unhinged by the inability to unwind positions as the market fell. The failure to allow for illiquidity led to much larger losses than the models anticipated—a classic form of model risk.

There is empirical evidence that model misspecification risk is a major problem. To give a couple of examples: Hendricks (1996) investigated differences between alternative VaR estimation procedures applied to 1,000 randomly selected simple foreign exchange portfolios, finding that these differences were sometimes substantial; more alarmingly, a famous study by Beder 1995 examined eight common VaR methodologies used by a sample of commercial institutions applied to three hypothetical portfolios, and among other worrying results found that alternative VaR estimates for the same portfolio could differ by a factor of up to 14. Some further evidence is provided by Berkowitz and O’Brien (2001) who examined the VaR models used by six leading U.S. financial institutions. Their results indicated that these models can be highly inaccurate: Banks sometimes experienced high losses very much larger than their models predicted, and this suggests that these models are poor at dealing with heavy tails or extreme risks. Their results also suggest that banks’ structural models embody so many approximations and other implementation compromises that they lose any edge over much simpler models such as generalized autoregressive conditional heteroskedasticity (GARCH) ones. The implication is that financial institutions’ risk models are very exposed to model risk—and one suspects many risk managers are not aware of the extent of the problem.

Incorrect Model Application

Model risk can also arise because a good model is incorrectly applied. To quote Emanuel Derman:

There are always implicit assumptions behind a model and its solution method. But human beings have limited foresight and great imagination, so that, inevitably, a model will be used in ways its creator never intended. This is especially true in trading environments, where not enough time can be spent on making interfaces fail-safe, but it's also a matter of principle: you just cannot foresee everything. So, even a "correct" model, "correctly" solved, can lead to problems. The more complex the model, the greater this possibility. (Derman, 1997, p. 86)

One can give very many instances of this problem: We might use the wrong model in a particular context (e.g., we might use a Black-Scholes model for pricing options when we should have used a stochastic volatility model, etc.); we might have initially had the right model, but have fallen behind best market practice and not kept the model up to date, or not replaced it when a superior model became available; we might run Monte Carlo simulations with a poor random number generator or an insufficient number of trials, and so on. We can also get "model creep," where a model is initially designed for one type of problem and performs well on that problem, but is then gradually applied to more diverse situations to which it is less suited or not suited at all. A perfectly good model can then end up as a major liability not because there is anything wrong with it, but because users don't appreciate its limitations.

Implementation Risk

Model risk also arises from the ways in which models are implemented. No model can provide a complete specification of model implementation in every conceivable circumstance because of the very large number of possible instruments and markets, and because of their

varying institutional, statistical, and other properties. However complete the model, implementation decisions still need to be made about such factors as valuation (e.g., mark to market versus mark to model, whether to use the mean bid-ask spread, etc.), whether and how to clean data, how to map instruments, how to deal with legacy systems, and so on.

The possible extent of *implementation risk* is illustrated by the results of a study by Marshall and Siegel (1997). They sought to quantify implementation risk by looking at differences between how various commercial systems applied the RiskMetrics variance-covariance approach to specified positions based on a common set of assumptions (that is, a one-day holding period, a 95% VaR confidence level, delta-valuation of derivatives, RiskMetrics mapping systems, etc.). They found that any two sets of VaR estimates were always different, and that VaR estimates could vary by up to nearly 30% depending on the instrument class; they also found these variations were in general positively related to complexity: The more complex the instrument or portfolio, the greater the range of variation of reported VaRs. These results suggested that:

[A] naive view of risk assessment systems as straightforward implementations of models is incorrect. Although software is deterministic (i.e., given a complete description of all the inputs to the system, it has well-defined outputs), as software and the embedded model become more complex, from the perspective of the only partially knowledgeable user, they behave stochastically. . . . Perhaps the most critical insight of our work is that as models and their implementations become more complex, treating them as entirely deterministic black boxes is unwise, and leads to real implementation and model risks. (Marshall and Siegel, 1997, pp. 105–106)

Endogenous Model Risk

There is also a particularly subtle and invidious form of model risk that arises from the ways in which traders or asset managers respond to the

models themselves: Traders or asset managers will “game” against the model. Traders are likely to have a reasonable idea of the errors in the parameters—particularly volatility or correlation parameters—used to estimate VaR, and such knowledge will give the traders an idea of which positions have under- and overestimated risks. If traders face VaR limits or face risk-adjusted remuneration with risks specified in VaR terms, they will therefore have an incentive to seek out such positions and trade them. To the extent they do, they will take on more risk than suggested by VaR estimates, which will therefore be biased downward. Indeed, VaR estimates are likely to be biased even if traders do not have superior knowledge of underlying parameter values. The reason for this is that if a trader uses an estimated variance-covariance matrix to select trading positions, then he or she will tend to select positions with low estimated risks, and the resulting changes in position sizes mean that the initial variance-covariance matrix will tend to underestimate the resulting portfolio risk. As Shaw nicely puts it:

[M]any factor models fail to pick up the risks of *typical* trading strategies which can be the greatest risks run by an investment bank. According to naïve yield factor models, huge spread positions between on-the-run bonds and off-the-run bonds are riskless! According to naïve volatility factor models, hedging one year (or longer dated) implied volatility with three month implied volatility is riskless, provided it is done in the “right” proportions—i.e., the proportions built into the factor model! It is the *rule*, not the exception, for traders to put on spread trades which defeat factor models *since they use factor type models to identify richness and cheapness!* (Shaw, 1997, p. 215; his emphasis)

Other Sources of Model Risk

There are also other sources of model risk. Programs might have errors or bugs in them, simulation methods might use poor random number generators or suffer from discretization errors, approximation routines might be inaccurate or fail to converge to sensible solutions, rounding

errors might add up, and so on. We can also get problems when programs are revised by people who did not originally write them, when programs are not compatible with user interfaces or other systems (e.g., datafeeds), when programs become complex or hard to read (e.g., when programs are rewritten to make them computationally more efficient but then become less easy to follow). We can also get simple blunders. Derman (1997, p. 87) reported the example of a convertible bond model that was good at pricing many of the options features embedded in convertible bonds, but sometimes miscounted the number of coupon payments left to maturity.

Finally, models can give incorrect answers because poor data are fed into them—“garbage in, garbage out,” as the saying goes. Data problems can arise from many sources: from the way data are constructed (e.g., whether we mark to market or mark to model, whether we use actual trading data or end-of-day data, how we deal with bid-ask spreads, etc.), from the way time is handled (e.g., whether we use calendar time, trading time, how we deal with holidays, etc.), from the way in which data are cleansed or standardized, from data being non-synchronous, and from many other sources.

MANAGING MODEL RISK

Some Guidelines for Risk Managers

Given that risk managers can never eliminate model risk, the only option left is to learn to live with it and, hopefully, manage it. Practitioners can do so in a number of ways:

- **Be aware of model risk.** First and foremost, practitioners should simply be aware of it, and be aware of the limitations of the models they use. They should also be aware of the comparative strengths and weaknesses of different models, be knowledgeable of which models suit which problems, and be on the

lookout for models that are applied inappropriately.

- **Identify, evaluate, and check key assumptions.** Users should explicitly set out the key assumptions on which a model is based, evaluate the extent to which the model's results depend on these assumptions, and check them as much as possible (e.g., using statistical tests).
- **Choose the simplest reasonable model.** Exposure to model risk is reduced if practitioners always choose the simplest reasonable model for the task at hand. Occam's razor applies just as much in model selection as in anything else: Unnecessary complexity is never a virtue. Whenever we choose a more complex model over a simpler one, we should always have a clear reason for doing so.
- **Don't ignore small problems.** Practitioners should resist the temptation to explain away small discrepancies in results and sweep them under the rug. Small discrepancies are often good warning signals of larger problems that will manifest themselves later if they are not sorted out.
- **Test models against known problems.** It is always a good idea to check a model on simple problems to which one already knows the answer, and many problems can be distilled to simple special cases that have known answers. If the model fails to give the correct answer to a problem whose solution is already known, then we immediately know that there must be something wrong with it.
- **Plot results and use nonparametric statistics.** Graphical outputs can be extremely revealing, and simple histograms or plots often show up errors that might otherwise be very hard to detect. For example, a plot might have the wrong slope or shape or have odd features such as kinks that flag an underlying problem. Summary statistics and simple nonparametric tests can also be useful for helping to impart a feel for data and results.

- **Back-test and stress-test the model.** Practitioners should evaluate model adequacy using stress tests and back tests.
- **Estimate model risk quantitatively.** Where feasible, practitioners should seek to estimate model risk quantitatively (e.g., using simulation methods). However, it helps to keep in mind that any quantitative estimate of model risk is almost certainly an underestimate because not all model risk is quantifiable.
- **Reevaluate models periodically.** Models should be re-calibrated and reestimated on a regular basis, and the methods used should be kept up to date.

Some Institutional Guidelines

Financial institutions themselves can also combat model risk through appropriate institutional devices. One defense is a sound system to vet models before they are approved for use and then periodically review them. A good model-vetting procedure is proposed by Crouhy et al. (2001, pp. 607–608) and involves the following four steps:

1. **Documentation.** The risk manager should ask for a complete specification of the model, including its mathematics, components, computer code, and implementation features (e.g., numerical methods and pricing algorithms used). The information should be in sufficient detail to enable the risk manager to reproduce the model from the information provided.
2. **Soundness.** The risk manager should check that the model is a reasonable one for the instrument(s) or portfolio concerned.
3. **Benchmark modeling.** The risk manager should develop a benchmark model and test it against well-understood approximation or simulation methods.
4. **Check results and test the proposed model.** The final stage involves the risk manager using the benchmark model to check the

performance of the proposed model. The model should also be checked for zero-arbitrage properties such as put-call parity, and should then be stress tested to help determine the range of parameter values for which it will give reasonable estimates.

All these stages should be carried out free of undue pressures from the front office, and traders should not be allowed to vet their own pricing models. It is also important to keep good records, so each model should be fully documented in the middle (or risk) office. Risk managers should have full access to the model at all times, as well as access to real trading and other data that might be necessary to check models and validate results. The ideal should be to give the middle office enough information to be able to check any model or model results at any time, and do so using appropriate (that is, up to date) data sets. This information set should include a log of model performance with particular attention to any problems encountered and what (if anything) has been done about them. There should also be a periodic review (as well as occasional spot check) of the models in use, to ensure that model calibration is up to date and that models are upgraded in line with market best practice, and to ensure that obsolete models are identified as such and taken out of use. Such risk audits should also address not just the risk models, but all aspects of the firm's risk management. And, of course, all these measures should take place in the context of a strong and independent risk oversight or middle office function.

KEY POINTS

- A model attempts to identify the key features of whatever it is meant to represent and is, by its very nature, a highly simplified structure.
- In financial modeling, the concern is with both pricing (or valuation) models and risk (or VaR) models. The risk of error in pricing or risk-forecasting models is referred to as model risk.

ing or risk-forecasting models is referred to as model risk.

- Model risk is an inescapable consequence of model use and affects both pricing models and VaR models.
- The main sources of model risk include incorrect specification, incorrect application, implementation risk, and the problem of *endogenous model risk* where traders “game” against the model.
- There are ways in which practitioners can manage model risk. These include (1) recognizing model risk, (2) identifying, evaluating, and checking the model's key assumptions, (3) selecting the simplest reasonable model, (4) resisting the temptation to ignore small discrepancies in results, (5) testing the model against known problems, (6) plotting results and employing nonparametric statistics, (7) back-testing and stress-testing the model, (8) estimating model risk quantitatively, and (9) reevaluating models periodically.

Courant Institute of Mathematical Sciences, New York University

Abstract: Financial modelers have to solve the critical problem of selecting or perhaps building the optimal model to represent the phenomena they seek to study. The task calls for a combination of personal creativity, theory, and machine learning.

In this entry we discuss methods for model selection and analyze the many pitfalls of the model selection process.

MODEL SELECTION AND ESTIMATION

In his book *Complexity*, Mitchell Waldrop (1992) describes the 1987 Global Economy Workshop held at The Santa Fe Institute, a research center dedicated to the study of complex phenomena and related issues. Organized by the economist Bryan Arthur and attended by distinguished economists and physicists, the seminar introduced the idea that economic laws might be better understood applying the principles of physics and, in particular, the newly developed theory of complex systems. The seminar proceedings were to become the influential

book *The Economy as an Evolving Complex System* (Anderson, Arrow, and Pines, 1998).

An anecdote from the book is revealing of the issues specific to economics as a scientific endeavor. According to Waldrop, physicists attending the seminar were surprised to learn that economists used highly sophisticated mathematics.

A physicist attending the seminar reportedly asked Kenneth Arrow, the 1972 Nobel Prize winner in economics, why, given the lack of data to support theories, economists use such sophisticated mathematics. Arrow replied, "It is just because we do not have enough data that we use sophisticated mathematics. We have to ensure the logical consistency of our arguments." For physicists, on the other hand, explaining empirical data is the best guarantee of the logical consistency of theories. If theories work empirically, then mathematical details are

not so important and will be amended later; if theories do not work empirically, no logical subtlety will improve them.

This anecdote is revealing of one of the key problems that any modeler of economic phenomena has to confront. On the one side, economics is an empirical science based on empirical facts. However, as data are scarce, many theories and models fit the same data. One is tempted to rely on “clear reasoning” to compensate for the scarcity of data. In economics, there is always a tension between the use of pure reasoning to develop *ex ante* economic theories and the need to conform to generally accepted principles of empirical science. The development of high-performance computing has aggravated the problem, making it possible to discover subtle patterns in data and to build models that fit data samples with arbitrary precision. But patterns and models selected in this way are meaningless and reveal no true economic feature.

Given the importance of model selection, let us discuss this issue before actually discussing estimation issues. It is perhaps useful to compare again the methods of economics and of physics. In physics, the process of model choice is largely based on human creativity. Facts and partial theories are accumulated until scientists make a major leap forward, discovering a new unifying theory. Theories are generally expressed through differential equations and often contain constants (i.e., numerical parameters) to be empirically ascertained. Note that the discovery of laws and the determination of constants are separate moments. Theories are often fully developed before the constants are determined; physical constants often survive major theoretical overhauls in the sense that new theories must include the same constants plus, eventually, additional ones.

Physicists are not concerned with problems of “data snooping,” that is, of fitting the data to the same sample that one wants to predict. In general, data are overabundant and models are not determined through a process of fitting

and adaptation. Once a physical law that accurately fits all available data is discovered, scientists are confident that it will fit similar data in the future. The key point is that physical laws are known with a high level of precision. Centuries of theoretical thinking and empirical research have resulted in mathematical models that exhibit an amazing level of correspondence with reality. Any minor discrepancy from predictions to experiments entails a major scientific reevaluation. Often new laws have completely different forms but produce quite similar results. Experiments are devised to choose the winning theory.

Now consider economics, where the conceptual framework is totally different. First, though apparently many data are available, these data come in vastly different patterns. For example, the details of economic development are very different from year to year and from country to country. Asset prices seem to wander about in random ways. Introducing a concept that plays a fundamental role later in this entry, we can state: From the point of view of statistical estimation, economic data are always scarce given the complexity of their patterns.

Attempts to discover simple deterministic laws that accurately fit empirical economic data have proved futile. Furthermore, as economic data are the product of human artifacts, it is reasonable to believe that they will not follow the same laws for very long periods of time. Simply put, the structure of any economy changes too much over time to believe that economic laws are time-invariant laws of nature. One is, therefore, inclined to believe that only approximate laws can be discovered.

However the above considerations create an additional problem: The precise meaning of approximation must be defined. The usual response is to have recourse to probability theory. Here is the reasoning. Economic data are considered one realization of stochastic (i.e., random) data. In particular, economic time series are considered one realization of a stochastic process. The attention of the modeler has

therefore to switch from discovering deterministic paths to determining the time evolution of probability distributions. In physics, this switch was made at the end of the 19th century, with the introduction of statistical physics. It later became an article of scientific faith that we can arrive at no better than a probabilistic description of nature.

The adoption of probability as a descriptive framework is not without a cost: Discovering probabilistic laws with confidence requires working with very large populations (or samples). In physics, this is not a problem as we have very large populations of particles. (Although this statement needs some qualification because physics has now reached the stage where it is possible to experiment with small numbers of elementary particles, it is sufficient for our discussion here.) In economics, however, populations are too small to allow for a safe estimate of probability laws; small changes in the sample induce changes in the laws. We can, therefore, make the following statement: Economic data are too scarce to allow us to make sure probability estimates.

For example, Gopikrishnan, Meyer, Nunes Amaral, and Stanley (1998) conducted a study to determine the distribution of stock returns at short time horizons, from a few minutes to a few days. They found that returns had a power tail distribution with exponent $\alpha \approx 3$. One would expect that the same measurement repeated several times over would give the same result. But this is not the case. Since the publication of the aforementioned paper, the return distribution has been estimated several times, obtaining vastly different results. Each successive measurement was made in *bona fide*, but a slightly different empirical setting produced different results.

As a result of the scarcity of economic data, many statistical models, even simple ones, can be compatible with the same data with roughly the same level of statistical confidence. For example, if we consider stock price processes, many statistical models—including the ran-

dom walk—compete to describe each process with the same level of significance. Before discussing the many issues surrounding model selection and estimation, we will briefly discuss the subject of *machine learning* and the machine-learning approach to modeling.

THE (MACHINE) LEARNING APPROACH TO MODEL SELECTION

There is a fundamental distinction between (1) estimating parameters in a well-defined model and (2) estimating models through a process of learning. Models, as mentioned, are determined by human modelers using their creativity. For example, a modeler might decide that stock returns in a given market are influenced by a set of economic variables and then write a linear model as follows:

$$r_{i,t} = \sum_{k=1}^K \beta_k f_{k,t}$$

where the f are stochastic processes that represent a set of given economic variables. The modeler must then estimate the β_k and test the validity of his model.

In the machine-learning approach to modeling—ultimately a byproduct of the diffusion of computers—the process is the following:

- There is a set of empirical data to explain.
- Data are explained by a family of models that include an unbounded number of parameters.
- Models fit with arbitrary precision any set of data.

That models can fit any given set of data with arbitrary precision is illustrated by *neural networks*, one of the many machine learning tools used to model data that includes *genetic algorithms*. As first demonstrated by Cybenko (1989), neural networks are universal function approximators. If we allow a sufficient number of layers and nodes, a neural network

can approximate any given function with arbitrary precision. The idea of universal function approximators is well known in calculus. The Taylor and Fourier series are universal approximators for broad classes of functions.

Suppose a modeler wants to model the unknown *data generation process* (DGP) of a time series $X(t)$ using a neural network. A DGP is a possibly nonlinear function of the following type:

$$X(t) = F(X(t-1), \dots, X(t-k))$$

that links the present value of the series to its past. A neural network will try to learn the function F using empirical data from the series. If the number of layers and nodes is not constrained, the network can learn F with unlimited precision.

However, the key concept of the theory of machine learning is that a model that can fit any data set with arbitrary precision has no explanatory power, that is, it does not capture any true feature of the data, neither in a de-

terministic setting nor in a statistical setting. In an economic context, machine learning perfectly explains sample data but has no forecasting power. It is only a mathematical device; it does not correspond to any economic property.

We can illustrate this point in a simplified setting. Let us generate an autoregressive trend stationary process according to the following model:

$$X(i) = X(i-1) + \lambda(Di - X(i-1)) + \sigma\varepsilon(i) \\ \lambda = 0.1, \quad D = 0.1, \quad \sigma = 0.5$$

where $\varepsilon(i)$ are normally distributed zero-mean unit-variance random numbers generated with a random number generator. The initial condition is $X = 1$. This process is asymptotically trend stationary. Using the ordinary least squares (OLS) method, let us fit to the process X two polynomials of degree 2 and 20 respectively on a training window of 200 steps. We continue the polynomials five steps after the training window. Figure 1 represents the process plot and the two polynomials. Observe from the

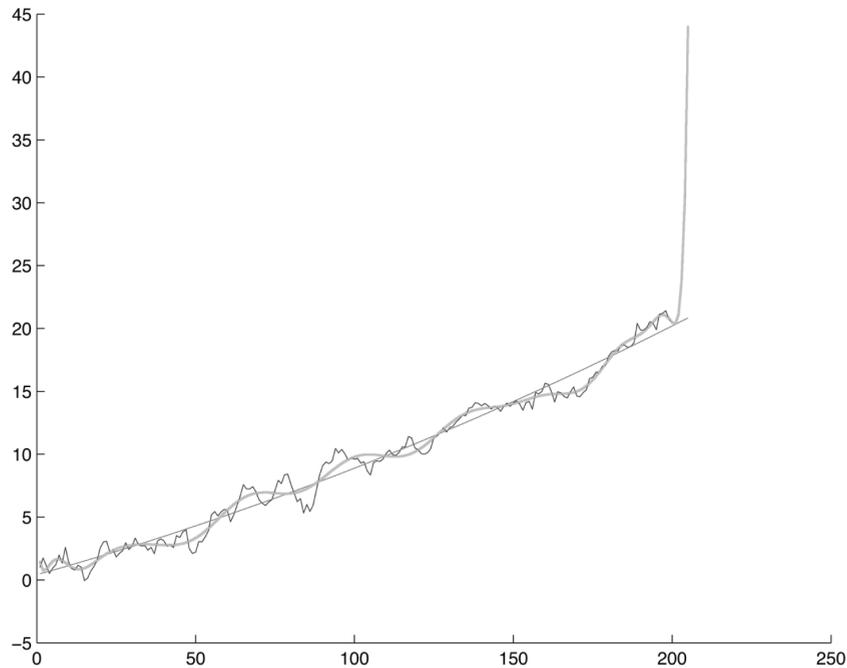

Figure 1 Polynomial Fitting of a Trend Stationary Process Using Two Polynomials of Degree 2 and 20 Respectively on a Training Window of 200 Steps

exhibit the different behavior of the two polynomials. The polynomial of degree 2 essentially repeats the linear trend, while the polynomial of degree 20 follows the random fluctuations of the process quite accurately. Immediately after, however, the training window it diverges.

To address the problem, the theory of machine learning suggests criteria to constrain models so that they fit sample data only partially but, as a trade-off, retain some forecasting power. The intuitive meaning is the following: *The structure of the data and the sample size dictate the complexity of the laws that can be learned by computer algorithms.*

This is a fundamental point. If we have only a small sample data set we can learn only simple patterns, provided that these patterns indeed exist. The theory of machine learning constrains the dimensionality of models to make them adapt to the sample size and structure.

In most practical applications, the theory of machine learning works by introducing a *penalty function* that constrains the models. The penalty function is a function of the size of the sample and of the complexity of the model. One compares models by adding the penalty function to the likelihood function (a definition of the likelihood function is provided later). In this way one can obtain an ideal trade-off between model complexity and forecasting ability.

Several proposals have been made as regards the shape of the penalty function. Three criteria are in general use:

- The Akaike Information Criterion (AIC)
- The Bayesian Information Criterion (BIC) of Schwartz
- The Maximum Description Length principle of Rissanen

More recently, Vapnik and Chervonenkis (1974) have developed a full-fledged quantitative theory of machine learning. While this theory goes well beyond the scope of this book, the practical implication of the theory of learning is important to note: Model complexity must be constrained in function of the sample.

Consider that some “learning” appears in most financial econometric endeavors. For example, determining the number of lags in an autoregressive model is a problem typically solved with methods of learning theory, that is, by selecting the number of lags that minimize the sum of the loss function of the model plus a penalty function. Ultimately, in modern computer-based financial econometrics, there is no clear-cut distinction between a learning approach versus a theory-based a priori approach.

Note, however, that the theory of machine learning offers no guarantee of success. To see this point, let’s generate a random walk and fit two polynomials of degree 3 and 20, respectively. Figure 2 illustrates the random path and the two polynomials. The two polynomials appear to fit the random path quite well. Following the above discussion, the polynomial of order 3 seems to capture some real behavior of the data. But as the data are random, the fit is spurious. This is by no means a special case. In general, it is often possible to fit models to sample data even if the data are basically unpredictable.

Figures 1 and 2 are examples of the simplest cases of model fitting. One might be tempted to object that fitting a curve with a polynomial is not a good modeling strategy for prices or returns. This is true, as one should model a dynamic DGP. However, fitting a DGP implies a multivariate curve fitting. For illustration purposes, we chose the polynomial fitting of a univariate curve: It is easy to visualize and contains all the essential elements of model fitting.

SAMPLE SIZE AND MODEL COMPLEXITY

The four key conclusions reached thus far are

- Economic data are generally scarce for statistical estimation given the complexity of their patterns.
- Economic data are too scarce for sure statistical estimates.

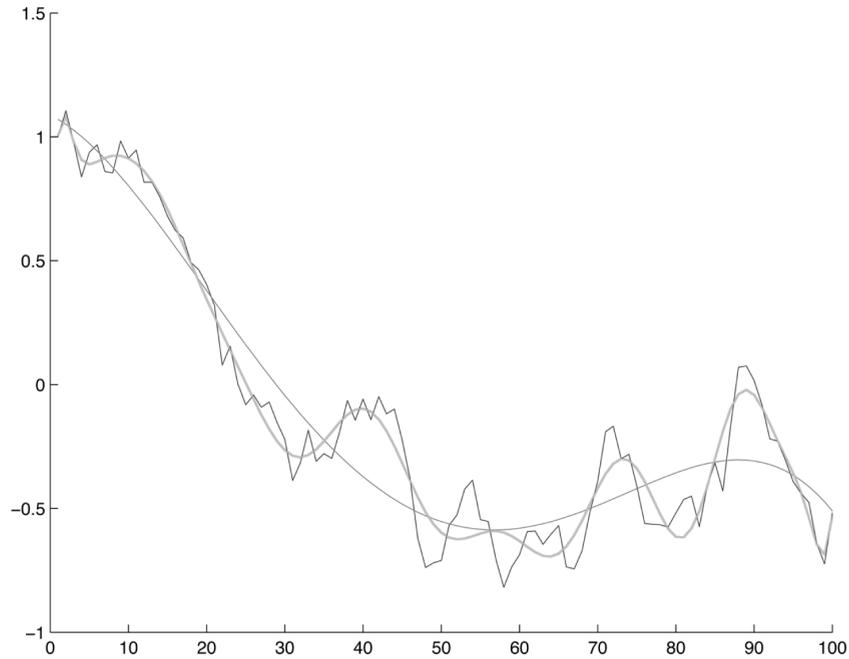

Figure 2 Polynomial Fitting of a Random Walk Using Two Polynomials of Degree 3 and 20 Respectively on a 100-Step Sample

- The scarcity of data means that the data might be compatible with many different models.
- There is a trade-off between model complexity and the size of the data sample.

The last two considerations are critical. To illustrate the quantitative trade-off between the size of a data sample and model complexity, consider an apparently straightforward case: estimating a correlation matrix.

It is well known from the theory of random matrices that the eigenvalues of the correlation matrix of independent random walks are distributed according to the following law:

$$\rho(\lambda) = \frac{Q}{2\pi\sigma^2} \frac{\sqrt{(\lambda_{\max} - \lambda)(\lambda_{\min} - \lambda)}}{\lambda}$$

where Q is the ratio between the number N of sample points and the number M of time series. Figure 3 illustrates the theoretical distribution of eigenvalues for three values of Q : $Q = 1.8$, $Q = 4$, and $Q = 16$.

As can be easily predicted by examining the above formula, the distribution of eigenvalues

is broader when Q is smaller. The corresponding λ_{\max} is larger for the broader distribution. The λ_{\max} are respectively:

$$\lambda_{\max} = 3.0463 \text{ for } Q = 1.8$$

$$\lambda_{\max} = 2.2500 \text{ for } Q = 4$$

$$\lambda_{\max} = 1.5625 \text{ for } Q = 16$$

The eigenvalues of a random matrix do not carry any true correlation information. If we now compute the eigenvalues of an empirical correlation matrix of asset returns with a given Q (i.e., the ratio between number of samples and the number of series), we find that only a few eigenvalues carry information as they are outside the area of pure randomness corresponding to the Q . In fact, with good approximation, λ_{\max} is the cut-off point that separates meaningful correlation information from noise. (The application of random matrices to the estimation of correlation and covariance matrices is developed in Plerou, Gopikrishnan, Rosenow, Nunes Amaral, Guhr, and Stanley [2002].) Therefore, as the ratio of sample points to the number of asset

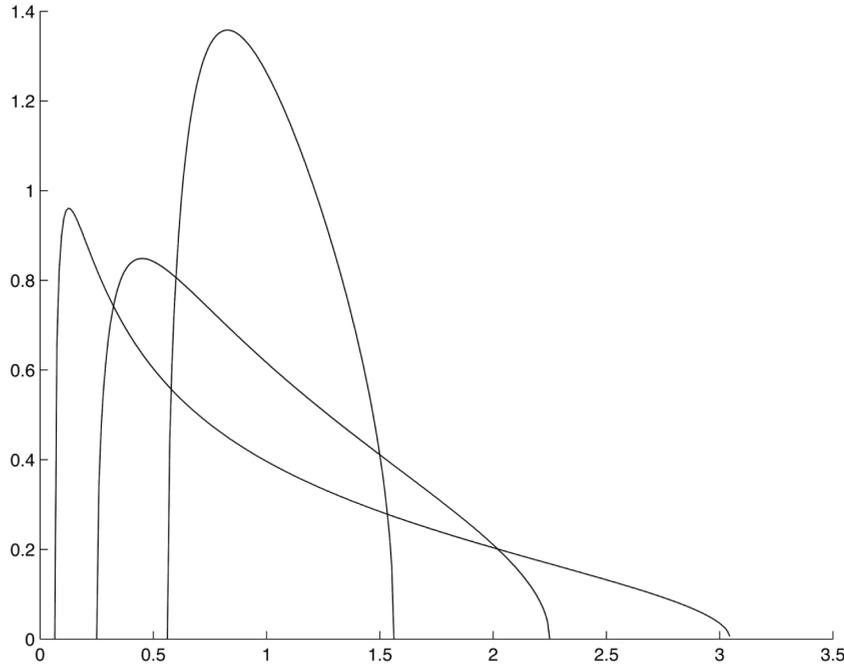

Figure 3 The Theoretical Distribution of Eigenvalues for Three Values of Q : $Q = 1.8$, $Q = 4$, and $Q = 16$

prices grows (i.e., we have more points for each price process) the “noise area” gets smaller.

To show the effects of the ratio Q on the estimation of empirical correlation matrices, let’s compute the correlation matrix for three sets of 900, 400, and 100 stock prices that appeared in the MSCI Europe in a six-year period from December 1998 to February 2005. The return series contain in total 1,611 sample points, each corresponding to a trading day.

First we compute the correlation matrices. The average correlation (excluding the diagonal) is approximately 10% for the three sets of 100, 400, and 900 stocks. Then we compute the eigenvalues. The plot of sorted eigenvalues for the three samples is shown in Figures 4, 5, and 6. One can see from these exhibits that when the ratio Q is equal to 16 (i.e., we have more sample points per stock price process), the plot of eigenvalues decays more slowly.

Now compare the distribution of empirical eigenvalues with the theoretical cut-off point λ_{\max} that we computed above. The parameter Q was chosen to approximately represent the ra-

tios between 1,611 sample points and 100, 400, and 900 stocks. Results are tabulated in Table 1. This exhibit shows that the percentage of meaningful eigenvalues grows as the ratio between the number of sample points and the number of processes increases. If we hold the number of sample points constant (i.e., 1,611) and increase the number of time series from 100 to 900, a larger percentage of eigenvalues becomes essentially noise (i.e., they do not carry information). Obviously the number of meaningful eigenvalues increases with the number of series, but, due to loss of information, it does so more slowly than does the number of series due to loss of information.

Two main conclusions can be drawn from Table 1:

- Meaningful eigenvalues represent a small percentage of the total, even when $Q = 16$.
- The ratio of meaningful eigenvalues to the total grows with Q , but the gain is not linear.

The above considerations apply to estimating a correlation matrix. As we will see, however,

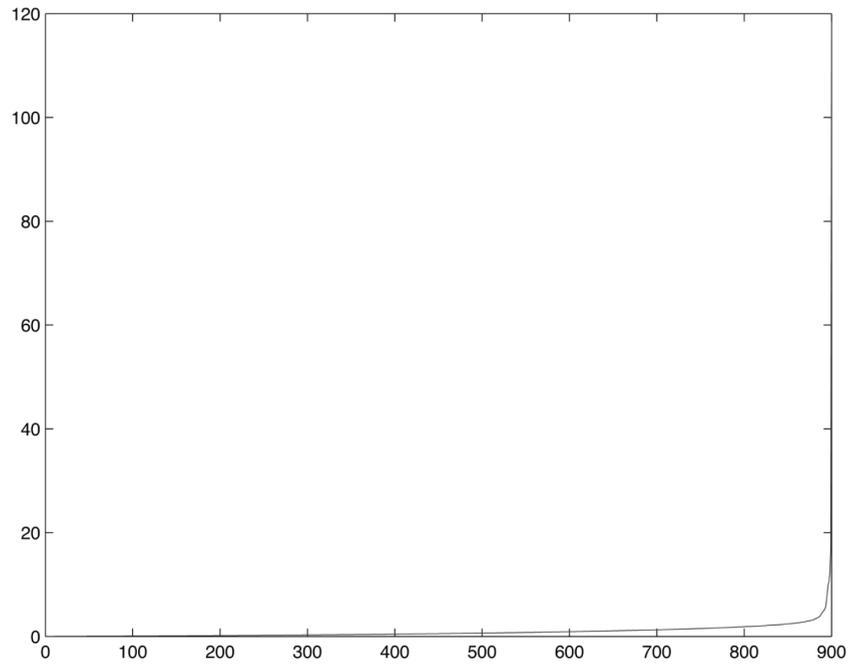

Figure 4 Plot of Eigenvalues for 900 Prices, $Q = 1.8$

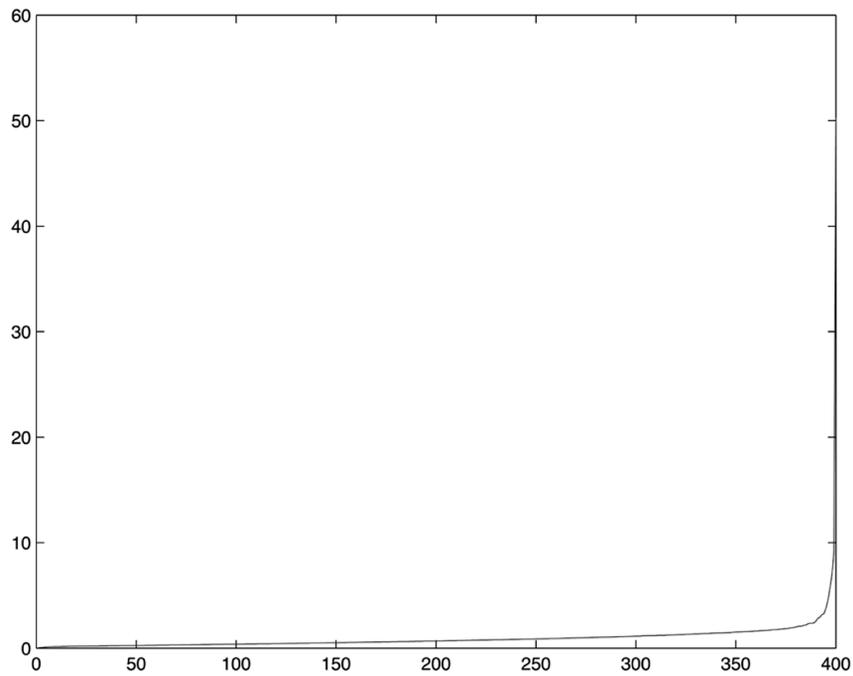

Figure 5 Plot of Eigenvalues for 400 Prices, $Q = 4$

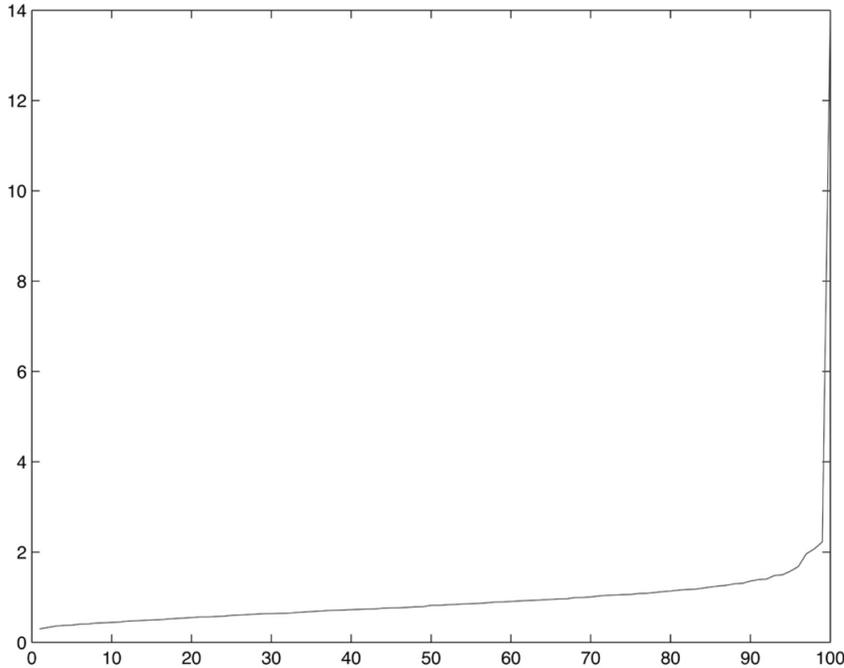

Figure 6 Plot of Eigenvalues for 100 Prices, $Q = 16$

Table 1 Comparison of the Distribution of Empirical Eigenvalues with the Theoretical Cutoff Point for Different Values of Q

Number of processes	Average correlation	Max eigenvalue	Number of meaningful eigenvalues	Percentage of meaningful eigenvalues
900; $Q = 1.8$	10%	118	26	0.029
400; $Q = 4$	9.5%	50	15	0.038
100; $Q = 16$	9.8%	14	6	0.06

they carry over, at least qualitatively, to the estimation of any linear dynamic model. In fact, the estimation of linear dynamic models is based on estimating correlation and covariance matrices.

DANGEROUS PATTERNS OF BEHAVIOR

One of the most serious mistakes that a financial modeler can make is to look for rare or unique patterns that look profitable in-sample but produce losses out-of-sample. This mistake is made easy by the availability of powerful computers that can explore large amounts of data: Any

large data set contains a huge number of patterns, many of which look very profitable. Otherwise expressed, any large set of data, even if randomly generated, can be represented by models that appear to produce large profits. To see the point, perform the following simple experiment. Using a good random number generator, generate a large number of independent random walks with zero drift. In sample, these random walks exhibit large profit opportunities. There are numerous reasons for this. In fact, if we perform a sufficiently large number of simulations, we will generate a number of paths that are arbitrarily close to any path we want. Many paths will look autocorrelated and will

be indistinguishable from trend-stationary processes. In addition, many stochastic trends will be indistinguishable from deterministic drifts.

There is nothing surprising in the above phenomena. A stochastic process or a discrete time series is formed by all possible paths. For example, a trend-stationary process and a random walk are formed by the same paths. What makes the difference between a trend-stationary process and a random walk are not the paths—which are exactly the same—but the probability assignments. Suppose processes are discrete, for example because time is discrete and prices move by only discrete amounts. Any computer simulation is ultimately a discrete process, though the granularity of the process is very small. In this discrete case, we can assign a discrete probability to each path. The difference between processes is the probability assigned to each path. In a large sample, even low probability paths will occur, albeit in small numbers.

In a very large data set, almost any path will be approximated by some path in the sample. If the computer generates a sufficiently large number of random paths, we will come arbitrarily close to any given path, including, for example, to any path that passes the test for trend stationarity. In any large set of price processes, one will therefore always find numerous interesting paths, such as cointegrated pairs and trend-stationary processes.

To avoid looking for ephemeral patterns, we must stick rigorously to the paradigm of machine learning and statistical tests. This sounds conceptually simple, but it is very difficult to do in practice. It means that we have to decide the level of confidence that we find acceptable and then compute probability distributions for the entire sample. This has somewhat counterintuitive consequences. We illustrate this point using as an example the search for cointegrated pairs; the same reasoning applies to any statistical property.

Suppose that we have to decide whether a given pair of time series is cointegrated or not. We can use one of the many cointegration tests.

If the time series are short, no test will be convincing; the longer the time series, the more convincing the test. The problem with economic data is that no test is really convincing as the confidence level is generally in the range of 95% or 99%. Whatever confidence level we choose, given one or a small number of pairs, we decide the cointegration properties of each pair individually. For example, in macroeconomic studies where only a few time series are given, we decide if a given pair of time series is cointegrated or not by looking at the cointegration test for that pair.

Does having a large number of data series, for example 500 price time series, require any change in the testing methodology? The answer, in fact, is that *additional* care is required: In a large data set, for the reasons we outlined above, any pattern can be approximated. One has to look at the probability that a pattern will appear in that data set. In the example of cointegration, if one finds, say, ten cointegrated pairs in 500 time series, the question to ask is: What is the probability that in 500 time series 10 time series are cointegrated? Answering this question is not easy because the properties of pairs are not independent. In fact, given three series a , b , and c we can form three distinct pairs whose cointegration properties are not, however, mutually independent. This makes calculations difficult.

To illustrate the above, let us generate a simulated random walk using the following formula:

$$\begin{aligned} \mathbf{X}(i) &= \mathbf{X}(i-1) + \varepsilon(i) \\ \mathbf{X}(1) &= 1 \end{aligned}$$

where $\mathbf{X}(i)$ is a random vector with 500 elements, and the noise term is generated with a random number generator as 500 independent normally distributed zero-mean unitary-variance numbers. Now run simulations for 500 steps. Next, eliminate linear trends from each realization. (Cointegration tests can handle linear trends. We detrended for clarity of illustrations.) A sample of three typical realizations of

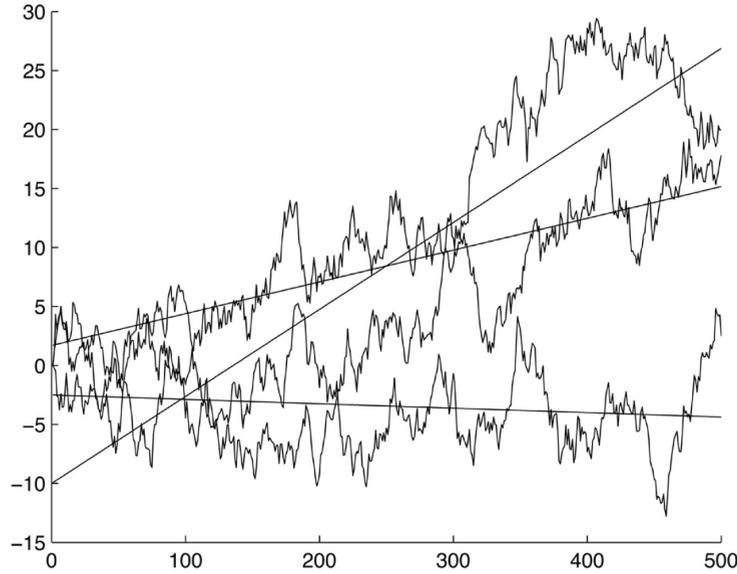

Figure 7 A Sample of Three Typical Realizations of a 500-Step Random Walk with Their Trends

the random walks is illustrated in Figure 7 and the corresponding residuals after detrending in Figure 8.

Now run the cointegration test at a 99% confidence level on each possible pair. In a sample of 10 simulation runs, we obtain the following

number of pairs that pass the cointegration test: 74, 75, 89, 73, 65, 91, 91, 93, 84, 62. There are in total

$$\binom{500}{2} = \frac{500 \times 499}{2} = 124,750 \text{ distinct pairs}$$

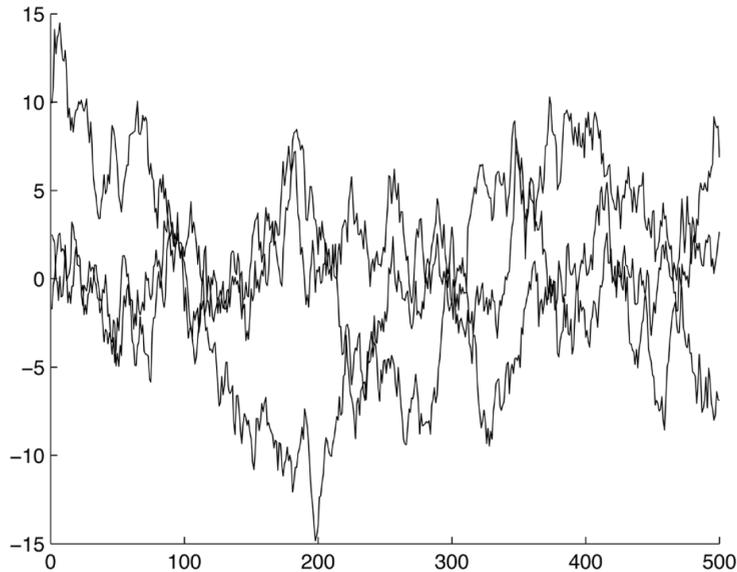

Figure 8 The Residuals of the Same Random Walks after Detrending

If cointegration properties of pairs were independent, given 500 random walks, on the average we should find 124 pairs that pass the cointegration test at the 99% confidence level. However, cointegration properties of pairs are not independent for the reasons mentioned above. This explains why we obtained a smaller number of pairs than expected. This example illustrates the usefulness of running Monte Carlo experiments to determine the number of cointegrated pairs found in random walks.

If, however, the patterns we are looking for are all independent, calculations are relatively straightforward. Suppose we are looking for stationary series applying an appropriate test at a 99% confidence interval. This means that a sample random walk has a 1% probability of passing the test (i.e., to be wrongly accepted as stationary) and a 99% probability of being correctly rejected. In this case, the probability distribution of the number of paths that pass the stationarity test given a sample of 500 generated random walks is a binomial distribution with probabilities $p = 0.01$ and $q = 1 - p = 0.99$ and mean 5.

We apply criteria of this type very often in our professional and private lives. For example, suppose that an inspector has to decide whether to accept or reject a supply of spare parts. The inspector knows that on average one part in 100 is defective. He randomly chooses a part in a lot of 100 parts. If the part is defective, he is likely to ask for additional tests before accepting the lot. Suppose now that he tests 100 parts from 100 different lots of 100 parts and finds only one defective part. He is likely to accept the 100 lots because the incidence of faulty parts is what he expected it to be, that is, one in 100. The point is that we are looking for statistical properties, not real identifiable objects.

A profitable price time series is not a recognizable object. We find what seems to be a profitable time series but we cannot draw any conclusion because the level of the “authenticity test” of each series is low. When looking at very large data sets, we have to make data work for

us and not against us, examining the entire sample. For example, consider a strategy known as “pair trading.” In this strategy, an investor selects pairs from a stock universe and maintains a market neutral (i.e., zero beta) long-short portfolio of several pairs of stocks with a mean-reverting spread. When there are imbalances in the market causing the spread to diverge, the investor seeks to determine the reason for the divergence. If the investor believes that the spread will revert, he or she takes a position in the two stocks to capitalize on the reversion. A modeler who would define a pair trading strategy based on the cointegrated pair in the previous example would be disappointed. Based on extensive Monte Carlo simulations to compare the number of cointegrated pairs among the stocks in the S&P 500 index for the period 2001–2004 and in computer-generated random walks, the number of cointegrated pairs we found was slightly larger in the real series than in the simulated random walks.

We can conclude that it is always good practice is to test any model or pattern recognition method against a surrogated random sample generated with the same statistical characteristics as the empirical ones. For example, it is always good practice to test any model and any strategy intended to find excess returns on a set of computer-generated random walks. If the proposed strategy finds profit in computer-generated random walks, it is highly advisable to rethink the strategy.

DATA SNOOPING

Given the scarcity of data and the basically uncertain nature of any econometric model, it is generally required to calibrate models on some data set, the so-called *training set*, and test them on another data set, the *test set*. In other words, it is necessary to perform an out-of-sample validation on a separate test set. The rationale for this procedure is that any machine-learning process—or even the calibration mechanism itself—is a heuristic methodology, not

a true discovery process. Models determined through a machine-learning process must be checked against the reality of out-of-sample validation. Failure to do so is referred to as *data snooping*, that is, performing training and tests on the same data set.

Out-of-sample validation is typical of machine-learning methods. Learning entails models with unbounded capabilities of approximation constrained by somewhat artificial mechanisms such as a penalty function. This learning mechanism is often effective but there is no guarantee that it will produce a good model. Therefore, the learning process is considered *discovery heuristics*. The true validation test, say the experiments, has to be performed on the test set. Needless to say, the test set must be large and cover all possible patterns, at least in some approximate sense. For example, in order to test a trading strategy one would need to test data in many different market conditions: with high volatility and low volatility, in expansionary and recessionary economic periods, under different correlation situations, and so on.

Data snooping is not always easy to understand or detect. Suppose that a modeler wants to build the DGP of a time series. A DGP is often embodied in a set of difference equations with parameters to be estimated. Suppose that four years of data of a set of time series are available. A modeler might be tempted to use the entire four years to perform a “robust” model calibration and to “test” the model on the last year. This is an example of data snooping that might be difficult to recognize and to avoid. In fact, one might (erroneously) reason as follows. If there is a true DGP, it is more likely that it is “discovered” on a four-year sample than on shorter samples. If there is a true DGP, data snooping is basically innocuous and it is therefore correct to use the entire data set. On the other hand, if there is no stable DGP, then it does not make sense to calibrate models as their coefficients would be basically noise.

This reasoning is wrong. In general, there is no guarantee that, even if a true DGP exists, a learning algorithm will learn it. Among the reasons for learning failure are (1) the slow convergence of algorithms which might require more data than that available, and (2) the possibility of getting stuck in local optima. However, the real danger is the possibility that no true DGP exists. Should this be the case, the learning algorithm might converge to a false solution or not converge at all. We illustrated this fact earlier in this entry where we showed how it is possible to successfully fit a low dimensionality polynomial to a randomly generated path.

There are other forms of data snooping. Suppose that a modeling team works on a sample of stock price data to find a profitable trading strategy. Suppose that they respect all of the above criteria of separation of the training set and the data set. Different strategies are tried and those that do not perform are rejected. Though sound criteria are used, there is still the possibility that by trial and error the team hits a strategy that performs well in sample but poorly when applied in the real world. Another form of hidden data snooping is when a methodology is finely calibrated to sample data. Again, there is the possibility that by trial and error one finds a calibration parameterization that works well in sample and poorly in the real world.

There is no sound theoretical way to avoid this problem *ex ante*. In practice, the answer is to separate the sets of training data and test data, and to decide on the existence of a DGP in function of performance on the test data. However, this type of procedure requires a lot of data. “Resampling” techniques have been proposed to alleviate the problem. Intuitively, the idea behind resampling methods is that a stable DGP calibrated on any portion of the data should work on the remaining data. Widely used resampling techniques include “leave-one-out” and “bootstrapping.” The bootstrap technique creates surrogated data from the initial sample data. (The bootstrap is an important technique but its description goes beyond the scope of this

entry. For a review of bootstrapping, see Davison and Hinkley [1997].)

Data snooping is a defect of training processes which must be controlled but which is very difficult to avoid given the size of data samples currently available. Suppose samples in the range of ten years are available. (Technically much longer data sets on financial markets, up to 50 years of price data, are available. While useful for some applications, these data are useless for most asset management applications given the changes in the structure of the economy.) One can partition these data and perform a single test free from data snooping biases. However, if the test fails, one has to start all over again and design a new strategy. The process of redesigning the modeling strategy might have to be repeated several times over before an acceptable solution is found. Inevitably, repeating the process on the same data includes the risk of data snooping. The real danger in data snooping is the possibility that by trial and error or by optimization, one hits upon a model that casually performs well on the sample data but that will perform poorly in real-world forecasts. Fabozzi, Focardi, and Ma (2005) explore at length different ways in which data snooping and other biases might enter the model discovery process and propose a methodology to minimize the risk of biases, as will be explained in the last section of this entry.

SURVIVORSHIP BIASES AND OTHER SAMPLE DEFECTS

We now examine possible defects of the sample data themselves. In addition to errors and missing data, one of the most common (and dangerous) defects of sample data are the so-called *survivorship biases*. The survivorship bias is a consequence of selecting time series, in particular asset price time series, based on criteria that apply at the end of the period. For example, suppose a sample contains 10 years of price data for all stocks that are in the S&P 500 today and that existed for the last 10 years. This sample, ap-

parently well formed, is, however, biased: The selection, in fact, is made on the stocks of companies that are in the S&P 500 today, that is, those companies that have “survived” in sufficiently good shape to still be in the S&P 500 aggregate. The bias comes from the fact that many of the surviving companies successfully passed through some difficult period. Surviving the difficulty is a form of reversion to the mean that produces trading profits. However, at the moment of the crisis it was impossible to predict which companies in difficulty would indeed have survived.

To gauge the importance of the survivorship bias, consider a strategy that goes short on a fraction of the assets with the highest price and long on the corresponding fraction with the lowest price. This strategy might appear highly profitable in sample. Looking at the behavior of this strategy, however, it becomes clear that profits are very large in the central region of the sample and disappear approaching the present day. This behavior should raise flags. Although any valid trading strategy will have good and bad periods, profit reduction when approaching the present day should command heightened attention.

Avoiding the survivorship bias seems simple in principle: It might seem sufficient to base any sample selection at the moment where the forecast begins, so that no invalid information enters the strategy prior to trading. However, the fact that companies are founded, merged, and closed plays havoc with simple models. In fact, calibrating a simple model requires data of assets that exist over the entire training period. This in itself introduces a potentially substantial training bias.

A simple model cannot handle processes that start or end in the middle of the training period. On the other hand, models that take into account the foundation or closing of firms cannot be simple. Consider, for example, a simple linear autoregressive model. Any addition or deletion of companies introduces a nonlinearity in the model and precludes using standard tools such as the OLS method.

There is no ideal solution. Care is required in estimating possible performance biases consequent to sample biases. Suppose that we make a forecast of return processes based on models trained on the past three or four years of returns data on the same processes that we want to forecast. Clearly there is no data snooping, as we use only information available prior to forecasting. However, it should be understood that we are estimating our models on data that contain biases. If the selection of companies to forecast is subject to strong criteria, for example companies that belong to a major index, it is likely that the model will suffer a loss of performance. This is due to the fact that models will be trained on spurious past performance. If the modeler is constrained to work on a specific stock selection, for example because he has to create an active strategy against a selected benchmark, he might want to consider Bayesian techniques to reduce the biases.

The survivorship bias is not the only possible bias of sample data. More in general, any selection of data contains some bias. Some of these biases are intentional. For example, selecting large caps or small caps introduces special behavioral biases that are intentional. However, other selection biases are more difficult to appreciate. In general, any selection based on belonging to indexes introduces index-specific biases in addition to the survivorship bias. Consider that presently thousands of indexes are in use—the FTSE alone has created some 60,000. Institutional investors and their consultants use these indexes to create asset allocation strategies and then give the indexes to asset managers for active management.

Anyone creating active management strategies based on these indexes should be aware of the biases inherent in the indexes when building their strategies. Data snooping applied to carefully crafted stock selection can result in poor performance because the asset selection process inherent in the index formation process can produce very good results in sample; these results vanish out-of-sample as “snow under the sun.”

MOVING TRAINING WINDOWS

Thus far we assumed that the DGP exists as a time-invariant model. Can we also assume that the DGP varies and that it can be estimated on a moving window? If yes, how can it be tested? These are complex questions that do not admit an easy answer. It is often assumed that the economy undergoes “structural breaks” or “regime shifts” (i.e., that the economy undergoes discrete changes at fixed or random time points).

If the economy is indeed subject to breaks or shifts and the time between breaks is long, models would perform well for a while and then, at the point of the break, performance would degrade until a new model is learned. If regime changes are frequent and the interval between the changes short, one could use a model that includes the changes. The result is typically a nonlinear model such as the Markov-switching models. Estimating models of this type is very onerous given the nonlinearities inherent in the model and the long training period required.

There is, however, another possibility that is common in modeling. Consider a model that has a defined structure, for example a linear VAR model, but whose coefficients are allowed to change in time with the moving of the training window. In practice, most models used work in this way as they are periodically recalibrated. The rationale of this strategy is that models are assumed to be approximate and sufficiently stable for only short periods of time. Clearly there is a trade-off between the advantage of using long training sets and the disadvantage that a long training set includes too much change.

Intuitively, if model coefficients change rapidly, this means that the model coefficients are noisy and do not carry genuine information. We have seen an example above in the simple case of estimating a correlation matrix. Therefore, it is not sufficient to simply reestimate the model: One must determine how to separate the noise from the information in the coefficients.

For example, a large VAR model used to represent prices or returns will generally be unstable. It would not make sense to reestimate the model frequently; one should first reduce model dimensionality with, for example, factor analysis. Once model dimensionality has been reduced, coefficients should change slowly. If they continue to change rapidly, the model structure cannot be considered appropriate. One might, for example, have ignored fat tails or essential nonlinearities.

How can we quantitatively estimate an acceptable rate of change for model coefficients? Are we introducing a special form of data snooping in calibrating the training window? Clearly the answer depends on the nature of the true DGP—assuming that one exists. It is easy to construct artificially DGPs that change slowly in time so that the learning process can progressively adapt to them. It is also easy to construct true DGPs that will play havoc with any method based on a moving training window. For example, if one constructs a linear model where coefficients change systematically at a frequency comparable with a minimum training window, it will not be possible to estimate the process as a linear model estimated on a moving window.

Calibrating a training window is clearly an empirical question. However, it is easy to see that calibration can introduce a subtle form of data snooping. Suppose a rather long set of time series is given, say six to eight years, and that one selects a family of models to capture the DGP of the series and to build an investment strategy. Testing the strategy calls for calibrating a moving window. Different moving windows are tested. Even if training and test data are kept separate so that forecasts are never performed on the training data, clearly the methodology is tested on the same data on which the models are learned.

Other problems with data snooping stem from the psychology of modeling. A key precept that helps to avoid biases is the following: Modeling hunches should be based on theoretical reasoning and not on looking at the data.

This statement might seem inimical to an empirical enterprise, an example of the danger of “clear reasoning” mentioned above. Still, it is true that by looking at data too long one might develop hunches that are sample-specific. There is some tension between looking at empirical data to discover how they behave and avoiding to capture the idiosyncratic behavior of the available data.

In his best-seller *Chaos: Making a New Science*, James Gleick (1987) reports that one of the initiators of chaos theory used to spend long hours flying planes (at his own expense) just to contemplate clouds to develop a feeling for their chaotic movement. Obviously there is no danger of data snooping in this case as there are plenty of clouds on which any modeling idea can be tested. In other cases, important discoveries have been made working on relatively small data samples. The 20th-century English hydrologist Harold Hurst developed his ideas of rescaled range analysis from the yearly behavior of the Nile River, approximately 500 years of sample data, not a huge data sample.

Clearly simplicity (i.e., having only a small number of parameters to calibrate) is a virtue in modeling. A simple model that works well should be favored over a complex model that might produce unpredictable results. Nonlinear models in particular are always subject to the danger of unpredictable chaotic behavior. It was a surprising discovery that even simple maps originate highly complex behavior. The conclusion is that every step of the discovery process has to be checked for empirical, theoretical, and logical consistency.

MODEL RISK

As we have seen above, any model choice and estimation process might result in biases and poor performance. In other words, any model selection process is subject to *model risk*. One might well ask if it is possible to mitigate model risk. In statistics, there is a long tradition,

initiated by the 18th-century English mathematician Thomas Bayes, of considering uncertain not only individual outcomes but the probability distribution itself. It is therefore natural to see if ideas from Bayesian statistics and related concepts could be applied to mitigate model risk.

A simple idea that is widely used in practice is to take the average of different models. This idea can take different forms. Suppose that we have to estimate a variance-covariance matrix. It makes sense to take radically different estimates such as noisy empirical estimates and capital asset pricing model (CAPM) estimates that only consider covariances with the market portfolio and average. Averaging is done with the principle of *shrinkage*, that is, one does not form a pure average but weights the two matrices with weights a and $1 - a$, choosing a according to some optimality principle. This idea can be extended to dynamic models, weighting all coefficients in a model with a probability distribution. Here we want to make some additional qualitative considerations that lead to strategies in model selection.

There are two principal reasons for applying model risk mitigation. First, we might be uncertain as to which model is best, and so mitigate risk by diversification. Second, perhaps more cogent, we might believe that different models will perform differently under different circumstances. By averaging, we hope to reduce the volatility of our forecasts. It should be clear that averaging model results or working to produce an average model (i.e., averaging coefficients) are two different techniques. The level of difficulty involved is also different.

Averaging results is a simple matter. One estimates different models with different techniques, makes forecasts and then averages the forecasts. This simple idea can be extended to different contexts. For example, in rating stocks one might want to do an exponential averaging over past ratings, so that the proposed rating today is an exponential average of the model rating today and model ratings in the past.

Obviously parameters must be set correctly, which again forces a careful analysis of possible data snooping biases. Whatever the averaging process one uses, the methodology should be carefully checked for statistical consistency. For example, one obtains quite different results applying methodologies based on averaging to stationary or nonstationary processes. The key principle is that averaging is used to eliminate noise, not genuine information.

Averaging models is more difficult than averaging results. In this case, the final result is a single model, which is, in a sense, the average of other models. Shrinkage of the covariance matrix is a simple example of averaging models.

MODEL SELECTION IN A NUTSHELL

It is now time to turn all the caveats into some positive approach to model selection. As remarked in Fabozzi, Focardi, and Ma (2005), any process of model selection must start with strong economic intuition. Data mining and machine learning alone are unlikely to produce significant positive results. The possibility that scientific discovery, and any creative process in general, can be “outsourced” to computers is still far from today’s technological reality. A number of experimental artificial intelligence (AI) programs have indeed shown the ability to “discover” scientific laws. For example, the program KAM developed by Yip (1989) is able to analyze nonlinear dynamic patterns and the program TETRAD developed at Carnegie Mellon is able to discover causal relationships in data (see Glymour, Scheines, Spirtes, and Kelly, 1987). However, practical applications of machine intelligence use AI as a tool to help perform specific tasks.

Economic intuition clearly entails an element of human creativity. As in any other scientific and technological endeavor, it is inherently dependent on individual abilities. Is there a body of true, shared science that any modeler can

use? Or do modelers have to content themselves with only partial and uncertain findings reported in the literature? As of the writing of this book, the answer is probably a bit of both.

One would have a hard time identifying economic laws that have the status of true scientific laws. Principles such as the absence of arbitrage are probably what comes closest to a true scientific law but are not, per se, very useful in finding, say, profitable trading strategies. Most economic findings are of an uncertain nature and are conditional on the structure of the economy or the markets.

It is fair to say that economic intuition is based on a number of broad economic principles plus a set of findings of an uncertain and local nature. Economic findings are statistically validated on a limited sample and probably hold only for a finite time span. Consider, for example, findings such as volatility clustering. One might claim that volatility clustering is ubiquitous and that it holds for every market. In a broad sense this is true. However, no volatility clustering model can claim the status of a law of nature as all volatility clustering models fail to explain some essential fact.

It is often argued that profitable investment strategies can be based only on secret proprietary discoveries. This is probably true but its importance should not be exaggerated. Secrecy is typically inimical to knowledge building. Secrets are also difficult to keep. Historically, the largest secret knowledge-building endeavors were related to military efforts. Some of these efforts were truly gigantic, such as the Manhattan Project to develop the first atomic bomb. Industrial projects of a non-military nature are rarely based on a truly scientific breakthrough. They typically exploit existing knowledge.

Financial econometrics is probably no exception. Proprietary techniques are, in most cases, the application of more or less shared knowledge. There is no record of major economic breakthroughs made in secrecy by investment teams. Some firms have advantages in terms of data. Custodian banks, for example, can ex-

plot data on economic flows that are not available to (or in any case are very expensive for) other entities. Until the recent past, availability of computing power was also a major advantage, reserved to only the biggest Wall Street firms; however, computing power is now a commodity.

As a consequence, it is fair to say that economic intuition can be based on a vast amount of shared knowledge plus some proprietary discovery or interpretation. In the last 25 years, a number of computer methodologies were experimented with in the hope of discovering potentially important sources of profits. Among the most fascinating of these were nonlinear dynamics and chaos theory, as well as neural networks and genetic algorithms. None has lived up to initial expectations. With the maturing of techniques, one discovers that many new proposals are only a different language for existing ideas. In other cases, there is a substantial equivalence between theories.

After using intuition to develop an *ex ante* hypothesis, the process of model selection and calibration begins in earnest. This implies selecting a sample free from biases and determining a quality-control methodology. In the production phase, an independent risk control mechanism will be essential. A key point is that the discovery process should be linear. If at any point the development process does not meet the quality standards, one should resist the temptation of adjusting parameters and go back to develop new economic intuition.

This process implies that there is plenty of economic intuition to work on. The modeler must have many ideas to develop. Ideas might range from the intuition that certain market segments have some specific behavior to the discovery that there are specific patterns of behavior with unexploited opportunities. In some cases it will be the application of ideas that are well known but have never been applied on a large scale.

A special feature of the model selection process is the level of uncertainty and noise.

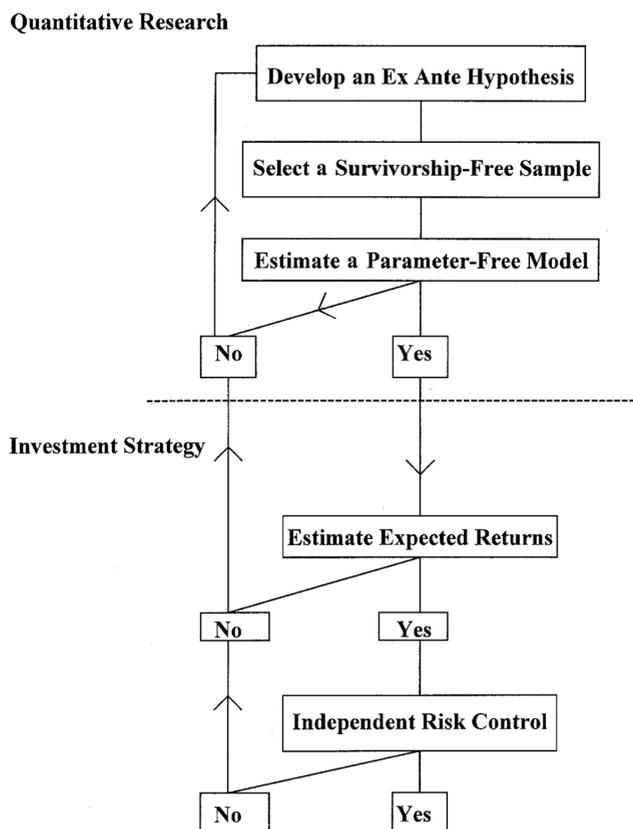

Figure 9 Process of Quantitative Research and Investment Strategy
 Source: Fabozzi, Focardi, and Ma (2005, p. 73)

Models capture small amounts of information in a vast “sea of noise.” Models are always uncertain, and so is their potential longevity. The psychology of discovery plays an important role. These considerations suggest the adoption of a rigorous objective research methodology. Figure 9 illustrates the work flow for a sound process of discovery of profitable strategies. (For a further discussion, see Fabozzi, Focardi, and Ma (2005).)

A modeler working in financial econometrics is always confronted with the risk of finding an artifact that does not, in reality, exist. And, as we have seen, paradoxically one cannot look too hard at the data; this risks introducing biases formed by available but insufficient data sets. Even trying too many possible solutions, one risks falling into the trap of data snooping.

KEY POINTS

- Model selection in financial econometrics requires a blend of theory, creativity, and machine learning.
- The machine-learning approach starts with a set of empirical data that we want to explain. Data are explained by a family of models that include an unbounded number of parameters and are able to fit data with arbitrary precision.
- There is a trade-off between model complexity and the size of the data sample. To implement this trade-off, ensuring that models have forecasting power, the fitting of sample data is constrained to avoid fitting noise. Constraints are embodied in criteria such as the Akaike Information Criterion (AIC) or the Bayesian Information Criterion (BIC).

- Economic data are generally scarce given the complexity of their patterns. This scarcity introduces uncertainty as regards our statistical estimates. It means that the data might be compatible with many different models with the same level of statistical confidence.
- A serious mistake in model selection is to look for models that fit rare or unique patterns; such patterns are purely random and lack predictive power.
- Another mistake in model selection is data snooping, that is, fitting models to the same data that we want to explain. A sound model selection approach calls for a separation of sample data and test data: Models are fitted to sample data and tested on test data.
- Because data are scarce, techniques have been devised to make optimal use of data; perhaps the most widely used of such techniques is bootstrapping.
- Financial data are also subject to “survivorship bias,” that is, data are selected using criteria known only a posteriori, for example companies that are presently in the S&P 500. Survivorship bias induces biases in models and results in forecasting errors.
- Model risk is the risk that models are subject to forecasting errors in real data. Techniques to mitigate model risk include Bayesian techniques, averaging/shrinkage, and random coefficient models.
- A sound model selection methodology includes strong theoretical considerations, the

rigorous separation of sample and testing data, and discipline to avoid data snooping.

Managing the Model Risk with the Methods of the Probabilistic Decision Theory

VACSLAV S. GLUKHOV, PhD

Head of Quantitative Strategies and Data Analytics, Liquidnet Europe Ltd, London, United Kingdom

Abstract: Practical applications of financial models require a proper assessment of the model risk due to uncertainty of the model parameters. Methods of the probabilistic decision theory achieve this objective. Probabilistic decision making starts from the Bayesian inference process, which supplies the posterior distribution of parameters. Bayesian incorporation of priors, or opinions, which influence posterior confidence intervals for the model parameters, is indispensable in real-world financial applications. Then, the utility function is used to evaluate practical implications of uncertainty of parameters by comparing the relative expected values of differing decisions. Probabilistic decision making involves computer simulations in all realistic situations. Still, a complete analytical treatment is possible in simple cases.

Practical applications of financial models require their parameters to be given concrete numerical values. These values are typically fitted to empirical data to ensure that the model predictions match historical observations. Parameter values obtained by such fitting procedures never propagate into the future unchanged: Tracing the model's steps back in time, we find that its parameters are always more or less in error. The convention is that predictions made by the model are better if its parameters are known with better precision.

Thus, financial models are always in error—to an extent. Additional variability of actual outcomes due to models themselves, or *model risks*, can be loosely associated with Knightian uncertainty. Methods of *Bayesian inference* estimate

the extent of this uncertainty, whereas the utility theory helps evaluate relative costs of decisions made under this uncertainty. *Probabilistic decision theory*, which combines Bayesian inference with the concept of utility, is the natural and powerful tool for handling intrinsic risks of financial models. The purpose of this chapter is to demonstrate how it works in practice.

AN OUTLINE OF PROBABLISTIC DECISION THEORY

As McKay (2008) cleverly puts it, probabilistic decision theory is trivial—apart from computational details. It has its roots in the Bayesian

inference and in the concept of the utility, or the loss, function. Bayesian inference with its pure probabilistic methods is now gaining its long-deserved position in financial applications.

The *utility function* $U : d \rightarrow V$ that maps the outcomes of possible decisions d onto the value space (or, conversely, the cost space) V is a concept that embodies personal choice and individual risk preferences. In its simplest form, the cost space is one-dimensional. This makes it possible to order decisions by their costs. The decision that has a minimum cost (or a maximum value) is the best decision in the sense of the utility function U .

We will proceed to the formulation of the probabilistic decision-making theory according to Jaynes (2003) and McKay (2008). If $E(\cdot)$ is the expectation, d is the decision, $U(d)$ is the utility function of the decision, θ is the probable future state of the world, and $P(\theta, d)$ is the probability of θ , possibly influenced by the decision, then the optimal decision that maximizes the expectation of the utility function is

$$d = \arg \max \{ E(U(d)) = \int d \theta U(\theta, d) P(\theta, d) \}$$

In exact sciences, the states of the world θ are represented by objective quantities such as temperature, energy density, barometric pressure, acidity, and the like. Measurements of these quantities are subject to errors whose distribution is often fairly well known from the theory of the underlying physical process. For example, in electronics, the probability of an error of a weak signal is closely linked to the ambient temperature, which is an objective and measurable quantity. In engineering the contribution of side factors can often be accounted for and controlled for to a great degree. The existence of the underlying theory capable of quantitative description of the noise and other factors greatly simplifies decision making under uncertainty in engineering and in other exact sciences in comparison with financial applications.

It is customary to employ the same reasoning in finance. When we talk about “more precise

prediction of volatility” or “an accurate correlation coefficient” we implicitly assume that these quantities and parameters in finance are objective. They are not. Not unless we supply an underlying micro-model derived from the first principles, as we routinely do in exact sciences. In contrast, states of the world θ in finance are not inexact measurements of some “true quantities” linked to natural phenomena. Rather, they are mental constructs, which help us reason about financial phenomena—with more or less success. In financial observations, controlling for other factors is not possible, so the concept of *ceteris paribus* does not exist in nontrivial cases of any practical significance. It is better to think about states of the world in financial applications as relatively stable properties of markets and financial instruments. Depending on circumstances, such mental concepts as volatility, correlations, liquidity, expected time to default, and so on can be regarded as states of the world in finance.

States θ are functions of the model employed $\theta = \theta(M)$. Given the set of observations Y and subjective priors I , each state θ is assigned a probability:

$$P(\theta, d) = P(\theta(M), d | Y, I)$$

Being the function of the model, the data, prior beliefs, and, possibly, the decision, the probability of the state θ encapsulates all that is known to be relevant about the phenomenon under consideration.

Probabilistic inference, apart from very special cases, is often tractable only by computer techniques: $P(\theta | Y)$ has no analytical representation and must be ultimately sampled from the data.

The utility function $U(\theta, d)$ introduces the cost (or utility) of each decision in each state of the world. In academic research, one typically chooses a smooth and convex utility function. This should not necessarily be the case in the real world of financial applications where various smooth and nonsmooth constraints must

be satisfied—such as *risk tolerance*, tax considerations, strict and soft budget constraints.

Note that except for the observable data, all other components in the probabilistic decision-making process are user-dependent—the model, the beliefs, and the utility preferences. In the world of subjective views, there is no universal truth, there are no unconditionally good or poor decisions. All decisions are ultimately conditional on personal preferences.

Let's consider how it works in two simple financial applications: risk management of a simple portfolio and valuation of a risky bond.

MODEL RISK OF A SIMPLE PORTFOLIO

A portfolio manager considers creating an investment vehicle based on the instrument Y . The portfolio manager's objective is to extract as much idiosyncratic alpha as possible from Y while reducing the risks associated with the factor X . Instruments highly correlated with X are available for short selling, or instruments highly negatively correlated with X are available for purchase. There are costs associated with these actions. The portfolio manager has an amount of capital equal to C and access to an abundant and relatively low-risk security Z , which can be used to preserve capital. The objective is to meet investment goals $G(T)$, which include return on capital and risk parameters over a definite time horizon T .

The portfolio manager's decisions are based on prior beliefs and the data. The portfolio manager begins splitting capital among X , Y , and Z such that

$$C = C_X + C_Y + C_Z$$

The allocation of capital is determined by the optimization of the utility function given by:

$$C_X, C_Y, C_Z = \arg \max (E(U(C(T) - C)))$$

Expectations of future returns depend on the model parameters. In the Bayesian decision

framework, the distributions of these parameters are important:

1. Distribution of future returns of X .
2. Uncertainty of knowledge about how Y and X are related.
3. Distribution of idiosyncratic risk of Y after Y 's relationship to X is accounted for.
4. Uncertainty of expectations about future alpha.

In the list, the first risk can be understood as the true risk; the last three risks are the model risks or uncertainty.

Consider the model that links contemporaneous data y_t and x_t in a linear fashion:

$$y_t = \beta x_t + \epsilon_t$$

This model is a simplification of the industry-standard factor *risk model* and is akin to that used in the capital asset pricing theory (Sharpe, 1964), where a similar relationship is defined implicitly, or Fama and French (1992), where several factors are used.

The probability of observing the datum y_t given the unknown parameter of the model β is

$$P(y_t | \beta x_t) = P(y_t - \beta x_t) = P(\epsilon_t)$$

It is customary to select a normal model of the idiosyncratic noise $P(\epsilon_t) \propto N(\mu, \sigma)$ as it is a well-behaving distribution that falls off very fast and which for this reason has all its moments well defined. This, in turn, assists in obtaining clear analytical results with helpful illustrative properties.

One needs to remember, however, that real financial noise is neither normal, nor log-normal: It has fat tails, which can be so poorly behaving that the distribution may not even have its first moment well defined. In the probabilistic decision framework, it is almost never possible to obtain a neat analytical expression for the final result. Consequently, the advantages of the normally distributed noise fade in comparison with more realistic models. Another advantage of the probabilistic framework is that

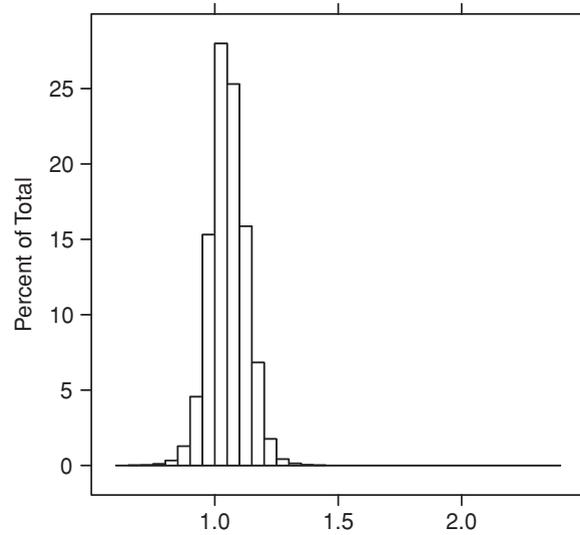

Figure 1 Distribution of β of Daily Price Changes over Three Years for Microsoft Corporation (MSFT) and the S&P 500 EFT (SPY)

one can easily compare evidence in favor of or against any conceivable model. In the presentation here, we retain the normalcy of the residual noise, bearing in mind that it is used for the sole purpose of illustrating the main idea.

Noise values being identically distributed and independent, which again is not a requirement for the probabilistic decision theory, the probability of observing the data set consisting of N points $x_1, y_t, \ell = 1 \dots N$ is

$$\begin{aligned} P(X|\beta X) &= \prod p(\epsilon_1) = \prod P(y_t - \beta x_t) \\ &= \prod P(\epsilon_t) \end{aligned}$$

It is easier to see the properties of the likelihood function by taking the logarithm:

$$\begin{aligned} \log P(Y|\beta X) &= -\frac{\sum_t (y_t - \beta x_t - \mu)^2}{2\sigma^2} \\ &\quad -\frac{1}{2} \log 2\pi\sigma^2 \end{aligned}$$

As a function of β , the log-likelihood attains a maximum at the same point where the ordinary least squares (OLS) method finds its optimum value of $\beta = \beta_{OLS}$. Contrary to the OLS, which boils down all the available data to one number, which is then taken as a real objective quan-

tity, the probabilistic framework retains more information about the relationship between Y and X , thereby preserving it in the distribution $P(\beta|XY)$.

In Figure 1 we show the distribution of β , $P(\beta|XY)$, when the dependent instrument Y is the daily change in the price of Microsoft Corporation stock and the independent instrument X is the daily price change of the exchange-traded fund SPY corresponding to the Standard & Poor's 500 index. Three years of daily data are used in the estimates of $P(\beta|XY)$. In Figure 2 the same amount of data is used to estimate $P(\beta|XY)$ when Y is the daily change in the price of the stock of a natural resource company, the Mosaic Company, and X is, again, the set of contemporaneous daily price changes in SPY.

Having obtained distributions of the model parameters β , μ , and σ from the data, the portfolio manager blends likelihoods with opinions about the distribution of the residual returns. The portfolio manager's alpha model is that the expectation of daily returns of Y is μ_0 with the confidence band $\pm\sigma_0$: $\mu_0 \sim N(\mu_0, \sigma_0)$. Combined with subjective opinions, the

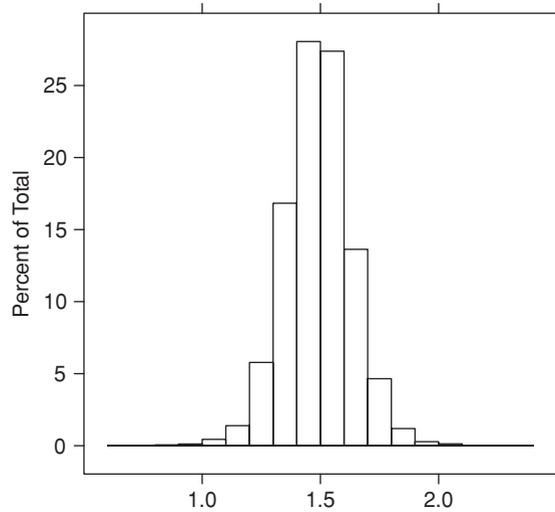

Figure 2 Distribution of β of Daily Price Changes over Three Years for the Mosaic Company (MOS) and the S&P 500 ETF

idiosyncratic distribution is again, normal:

$$\prod P(\epsilon_t) \propto N(\tilde{\mu}, \tilde{\sigma})$$

$$\tilde{\mu} = \frac{\frac{\mu_0}{\sigma_0^2} + \frac{\mu N}{\sigma^2}}{\frac{1}{\sigma_0^2} + \frac{N}{\sigma^2}}$$

$$\frac{1}{\tilde{\sigma}^2} = \frac{1}{\sigma_0^2} + \frac{N}{\sigma^2}$$

In order to overcome the evidence extracted from the data and given by μ , the portfolio manager’s confidence must be greater than the confidence range of the data: The portfolio manager’s confidence is high, that is, when $\sigma_0 \ll \sigma/N$, the posterior expectation of alpha is governed by the portfolio manager’s prognosis. In the opposite case, the data are trusted more than the portfolio manager’s judgment.

The portfolio manager sets risk preferences with the utility function

$$U(C(T), C, \eta) = -\exp\left(-\frac{C(T) - C}{C_\eta}\right)$$

Taking the expectations over one period $T = 1$ we obtain:

$$E(U) = -\int \alpha \beta \exp\left(-\frac{(\tilde{\mu} + \beta \mu_x)w_y + \mu_x w_x + \mu_z w_z}{\eta}\right) + 1/2\eta^2(w_y^2 \tilde{\sigma}^2 + w_x^2 \sigma_x^2 + \sigma_x^z(w_y^2 \beta^2 + 2w_y w_x \beta)) P(\beta)$$

Here

$$w_x = \frac{C_x}{C}, w_z = \frac{C_z}{C}, w_y = 1 - w_x - w_z$$

First, we focus on the problem of optimum allocation when there is no hedging: $w_x = 0, \mu_x = 0$. Define the certainty equivalent (CE) of the investment in Y and Z as such guaranteed change in C that results in the same utility as a risky investment in Y and Z . Mathematically, it is defined as the inverse of the utility function:

$$CE(C(T), C) = U^{-1}(E(U))$$

For the exponential utility function we obtain

$$CE(C(T), C) = -C_\eta \log E(U(C(T), C, \eta))$$

Adopting $P(\beta) = N(\beta_0, \Gamma)$ and integrating expected utility over the model parameter β , we finally arrive at

$$CE(w_y) = \tilde{\mu} w_y + \mu_z(1 - w_y) - \frac{1}{2\eta} \tilde{\sigma}^2 w_y^2 - \frac{1}{2\eta} \frac{\beta_0^2 \sigma_x^2 w_y^2}{1 - \frac{\Gamma^2 \sigma_x^2 w_y^2}{\eta^2}} + \frac{1}{2} \eta \log \left(1 - \frac{\Gamma^2 \sigma_x^2 w_y^2}{\eta^2}\right)$$

The first three terms in this equation represent the certainty equivalent of the investment without the risk model $\beta_0 = 0$ and without the

model risk $\Gamma = 0$. The optimal fraction of the capital invested in Y is a well-known expression (see, for example, Merton, 1969)

$$w_y = \eta \frac{\tilde{\mu} - \mu_z}{\tilde{\sigma}^2}$$

In this case, the fraction invested in the risky instrument is proportional to the portfolio manager's risk tolerance and inversely proportional to the instrument's idiosyncratic risk, which, in the absence of any model, is the total risk of the instrument.

Introduction of the risk model without uncertainty $\beta_0 \neq 0$, $\Gamma = 0$ results in the obvious extension:

$$w_y = \eta \frac{\tilde{\mu} - \mu_z}{\tilde{\sigma}^2 + \beta_0^2 \sigma_x^2}$$

Here $\tilde{\sigma}^2 + \beta_0^2 \sigma_x^2$ is, again, the total risk of Y as given by the model, split into the idiosyncratic part and the part coming from the influence of X .

When $\Gamma \neq 0$, the last two terms in the equation for $CE(w_y)$ represent the model risk. In some situations, the term $\Gamma^2 \sigma_x^2 w_y^2$ can be thought of as the contribution to the expected variance due to the model risk. Indeed, if $\Gamma^2 \sigma_x^2 w_y^2 \ll \eta^2$ (i.e., when the risk tolerance is much greater than possible risk associated with the factor X) in the expression for the certainty equivalent, the model risk is simply added to the total risk:

$$CE(w_y) \approx \tilde{\mu} w_y + \mu_z (1 - w_y) - \frac{1}{2\eta} (\tilde{\sigma}^2 + (\beta_0^2 + \Gamma^2) \sigma_x^2) w_y^2 + O(\sigma_x^1 w_y^1 / \eta^3)$$

In this expression, the last term is proportional to the magnitude of the expression in parentheses and is small in comparison with the preceding terms.

The contribution of the model risk is not so obvious in a general case. Clearly, when $\Gamma^2 \sigma_x^2 \sim \eta^2$, the model risk significantly affects optimal allocations.

Position Hedging

Now the portfolio manager aims to reduce the influence of the factor X on the variability of returns. The portfolio manager adds a position in X to the portfolio. Weight w_x allocated to X is chosen to maximize CE . Positive weight corresponds to a long position in X , whereas a negative weight corresponds to a short position or its equivalent. In the case when X is the daily performance of the Standard & Poor's 500 market index, a short position can be roughly replicated by taking a long position in an exchange-traded fund (ETF) whose daily returns correspond by design to the inverse—up to a constant factor—of the daily performance of the S&P 500 index.

The certainty equivalent of the portfolio is

$$E(w_y) = \tilde{\mu} w_y - \frac{1}{2\eta} \tilde{\sigma}^2 w_y^2 - \frac{1}{2\eta} \frac{\sigma_x^2 (w_x + \beta_0 w_y)^2}{1 - \frac{\Gamma^2 \sigma_x^2 w_y^2}{\eta^2}} + \frac{1}{2} \eta \log \left(1 - \frac{\Gamma^2 \sigma_x^2 w_y^2}{\eta^2} \right)$$

The first two terms in this expression are the idiosyncratic alpha and risk of the instrument Y .

The third term introduces the risk associated with the portfolio returns dependence on X . Let's take a closer look at it. Its structure is similar to the term describing the idiosyncratic risk: variance of the portfolio due to X divided by the portfolio manager's risk tolerance. In the third term, contribution from the risk model comes in two forms. In the numerator $w_x + \beta_0 w_y$ is the total weight of X in the portfolio: the sum of the weight of the position in X , w_x and the estimate of the contribution from exposure to X of the position in Y , $\beta_0 w_y$. The fact that the total contribution of X is the same as in the standard portfolio theory is purely accidental and is due to the choice of the model distribution of β .

In the denominator, the portfolio manager's risk tolerance is augmented by a factor that depends on the uncertainty of β :

$$1 - \frac{\Gamma \sigma_x^2 w_y^2}{\eta^2}$$

This term being less than unity, uncertainty effectively reduces the portfolio manager’s risk tolerance.

The fourth term is the contribution to CE from the model risk. Terms associated with the model risk indicate that when the uncertainty of the model approaches a critical value $\Gamma^2\sigma_x^2w_y^2 \sim \eta^2$ the portfolio becomes unfeasible unless w_y is sufficiently small.

In the absence of a risk model $\beta_0 = 0, \Gamma = 0$ optimal allocations maximizing CE of the portfolio are

$$w_x \sim 0$$

$$w_y \sim \frac{1}{\tilde{\sigma}^2}$$

When the risk model is present, but the uncertainty of the model is much bigger than its prediction $\beta_0 \ll \Gamma$, we obtain another useful result:

$$w_y \sim \frac{1}{\tilde{\sigma}^2 + \Gamma^2\sigma_x^2}$$

In this case the optimal allocation in Y is determined by the total risk of the instrument composed of the idiosyncratic risk and the uncertainty of the model.

When the risk model is present and is absolutely precise $\beta_0 \neq 0, \Gamma = 0$, the usual *hedging ratio* $\frac{w_x}{w_r} = -\beta$ completely eliminates the dependency of portfolio returns and their CE on X —the result conventionally obtained in the traditional formulation of the risk management problem.

From the probabilistic point of view, however, an absolutely precise model is nonsensical. Moreover, situations when both the model’s optimal parameters and the uncertainty of the parameters are of the same order of magnitude are most likely to occur in real applications.

Contribution from the risk model and from the uncertainty of the model become separated and especially simple when the portfolio manager’s risk tolerance is sufficiently large,

$$\Gamma^2\sigma_x^2w_y^2 \ll \eta^2:$$

$$CE(w_y, w_x) \approx \mu w_y - \frac{1}{2\eta}(\sigma^2 - \Gamma^2\sigma_x^2)w_y^2 - \frac{1}{2\eta}\sigma_x^2(w_x - \beta_\mu w_y)^2$$

Note that there is no combination of the instruments Y and X that can eliminate the effect of X . That the effect of the instrument X may never be eliminated completely is a better depiction of the everyday experience of the portfolio manager. Probabilistic decision theory accounting for the model risk, however, gives a reasonable indication of what the portfolio manager can expect from such or another composition of the portfolio when its components are mutually dependent.

In more complicated settings, once the portfolio manager introduces the costs of hedging, the decision whether to hedge or not comes naturally as the consequence of the interplay between the value of hedging and the costs. Let $y|w_xC| = y|\beta_0w_yC|$ be the cost associated with the hedge. Then one should hedge the position if

$$-\frac{1}{2\eta}(\tilde{\sigma}^2 + \Gamma^2\sigma_x^2)w_y^2 - \gamma|\beta_0w_yC| > -\frac{1}{2\eta}\sigma_y^2w_y^2$$

Hedging is justified if the model risk of the hedge plus the cost of implementing the model is smaller than the original risk that the hedge is meant to reduce.

In the equation above all quantities are evaluated from the data and the subjective prior beliefs using the methods of the Bayesian inference. Even when the model and the model parameters are relatively stable, the decision whether to hedge or not to hedge depends on the portfolio manager’s risk tolerance, which in turn can be represented by a combination of external constraints, or be inferred from another model.

A portfolio manager can readily extend the methodology of the preceding sections to more complicated cases of many interrelated instruments and many factors. The probability

distribution of the correlation matrix, however, will not necessarily appear in the calculations in place of the probability distribution of β : Noise models that have no concept of second or higher moments completely rule out correlation matrices in the calculations. Moreover, these distributions naturally lead to decisions being determined by a few extreme outliers. Fortunately, even pathological noise distributions, which seem to be the norm rather than an exception in finance, are treated equally well by the methods of the probabilistic decision theory, which is designed to incorporate all available data plus the portfolio manager's preferences and constraints.

In the next section we will address a problem of the model risk in an investment when the risk profile is different from that of an investment in an equity portfolio.

INVESTMENT IN A RISKY BOND

Let P be the face value of the zero-coupon bond, r the benchmark rate over the period of interest, ρ the multiplicative spread rate for the bond, so that

$$V = \frac{P}{(1+r)(1+\rho)}$$

is the current fair or market price of the bond, possibly unknown. An alternative investment vehicle Z is available as in the previous section, the rate of return for this instrument being r_z .

Let there be two possible states of the world. In the first state the bond is redeemed at the face value at the end of the period. In the second state of the world the bond is redeemed at P_y . The situation when $P_y = 0$ is possible, in which case the investment is a total loss. If the investor purchases N units of the risky bond and the remainder of the capital is preserved in the alternative vehicle, then, at the end of the period, the investor's capital is

$$C_1 = \begin{cases} NP + (1+r_z)(C_0 - NV), & \text{with } (1-p_d) \\ NP_r + (1+r_z)(C_0 - NV), & \text{with } p_d \end{cases}$$

In the traditional formulation the investment is justified if the expected return on capital when $N > 0$ is greater than the expected return when $N = 0$. This translates into the following expression, which links all the input data of the problem and the unknown value of the bond:

$$P(1-p_d) + P_r p_d > (1+r_z)V$$

This traditional approach is a reasonably good approximation under certain conditions. A much richer view along with the set of quantitative tools is required in a general case.

From the probabilistic decision theory viewpoint, the probabilities and other relevant parameters entering the decision-making process must be inferred from the model, from the data, and from the investor's prior beliefs, and are best represented by distributions of possible states of the world. We consider now a simple one-parametric risk model and show how the model risk contributes to the decision process.

Parameter Inference in the Bernoulli Model

In the Bernoulli-like model, the investment vehicle under consideration belongs to a class of essentially similar bonds. They are financial obligations issued by debtors facing essentially the same economic (financial, market, etc.) conditions. Given these conditions, it is customary to assume that the failure of each instrument is a random event. Failures in the class occur with the same probability p_d per unit time, which, for simplicity, will coincide in our analysis with the maturity time of the instrument.

The model of the random process, the empirical data, and the investor's prior beliefs determine all that we know about the model parameter p_d .

Assume that the empirical data are the sample of n observations of the class, and m is the number of cases when a debtor defaults. Adopting a beta-distribution of the model parameter, we obtain the following posterior distribution

given the data and the prior beliefs:

$$\pi(p_d, \alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} P_d^{\alpha-1} (1 - p_d)^{\beta-1}$$

where

$$\begin{aligned} \alpha &= \alpha_0 + m \\ \beta &= \beta_0 + n - m \end{aligned}$$

and α_0, β_0 are the parameters representing the investor's prior beliefs. In the prior distribution, α_0 can be interpreted as number of cases of default and β_0 is the number of cases when the bond was repaid in full. The prior distribution's parameters can come from the investor's own experience, or from the consensus of experts, or be inferred from agency ratings. The magnitude of α_0, β_0 versus n, m determines the relative weight the investor assigns to prior beliefs. Prior beliefs dominate the data when $\alpha_0 + \beta_0 \gg n$.

In Figure 3, the investor's prior beliefs follow the prior probability of default 0.1. Parameters of the prior distribution are $\alpha_0 = 2, \beta_0 = 11$. The newly arriving data point to the probability of default 0.2. Observe the change in the shape of the distribution: Its mode moves from ~ 0.1

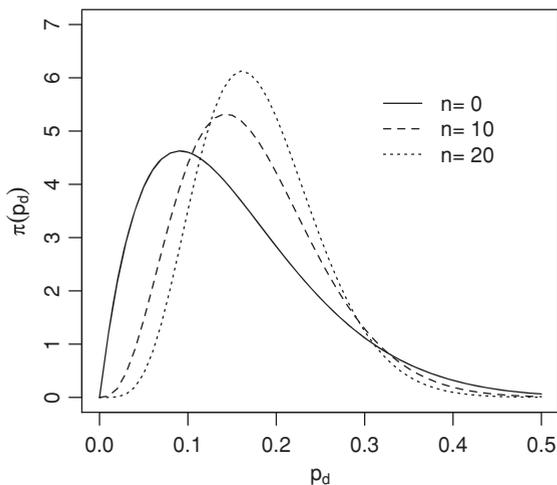

Figure 3 Distribution of the Probability of Default p_d
 Note: Prior distribution is defined by $\alpha_0 = 2, \beta_0 = 11$. Newly arriving data follow the new probability $\frac{n_i}{n} = 0.2$.

to ~ 0.2 as the new data gradually overcome the investor's prior beliefs. Note that the model risk—the width of the distribution—remains relatively high.

In the Bayesian perspective, the distribution of the *probability of default* is a convenient vehicle that carries all that the investor knows from the set of observations and the investor's prior beliefs: what is the most probable state of the world and what is the spread of possible states of the world given the investor's choice of the model of the world.

The rich framework offered by the Bayesian inference of the probability of default consequently brings in a rich set of valuation methods that naturally account for the model risk. In the next sections we will study the valuation effects of the risk of models.

Model Risk Contribution to the Fair Price of the Bond

First, we obtain an interesting estimate of the model risk contribution to the fair price of the bond under the assumption of the infinite risk tolerance. This is a degenerate case most closely resembling the traditional formulation. The utility function is linear if the investor's risk tolerance is infinite.

We obtain formally:

$$P(1 - E(p_d)) + P_r E(p_d) > (1 + r_z)V$$

Assume that the sample size is n of which there are m defaults. A flat prior distribution $\pi(p_d, \alpha_0, \beta_0) = \text{const}$ describes an investor who initially is ignorant. Expectation of the probability of default is then governed by the rule of succession (originally developed by Laplace):

$$E(p_d) = \frac{m + 1}{n + 2}$$

The difference between this posterior expectation and the naïve probability of default $p_d = m/n$ is the contribution of the model risk to the

fair price of the bond:

$$\delta V = \frac{P - P_r}{1 + Y_z} \left\{ E(p_\alpha) - \frac{m}{n} \right\}$$

For example, if the naïve default rate estimate is 0.1 and it is based on 100 observations, the contribution of the model risk to the fair price of the bond can be as big as 78 basis points—not an insignificant amount: The model risk can be a substantial contributor to the overall risk of the investment. Thus, the sampling risk and the prior beliefs bias yield a substantial contribution to the overall risk of the investment.

Even in the simplest Bernoulli-like model, the contribution of the model risk to the value of the bond is nonnegligible. This contribution is especially pronounced when the probability of default is small.

Now we will proceed to a case when the investor's risk tolerance is not infinite. We will show that average probabilities are likely insufficient for making an informed investment decision. Relying on just expected probabilities can result in catastrophic consequences for the investor.

Model Risk of Agency Ratings

Currently financial regulators recommend that expected losses be quantified as the expected probability of default times the exposure at default (see Basel, 2008). Consequently, credit scoring and rating agencies aim at developing models that generate expected probabilities of default. These models are calibrated by minimizing the difference between predicted and empirically observed probabilities of default (see, for example, Korablev and Dwyer, 2007). From the preceding section, it follows that the average rates based on thousands of credit events used in the calibration of the agency model alone are insufficient for making investment decisions concerning a portfolio of an arbitrary, possibly small, subset of instruments. Moreover, the naïve probability of default is likely to be useless in the valuation of a

singular derivative instrument, such as a credit default swap (CDS). For a financial practitioner it is important to know, however, that agencies possess and disclose substantially more information than ratings, scoring, or expected probabilities alone. We will now discuss briefly how this information is used in the probabilistic decision framework.

Korablev and Dwyer (2007) report that for a certain group of companies the Moody's KMV EDFTM model was predicting 2.5% as the mean probability of default in 2002. The value of 1.8% was actually observed. The 10 and 90 percentiles of the distribution of predicted rates were 0.5% and 5.4%. This information is sufficient to reconstruct the parameters of the beta-distribution discussed earlier. An approximate match is $\alpha = 1.12$, $\beta = 56.35$. In Figure 4 we show the set of implied distributions for the four years preceding 2002. The inferred distribution $\pi(p_d, \alpha, \beta)$ for the year 2002 is almost identical to that for 2000.

We will now show how the inferred model of the probability of default is used in the decision-making process.

It appears from the following analysis that due to idiosyncrasies of the distribution of the

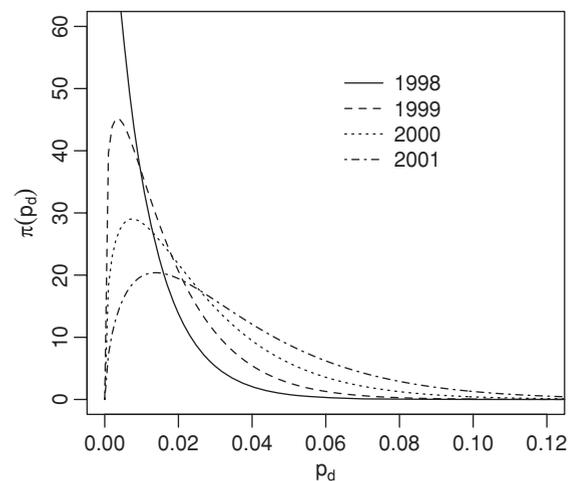

Figure 4 Implied Distribution of the Probability of Default p_d According to the Moody's Data for 1998, 1999, 2000, and 2001

probability of default, the effects of the model risk can be profound, even catastrophic. Describe the investor’s risk preferences with the following disutility function:

$$U(p_d) = -e^{\frac{p_d}{\eta}}$$

This function describes an investor who is progressively reluctant to tolerate deviations from the expected probability of default when these deviations exceed η . Note that disutility of positive deviations from the expected value is growing exponentially, while the beta-distribution of p_d falls off around its mode much slower, approximately as a power function. Using a beta-distributed probability of default $\pi(p_d, \alpha, \beta)$, we find for the certainty equivalent

$$CE(p_d) = U^{-1}(E(U(p_d))) = \eta \log \left(\Gamma(\alpha + \beta) F \left(\alpha, \alpha + \beta, \frac{1}{\eta} \right) \right)$$

where $F(a, b, z)$ is the regularized confluent hypergeometric function $F_1(a, b, z) / \Gamma(b)$ (Weinstein, 2010). The certainty equivalent of $CE(p_d)$ can be interpreted as an equivalent certain probability of default, which supplies the same value for the investor as the uncertain probability of default—given the investor’s risk preferences.

In the limit $\eta \rightarrow \infty$

$$CE(p_d) \rightarrow \frac{\alpha}{\alpha + \beta} \left(1 + \frac{1 + \alpha}{\alpha + \beta + 1} \frac{1}{\eta} \right) + 0(\eta^{-2})$$

At high tolerances $CE(p_d)$ coincides with the mean naïve probability of default. As the investor’s risk tolerance decreases, however, the certainty equivalent grows more and more rapidly. A plot of the exact certainty equivalent probability of default as the function of the model risk tolerance is shown in Figure 5. The parameters of the distribution are $\alpha = 1.45$ and $\beta = 15$, and the dashed line is the asymptote $\alpha / (\alpha + \beta)$.

The catastrophic divergence of the certainty equivalent probability occurs at the values of the tolerance that are close to the width of the distribution $\pi(p_d, \alpha, \beta)$: At the tolerance level

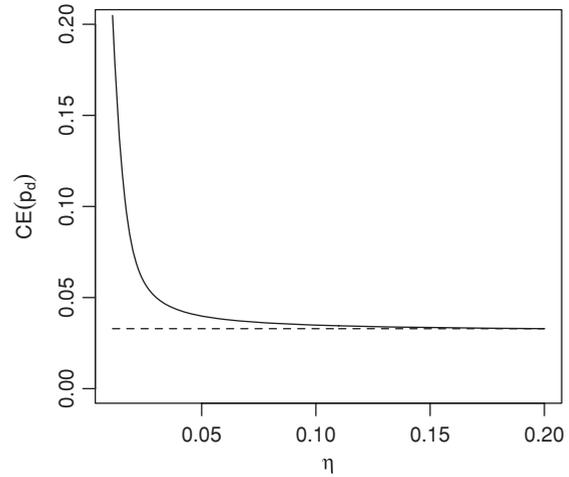

Figure 5 $CE(p_d)$ versus Risk Tolerance η
 Note: Dashed line is the asymptote value $\alpha / (\alpha + \beta)$, $\alpha = 1.45$, $\beta = 45$

$\eta = 0.01$ the $CE(p_d)$ is as big as 0.23, more than seven times the naïve value of the probability. From the practical decision-making standpoint it means that if the investor accepts the price of the bond or associated instruments defined by the naïve probability 0.031, it is likely that the investor is grossly mistaken about the value of the bond given the investor’s risk tolerance and the model risk.

KEY POINTS

- Probabilistic decision theory is a blend of the probabilistic, also called Bayesian, inference and the concept of utility.
- In the probabilistic decision theory optimal decisions maximize the expected value of the user’s utility over all possible states of the world.
- Probabilities of the states of the world are inferred from the empirical data, the model, and the user’s beliefs.
- Uncertainty in the model parameters results in the model risk; a financial model that is free of the model risk is an exception.
- Practical consequences of the model risk are evaluated using the utility function.

- Model risk significantly augments optimal allocations in equity portfolios and can result in a prospective portfolio being ruled out.
- Valuation of a risky bond is significantly affected by the model risk; ratings and expected probabilities of default alone are likely insufficient for the decision-making process.
- Failure to account for the model risk can lead to catastrophic consequences for the investor.
- Unhandled or unknown model risk produces risk exposure that remains indeterminate.

Abstract: Accounting for the likelihood of observing extreme returns and for return asymmetry is paramount in financial modeling. In addition to recognizing essential features of the returns' temporal dynamics, such as autocorrelations, volatility clustering, and long memory, a successful univariate model employs a distributional assumption flexible enough to accommodate various degrees of skewness and heavy-tailedness. At the same time, a model's usefulness depends on its scalability and practicality—the extent to which the univariate model can be extended to a multivariate one covering a large number of assets.

Risk models are employed in financial modeling to provide a measure of risk that could be employed in portfolio construction, risk management, and derivatives pricing. A *risk model* is typically a combination of a probability distribution model and a risk measure. In this entry, we discuss alternatives for building the probability distribution model, as well as the pros and cons of various *heavy-tailed* distributional choices. Our focus is univariate models; their multivariate extensions are only briefly mentioned. We start with the fundamentals—the Gaussian distribution. Then, we introduce fat-tailed alternatives, such as the *Student's t distribution* and its asymmetric version and the *Pareto*

stable class of distributions and their tempered extensions. Next, we discuss extreme value theory's risk modeling approach. We conclude with a comparative empirical example to contrast the models' performance over a 10-year period.

THE FUNDAMENTALS: NORMAL DISTRIBUTION

The use of normal (Gaussian) distribution in financial modeling has a long and distinguished tradition. The main reasons for its traditional popularity are several. First, its analytical

tractability means that deriving theoretical results and employing it in applications is (relatively) straightforward; numerical methods are widely available and implementable.¹ Second, certain central results in statistics underlie the importance of the Gaussian distribution.² Third, it has an intuitive appeal—random variables distributed with the Gaussian distribution tend to assume values around the average, with the odds of deviation from the average decreasing exponentially as one moves away from it.

Some of the most prominent financial frameworks built around the normal distribution are Markowitz's modern portfolio theory, the capital asset pricing model, and the Black-Scholes option pricing model. All of them assume (or imply) that asset returns follow a normal distribution and reflect a long-standing paradigm that rational investors' preferences can be described exclusively in terms of expected returns and risk as measured by the variance of the return distribution. However, they are inherently static frameworks. The underlying dynamic is either given exogenously or is based on the assumption that returns have independent and identical distributions. Such characteristics do not fit adequately with the empirically observed features of financial returns and investor choice.

In this section, we describe the fundamentals of a risk modeling approach based on the Gaussian distribution. We start with a review of some of its basic properties and facts.

Basics and Properties of the Gaussian Distribution

The normal distribution is characterized by two parameters—a location (mean) parameter and a scale (volatility, standard deviation) parameter.³ The location parameter serves to displace (shift) the whole distribution, while the scale parameter changes the shape of the distribution. For small values of the scale, the

distribution is narrow and peaked, while for (relatively) larger values, it widens and flattens. Since the normal distribution is symmetric around its mean, the location (mean) coincides with the center of the distribution. Commonly, the mean is denoted by μ and the standard deviation by σ .

Two important properties of the normal distribution are location-scale invariance and summation stability. They are directly related to the central role of the normal distribution in traditional financial modeling.

Location-Scale Invariance Property

Let us suppose a random variable X is normally distributed with parameters μ and σ . Now consider another random variable, Y , obtained as a linear function of X , that is, $Y = aX + b$. The variable Y is also normally distributed with parameters $\mu_Y = a\mu + b$ and $\sigma_Y = a\sigma$. That is, if a normal random variable is multiplied by a constant and/or is shifted, it remains distributed with the normal distribution.

Summation Stability Property

Let us take n independent random variables distributed with the Gaussian distribution with parameters μ_i and σ_i . The sum of the variables is normal as well. The resulting normal distribution has a mean and standard deviation obtained, respectively, as

$$\mu = \mu_1 + \mu_2 + \cdots + \mu_n$$

$$\sigma = \sqrt{\sigma_1^2 + \sigma_2^2 + \cdots + \sigma_n^2}$$

Location-scale invariance and summation stability are not universal properties of statistical distributions. In financial applications, however, they are clearly desirable properties.

The property of summation stability is often used to justify the predominant use of normal distributions in financial modeling. A statistical result, called the central limit theorem, states that, under certain technical conditions, the sum of a large number of random variables behaves

like a normally distributed random variable. More generally, we say that the normal distribution possesses a domain of attraction. In fact, the normal distribution is not the only distribution with this feature. As we will see later in the entry, it is the class of stable distributions (to which the Gaussian distribution belongs) that is unique with that property. A large sum of random variables can only converge to a stable distribution.

Density Function and Fitting of the Normal Distribution

The density function of a random variable X distributed with the normal distribution with mean μ and standard deviation σ is given by the following expression

$$f(x | \mu, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right) \quad (1)$$

We denote this distribution as $N(\mu, \sigma)$. The variable X and the parameter μ can take any real value, while σ can only take positive values. A normal random variable with zero mean and standard deviation of one is said to be distributed with the standard normal distribution ($N(0, 1)$). The presence of the exponential function in the normal density implies that the probability of events away from the mean decays at an exponential rate. In contrast, heavy-tailed distributions are characterized by power-law behaviors for large (small) values of the random variables, leading to increased chance for extreme events relative to the Gaussian setting.

Fitting of the Gaussian distribution is usually performed by maximizing the logarithm of the likelihood function given by

$$\ell(\mu, \sigma | x_1, x_2, \dots, x_n) = -\frac{n}{2} \log 2\pi - \frac{n}{2} \log \sigma^2 - \frac{1}{2} \sum_{i=1}^n \frac{(x_i - \mu)^2}{\sigma^2} \quad (2)$$

where x_1, x_2, \dots, x_n is the sample of observed data used for fitting. The resulting estimators of

the mean and the standard deviation are (using standard notation):

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \quad (3)$$

$$\hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2 \quad (4)$$

Unconditional models imply that returns are independent and identically distributed (IID), so that (among other implications) the returns' means and variances remain unchanged through time. However, empirical evidence abounds that financial returns exhibit time-series properties such as *autocorrelation* and *volatility clustering*, which make unconditional return modeling inadequate. The time-series properties of returns need to be modeled in a conditional framework with appropriate time series models. We consider conditional normal models next.

Conditional Normal Models and Time-Series Properties of Returns

Properly computing the risk of a portfolio depends on recognizing a number of essential features of the evolution of returns through time. We begin with the two most commonly accounted for by academics and practitioners—autocorrelation and volatility clustering.

Sometimes, a portfolio's past performance influences future performance. Current returns of a financial asset may depend on its past returns. This property of autocorrelation is modeled by including lagged (past) values of the return and/or lagged innovations (informational surprises). The resulting conditional model of the expected return is called an autoregressive moving average (ARMA) model.

Time-varying volatility concerns the empirically observed fact that large returns (of either sign) tend to be followed by large ones and small returns by small ones. To describe this volatility clustering effect, the class

of autoregressive conditional heteroskedasticity (ARCH) models, as well as their generalized (GARCH) extensions are widely used. GARCH models assume that volatility on a given day depends on the volatilities and also squared innovations of the one or more previous days.

The typical approach to building a risk model includes at least the elements of autoregressive component and volatility clustering component by means of a GARCH or alternative ARCH-type processes. A conditional normal ARMA(1,1)-GARCH(1,1) model combines the returns' conditional mean and volatility models with the assumption that returns are distributed with the Gaussian distribution. Analytically, the model is represented as

$$r_t = \mu_t + \epsilon_t \quad (5)$$

$$\mu_t = \phi_0 + \phi_1 r_{t-1} + \theta_1 \epsilon_{t-1} \quad (6)$$

$$\sigma_t^2 = \omega + \alpha \sigma_{t-1}^2 + \beta \epsilon_{t-1}^2 \quad (7)$$

where r_t , μ_t , and σ_t^2 are the return, expected return, and return variance at time t , respectively, and ϵ_t is the innovation at time t . The innovation is normally distributed with mean 0 and variance σ_t^2 .⁴

The standardized fitted residuals, $\hat{\epsilon}_t/\hat{\sigma}_t$, are the original returns with the effects of autocorrelation and volatility clustering removed (filtered out). Since the model innovations are assumed to be Gaussian, if the model is correctly specified, these filtered returns must exhibit the dynamics of a Gaussian white noise with variance one. Therefore, one easy way to determine whether the distributional assumptions are valid is to examine the properties of these residuals. Indeed, numerous studies have confirmed that in the case of financial returns the standardized fitted residuals are not Gaussian. That is, even after removing the autocorrelation and volatility clustering, fat tails, though smaller in magnitude, continue to be present in returns. Time-varying volatility then is not sufficient to explain the extreme events observ-

able in returns.⁵ Therefore, a more realistic risk model should allow for fat-tailed innovations. In the next section, we discuss parametric fat-tailed models, specifically, models based on the classical Student's t distribution and its asymmetric version, as well as on the stable and tempered stable distributions.

INCORPORATING HEAVY TAILS AND SKEWNESS: PARAMETRIC FAT-TAILED MODELS

The Student's t distribution has become the "go to" mainstream alternative of the normal distribution, when attempting to address asset returns' heavy-tailedness. Further below, we introduce an extension, called the skewed Student's t distribution, designed to deal with data asymmetries. First, we turn to discussing the "classical" Student's t distribution.

The "Classical" Student's t Distribution

The Student's t distribution (or simply the t -distribution) is symmetric and mound-shaped, like the normal distribution. However, it is more peaked around the center and has fatter tails. This makes it better suited for return modeling than the Gaussian distribution. Additionally, numerical methods for the t -distribution are widely available and easy to implement.

The t -distribution has a single parameter, called degrees of freedom (DOF), that controls the heaviness of the tails and, therefore, the likelihood for extreme returns. The DOF takes only positive values, with lower values signifying heavier tails. Values less than 2 imply infinite variance, while values less than 1 imply infinite mean. The t -distribution becomes arbitrarily close to the normal distribution as DOF increases above 30.

Density Function of the Student’s *t* Distribution

A random variable *X* (taking any real value) distributed with the Student’s *t* distribution with *v* degrees of freedom has a density function given by

$$f(x | v) = \frac{\Gamma(\frac{v+1}{2})}{\Gamma(\frac{v}{2})\sqrt{v\pi}} \left(1 + \frac{x^2}{v}\right)^{-(v+1)/2} \tag{8}$$

where “ Γ ” is the Gamma function. We denote this distribution by t_v . The mean of *X* is zero and its variance is given by

$$\text{var}(X) = \frac{v}{v-2} \tag{9}$$

The variance exists for values of *v* greater than two and the mean—for *v* greater than one.

The *t*-distribution above is sometimes referred to as the “standard” Student’s *t* distribution.⁶ In financial applications, it is often necessary to define the Student’s *t* distribution in a more general manner so that we allow for the mean (location) and scale to be different from zero and one, respectively. The density function of such a “scaled” Student’s *t* distribution is described by

$$f(x | v, \mu, \sigma) = \frac{\Gamma(\frac{v+1}{2})}{\sigma\Gamma(\frac{v}{2})\sqrt{v\pi}} \left(1 + \frac{1}{v} \left(\frac{x - \mu}{\sigma}\right)^2\right)^{-(v+1)/2} \tag{10}$$

where the mean μ can take any real value and σ is positive. The variance of *X* is then equal to $\sigma^2 v / (v - 2)$. We denote the distribution above by $t_v(\mu, \sigma)$.⁷

Finally, we make a note of an equivalent representation of the Student’s *t* distribution which is useful for obtaining simulations from it. The $t_v(\mu, \sigma)$ distribution is equivalently expressed as a scale mixture of the normal distribution where the mixing variable distributed with the inverse-gamma distribution,

$$X \sim N(\mu, \sqrt{W}\sigma)$$

$$W \sim \text{Inv-Gamma}\left(\frac{v}{2}, \frac{v}{2}\right)$$

Later in this entry we will again come across mixture representations in the context of our discussion of the skewed Student’s *t*, the stable Paretian, and the classical tempered stable distributions.

Degrees of Freedom Across Assets and Time

The typical approach to risk modeling based on the Student’s *t* distribution includes building an autoregressive and volatility clustering components, as well as assuming that DOF is the same for all assets’ returns. This assumption is essential if we want to extend the classical Student’s *t* model to a multivariate one. It is, however, an empirical fact that assets are not homogeneous with respect to the degree of non-normality of their returns. Moreover, tail thickness and shape are not constant through time either.

Consider the result of an empirical study of constituent stocks of the S&P 500 stock index during the period from January 2, 1991 to June 30, 2011. We calibrate the Student’s *t* distribution after filtering the equity returns for GARCH effects. The estimated DOF is shown in Figure 1. It is evident that tail behavior diverges dramatically across stocks. Around 44% of equity returns are very heavy tailed, with DOF estimate below five. Around 54% of equities have an estimated DOF parameter between five and 10. Only three stocks exhibit characteristics closer to the Gaussian, with a DOF exceeding 15. Obtaining accurate DOF estimates across assets is important in risk management, since these estimates can form the basis of an analysis of portfolio risk contributors and diversifiers.

Not only does tail behavior vary across assets, it also changes through time. In relatively calm periods, asset returns are almost Gaussian, while in turbulent periods, the tails become fatter. Figure 2 illustrates the time-varying behavior of DOF, suggesting temporal tail dynamics for the Dow Jones Industrial

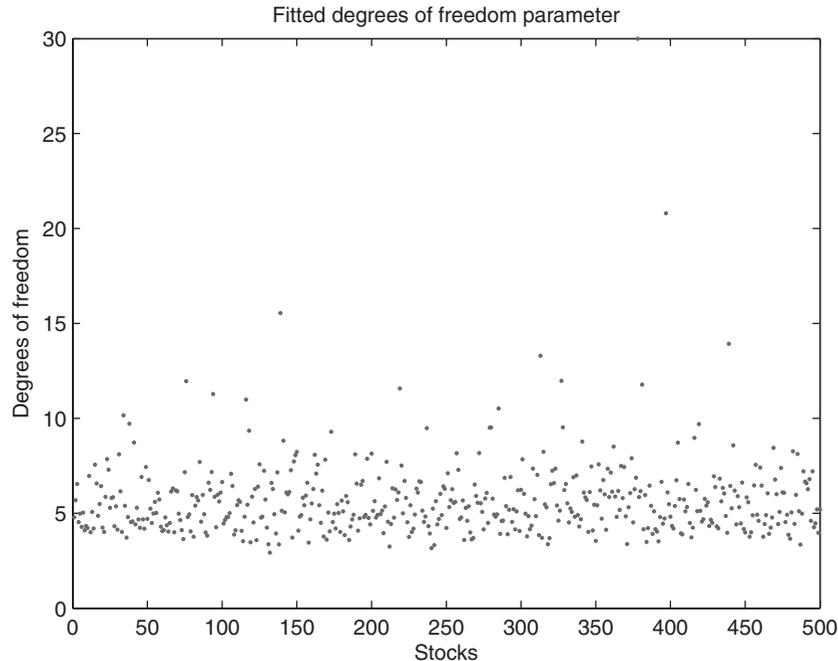

Figure 1 Fitted Degrees-of-Freedom Parameter for S&P 500 Index Stock Returns

Note: The Student's t distribution is calibrated on the residuals from a GARCH model fitted to the returns of the stocks in the S&P 500 index.

Average (DJIA) returns for the period from January 1, 1997 to June 30, 2011. The top and middle plots show the value and return of the DJIA, respectively. The bottom plot shows the DOF parameter estimates.⁸ In periods of “normal” market volatility, returns are almost normally distributed, with a fitted DOF over 30. However, when markets are unsettled, return tails grow heavier. Accounting for that time dynamics is important in risk budgeting and management to serve as an indicator for the transition between different market regimes—from calm to turbulent market or vice versa.

As pointed out earlier, a major limitation of employing the classical Student's t distribution for risk modeling is its symmetry. If there is significant asymmetry in the data, it will not be reflected in the risk estimate. There are at least several versions of the skewed Student's t distribution, depending on the analytical way in which asymmetry is introduced into the

distribution.⁹ Below, we consider the skewed Student's t distribution obtained as a mixture of Gaussian and inverse-gamma distributions.¹⁰

The Skewed Student's t Distribution

Suppose that a random variable X is distributed with the skewed Student's t distribution, obtained as a mixture of a Gaussian distribution and an inverse-gamma distribution,

$$X = \mu + \gamma W + Z\sqrt{W} \quad (11)$$

where

- W is an inverse-gamma random variable with parameters $\nu/2$, $W \sim \text{Inv-Gamma}(\nu/2, \nu/2)$.
- Z is a Gaussian random variable, $Z \sim N(0, \sigma)$, independent of W .

The parameters μ and γ are real-valued. The sign and magnitude of γ control the asymmetry in X . We say that X 's distribution is a mean-variance mixture of the normal

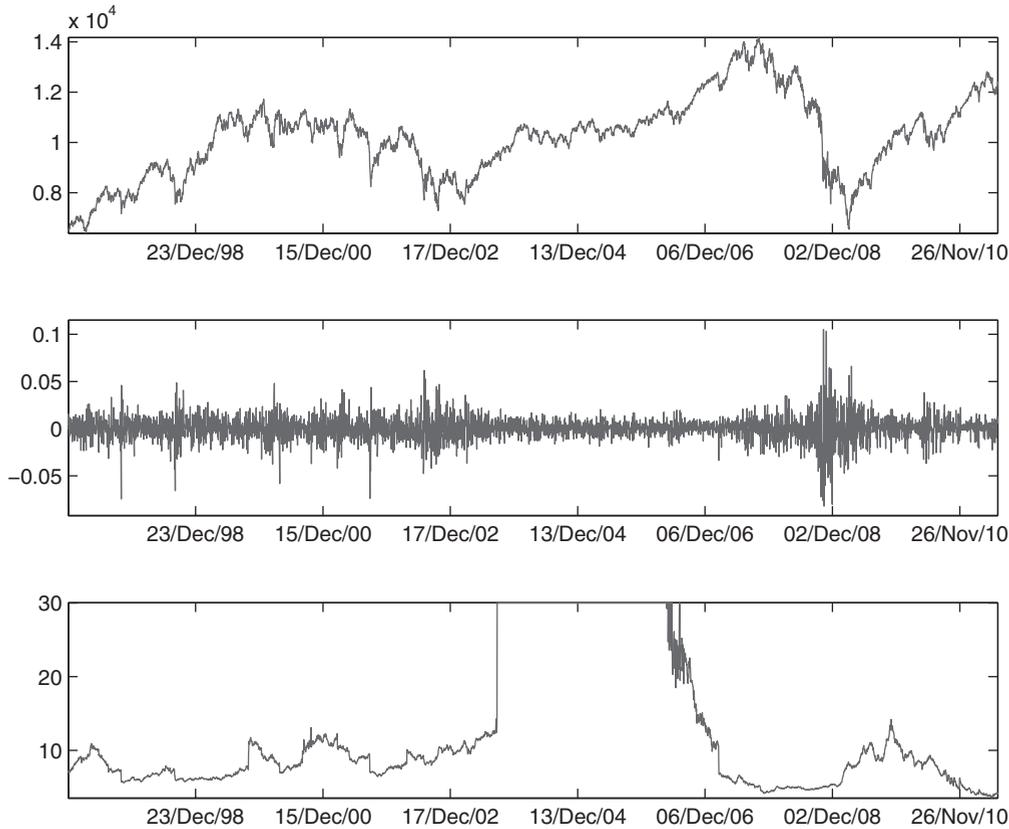

Figure 2 Fitted Degrees-of-Freedom Parameter for DJIA Returns
 Note: The Student’s *t* distribution is calibrated on the residuals from a GARCH model fitted to the return on the DJIA using a 500-day rolling window

distribution, since the mixing variable *W* modifies both the mean and the variance of the Gaussian *Z*. Notice that conditional on the value of *W*, the distribution of *X* is normal:

$$X | W = w \sim N(\mu + \gamma w, \sigma \sqrt{w}) \tag{12}$$

X’s unconditional distribution is what is defined as the skewed Student’s *t* distribution and its density is given by the expression

$$f(x | \mu, \sigma, \gamma, \nu) = A \times \frac{\exp\left(\frac{(x-\mu)\gamma}{\sigma^2}\right)}{\left(1 + \frac{(x-\mu)^2}{\nu\sigma^2}\right)^{(\nu+1)/2}} \times \frac{K_{(\nu+1)/2}(B)}{B^{-(\nu+1)/2}}$$

where

$$A = \frac{2^{1-(\nu+1)/2}}{\Gamma(\frac{\nu}{2})(\pi\nu)^{1/2}\sigma}$$

$$B = \sqrt{\left(\nu + \frac{(x-\mu)^2}{\sigma^2}\right) \frac{\gamma^2}{\sigma^2}}$$

and $K_\lambda(\cdot)$ is the so-called modified Bessel function with index λ .

Fitting and Simulation of the Classical and Skewed Student’s *t* Distributions

Estimation of the classical and skewed Student’s *t* distributions is carried out using the method of maximum likelihood. Simulations from the two distributions make use of their normal mixture representations. For given

parameters μ, σ , and γ (e.g., the maximum likelihood estimates), generation of t and skewed t observations consists of the steps below:

- Generate an observation w from the inverse-gamma distribution with parameters $\nu/2$.
- Generate an observation z from the normal distribution with mean 0 and variance σ^2 .
- Compute the corresponding observation of the t or skewed t -distribution, respectively, as

$$x = \mu + \sqrt{w}z \quad \text{and} \quad y = \mu + w\gamma + \sqrt{w}z \quad (13)$$

Stable Paretian and Classical Tempered Stable Distributions

Research on stable distributions in the field of finance has a long history.¹¹ In 1963, the mathematician Benoit Mandelbrot first used the stable distribution to model empirical distributions that have *skewness* and fat tails. The practical implementation of stable distributions to risk modeling, however, has only recently been developed. Reasons for the late penetration are the complexity of the associated algorithms for fitting and simulating stable models, as well as the multivariate extensions. To distinguish between Gaussian and non-Gaussian stable distributions, the latter are commonly referred to as stable Paretian, Lévy stable, or α -stable distributions.

Stable Paretian tails decay more slowly than the tails of the normal distribution and therefore better describe the extreme events present in the data. Like the Student's t distribution, stable Paretian distributions have a parameter responsible for the tail behavior, called tail index or index of stability.

Definition of Stable Paretian Distributions

We offer two definitions of the stable Paretian distribution. The first one establishes the stable distribution as having a domain of attraction. That is, (properly normalized) sums of IID random variables are distributed with the α -stable distribution as the number of summands n goes to infinity. Formally, let

Y_1, Y_2, \dots, Y_n be IID random variables and $\{a_n\}$ and $\{b_n\}$ be sequences of real and positive numbers, respectively. A variable X is said to have the stable Paretian distribution if

$$\frac{\sum_{i=1}^n Y_i - a_n}{b_n} \xrightarrow{d} X \quad (14)$$

where the symbol \xrightarrow{d} denotes convergence in distribution.

The density function of the stable Paretian distribution is not available in a closed-form expression in the general case. Therefore, the distribution of a stable random variable X is alternatively defined through its characteristic function. The density function can be obtained through a numerical method, as we explain further below. The characteristic function of the α -stable distribution is given by

$$\varphi_X(t) = \begin{cases} \exp\{i\mu t - \sigma^\alpha |t|^\alpha (1 - i\beta \text{sign}(t) \tan \frac{\pi\alpha}{2})\}, & \alpha \neq 1 \\ \exp\{i\mu t - \sigma |t| (1 - i\beta 2/\pi \text{sign}(t) \log(t))\}, & \alpha = 1 \end{cases} \quad (15)$$

where $\text{sign}(t)$ is 1 if $t > 0$, 0 if $t = 0$, and -1 if $t < 0$. The four parameters uniquely determining the α -stable distribution are:

- α : index of stability or tail index, $0 < \alpha \leq 2$.
- β : skewness parameter, $-1 \leq \beta \leq 1$.
- σ : scale parameter, $\sigma > 0$.
- μ : location parameter, $\mu \in \mathbb{R}$.

We denote the distribution by $S_\alpha(\sigma, \beta, \mu)$. The roles of α and β are illustrated in Figure 3. The sign of β reflects the asymmetry of the distribution. Positive (negative) β implies skewness to the right (left). As noted earlier, the index of stability controls the degree of heavy-tailedness of the distribution. Smaller values imply a fatter tail. The closer the tail index is to two, the more Gaussian-like the distribution is. Indeed, for $\alpha = 2$, we arrive at the Gaussian distribution—if X is distributed with $S_2(\sigma, \beta, \mu)$, then it has the normal distribution with mean equal to μ and variance equal to $2\sigma^2$.

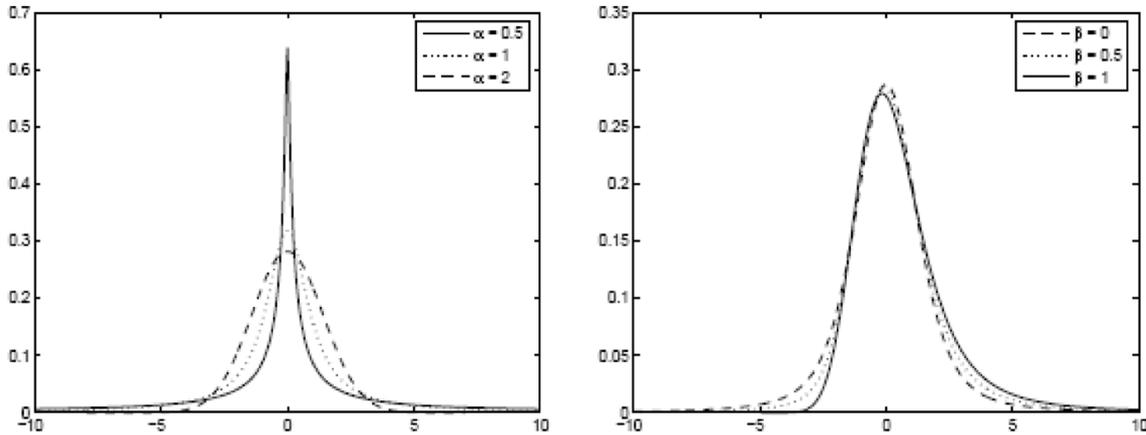

Figure 3 Stable Density: $\mu = 0, \sigma = 1, \beta = 0$, and varying α (left); $\alpha = 1.5, \mu = 0, \sigma = 1$, and varying β (right)

In this case, the parameter β loses its meaning as a skewness parameter and becomes irrelevant. Nevertheless, the normal distribution is usually associated with $\beta = 0$. Apart from the Gaussian distribution, there are two more special cases for which the density function of the stable distribution is available in a closed form: the Cauchy distribution ($\alpha = 1, \beta = 0$) and the completely skewed Lévy distribution ($\alpha = 1/2, \beta = \pm 1$).

Basic Properties of the Stable Distribution

We outline three basic properties of the α -stable distribution:

- *Power-tail decay.* The tail of the stable distribution’s density decays like a power function (slower than the exponential decay). It is this property that allows the stable distribution to capture the occurrence of extreme events. For a constant C , the property can be expressed as

$$P(|X| > x) \propto Cx^{-\alpha}, \quad \text{as } x \rightarrow \infty \quad (16)$$

- *Existence of raw moments.* The magnitude of the tail index determines the order up to which raw moments exist:

$$E|X|^p < \infty, \quad \text{for any } p: 0 < p < \alpha \quad (17)$$

$$E|X|^p = \infty, \quad \text{for any } p: p \geq \alpha$$

This property implies that, for non-Gaussian α -stable distributions ($\alpha < 2$), the variance (as well as higher moments such as skewness and kurtosis) does not exist. When the index of stability has a value less than one, the mean is infinite as well. Since the variance does not exist, one cannot express risk in terms of the variance. However, the scale parameter can play the role of a risk measure, in the same way that the standard deviation does in the normal distribution case.

- *Stability.* The property of stability characterizes the preservation of the distributional form under linear transformations. It is governed by the index of stability α and expressed as follows. Suppose that X_1, X_2, \dots, X_n are IID random variables, independent copies of a random variable X . Then, for a positive constant C_n and a real number D_n , X follows the stable distribution:

$$X_1 + X_2 + \dots + X_n \stackrel{d}{=} C_n X + D_n \quad (18)$$

The notation $\stackrel{d}{=}$ denotes equality in distribution. The constant $C_n = n^{1/\alpha}$ determines the stability property. The stability property means that the “classical” central limit theorem does not apply in the non-Gaussian case. A large sum of appropriately standardized IID random variables is distributed with the

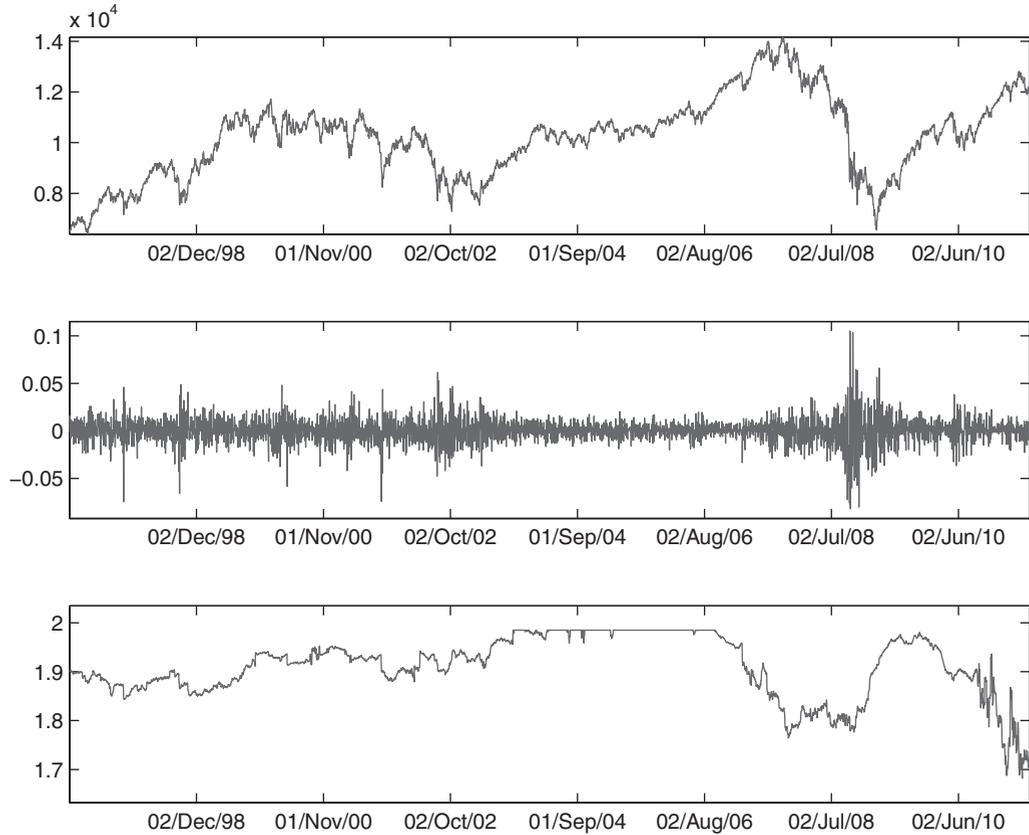

Figure 4 Fitted Stable Tail Index for DJIA Returns
 Note: The Stable Paretian distribution is calibrated on the residuals from a GARCH model fitted to the return on the DJIA using a 500-day rolling window

stable Paretian distribution as the number of terms increases indefinitely, not with the normal distribution.

When the variables $X_i, i = 1, \dots, n$, are themselves distributed with the α -stable distribution, $X_i \sim S_\alpha(\sigma_i, \beta_i, \mu_i)$, the stability property can be extended further:

1. The distribution of $Y = \sum_{i=1}^n X_i$ is α -stable with index of stability α and parameters:

$$\beta = \frac{\sum_{i=1}^n \beta_i \sigma_i^\alpha}{\sum_{i=1}^n \sigma_i^\alpha},$$

$$\sigma = \left(\sum_{i=1}^n \sigma_i^\alpha \right)^{1/\alpha}, \quad \mu = \sum_{i=1}^n \mu_i \quad (19)$$

2. The distribution of $Y = X_1 + a$ for some real constant a is α -stable with index of

stability α and parameters:

$$\beta = \beta_1, \quad \sigma = \sigma_1, \quad \mu = \mu + a \quad (20)$$

3. The distribution of $Y = a X_1$ for some real constant $a (a \neq 0)$ is α -stable with index of stability α and parameters:

$$\beta = \text{sign}(a)\beta_1, \quad \sigma = |a|\sigma_1,$$

$$\mu = \begin{cases} a\mu_1, & \text{for } a \neq 1 \\ a\mu_1 - \frac{2}{\pi}a \ln(a)\sigma_1\beta_1, & \text{for } a = 1 \end{cases}$$

In empirical analysis, the time-varying tail behavior of assets is reflected in the nonconstancy of the tail index of the α -stable distribution, as demonstrated in Figure 4. As in the earlier illustration, the tail index is estimated by fitting a stable distribution to the filtered returns

(after removing the volatility clustering with a GARCH model.) The tail index of the DJIA returns is very close to two in the upward market environment from 2003 to 2005 but starts decreasing right before the 2008 market crash and is smallest at the time of the crash itself. This implies that tail thickness is smallest in the bullish market from 2003 to 2005 and is largest during the crisis period.

As noted above, the variance of non-Gaussian stable distributions does not exist. To address this potentially undesirable feature, smoothly truncated stable distributions and various types of tempered stable distributions have been proposed. They are all obtained with a procedure known as “tempering” applied to the tails of the distribution to ensure that the variance is finite. This procedure replaces the power decay very far out in the tails of the distribution with an exponential (or faster) decay. We discuss the classical tempered stable distributions next.

Definition of Classical Tempered Stable Distributions

The characteristic function of the classical tempered stable (CTS) distribution is given by the following expression:

$$\varphi_X(t) = \exp\{imt - itC\Gamma(1 - \alpha)(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1}) + C\Gamma(-\alpha)((\lambda_+ - it)^\alpha - \lambda_+^\alpha + (\lambda_- + it)^\alpha - \lambda_-^\alpha)\} \tag{21}$$

We denote the distribution by CTS($\alpha, C, \lambda_+, \lambda_-, m$). The distribution parameters are characterized as follows:

- α : tail index, $\alpha \in (0, 1) \cup (1, 2)$.
- m : location parameter, $m \in \mathbb{R}$.
- C : scale parameter, $C > 0$.
- λ_+ and λ_- : parameters controlling the decay in the right and left tail, respectively; $\lambda_+, \lambda_- > 0$.

The relative magnitudes of λ_+ and λ_- determine the degree of skewness of the CTS distribution. When $\lambda_+ > \lambda_-$ ($\lambda_+ < \lambda_-$), the distribution is skewed to the left (right). Symmetry is obtained for $\lambda_+ = \lambda_-$. Tail heaviness is

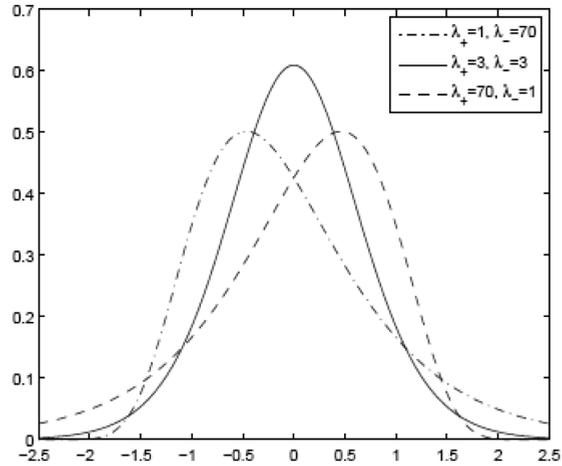

Figure 5 Probability Density of the CTS Distribution: Dependence on λ_+ and λ_-
 Note: CTS Parameter Values: $\alpha = 0.8, C = 1, m = 0$, and varying λ_+ and λ_-

determined in a more flexible manner in the CTS distribution than in the stable Paretian distribution. Three parameters play a role in that: λ_+, λ_- , and α . The former two have the effect of scaling the tails (smaller values correspond to heavier tails), while the latter one, of shaping the tails (as before, small values imply fatter tails). The effect of different values of these three parameters on the CTS distribution can be seen in Figures 5, 6, and 7.

Linear combinations of CTS-distributed random variables are also distributed with the CTS distribution. First, we define the standard CTS distribution. A random variable X has the standard CTS distribution if

$$C = (\Gamma(2 - \alpha) (\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}))^{-1} \tag{22}$$

The distribution is denoted by $X \sim \text{stdCTS}(\alpha, \lambda_-, \lambda_+)$. Its mean and variance are zero and one, respectively.

For a positive number σ and a real number m , the linear combination $Y = \sigma X + m$ has the CTS distribution:

$$Y \sim \text{CTS} \left(\alpha, \frac{\sigma^\alpha}{\Gamma(2 - \alpha) (\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})}, \frac{\lambda_+}{\sigma}, \frac{\lambda_-}{\sigma}, m \right) \tag{23}$$

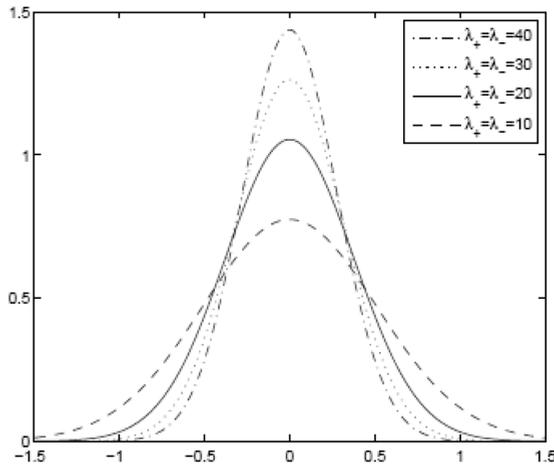

Figure 6 Probability Density of the Symmetric CTS Distribution: Dependence on λ_+ and λ_-
 Note: CTS Parameter Values: $\alpha = 1.1$, $C = 1$, $m = 0$, and varying λ_+ and λ_-

The mean and variance of Y are m and σ^2 , respectively.

Subordinated Representation of the α -Stable and CTS Distributions

Similar to the Student's t distribution, stable distributions can be represented as mixtures of other distributions. More generally,

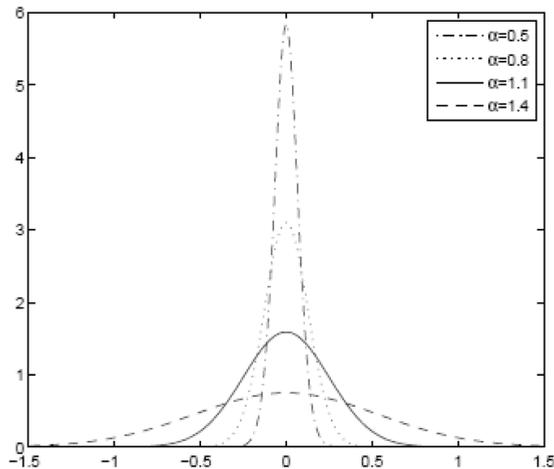

Figure 7 Probability Density of the CTS Distribution: Dependence on α
 Note: CTS Parameter Values: $C = 1$, $\lambda_+ = 50$, $\lambda_- = 50$, $m = 0$, and varying α

(continuous) mixture representations are analyzed within the framework of intrinsic time change and subordination. The price and return dynamics can be considered under two different time scales—the physical (calendar) time and an intrinsic (also called operational, trading or market) time. The intrinsic time is best thought of as the cumulative trading volume process which measures the cumulative trading volume of the transactions up to a point on the calendar-time scale. It is a measure of market activity and a reflection of the empirical observation that price changes are larger when market activity is more intense. Let us denote the intrinsic time process by $T(t)$ and the time-evolving random variable such as price or return by $X(t)$. $X(t)$ is assumed independent of $T(t)$. The compound process $X(T(t))$ is said to be subordinated to X by the intrinsic time $T(t)$ and $T(t)$ is referred to as a subordinator.¹² Since the increments of the intrinsic time $\Delta T(t) = T(t) - T(t - \Delta t)$ are non-decreasing and positive, distributions such as gamma, Poisson, and inverse-Gaussian can be used to describe them in probabilistic terms.¹³ Another distributional alternative is the completely skewed to the right α -stable distribution, $S_\alpha(\sigma, 1, 0)$, for $0 < \alpha < 1$, whose support is the positive real line. Therefore, when $0 < \alpha < 2$, the subordinator is a stable distribution given by $S_{\frac{\alpha}{2}}(\sigma, 1, 0)$.

Subordinated models with random intrinsic time, such as $X(T(t))$, are leptokurtic. They have heavier tails and higher peaks around the mode of zero than the normal distribution. As such, they provide a natural way to model the tail effects observed in prices and returns.

Subordinated representations' usefulness is in allowing for practical ways of simulating random numbers from the corresponding models. Subordinated processes are especially important in multiasset settings, where each marginal distribution has a different tail heaviness. This across-asset heterogeneity can be modeled by having subordinators with different parameters for each asset. As noted earlier, this characteristic of multivariate asset returns is crucially

important for a realistic risk model able to identify tail risk contributors and tail risk diversifiers.

The subordinated representation of the α -stable distribution can be expressed in the following way. Let Z be a standard normal random variable, $Z \sim N(0, 1)$, and Y be a positive $\alpha/2$ -stable random variable independent of Z , $Y \sim S_{\alpha/2}(s, 1, 0)$, where

$$s = \frac{\sigma^2}{2} \cos\left(\frac{\pi\alpha}{4}\right)^{2/\alpha} \tag{24}$$

Then, the variable

$$X = Y^{1/2}Z$$

is symmetric α -stable: $X \sim S_\alpha(\sigma, 0, 0)$. This implies that every symmetric stable variable is conditionally Gaussian (conditional on the value of the stable subordinator). Unconditionally, the symmetric α -stable distribution is expressed as a scale mixture of normal distributions.¹⁴

The CTS distribution has a subordinated representation as well and can be expressed as a mean-scale mixture of Gaussian distributions. For details, see Madan and Yor (2005).

Fitting and Simulations of α -Stable and CTS Distributions

Fitting techniques for the α -stable distributions can be divided into three categories: quantile methods, characteristic function-based methods, and maximum likelihood methods. The quantile method is similar to the method of moments estimation method in that it uses predetermined empirical quantiles to estimate the sample parameters.¹⁵ The characteristic function-based methods also resemble the method of moments and rely on transformations of the sample characteristic function.¹⁶ Finally, the latter method involves maximization of the likelihood function, which is computed numerically. Comparative studies of the three fitting approaches show that the method of maximum likelihood is superior in terms of

estimation accuracy. The quantile method requires the least amount of computational time but is the least accurate one. The second category of methods also have the benefit of computational simplicity but may have a difficulty in estimating the skewness parameter.¹⁷ For these reasons, here we focus on the method of maximum likelihood in some more detail.

In statistical theory, the relationship between the probability density function (pdf) and the characteristic function is expressed as follows:

$$f_X(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(-itx) \varphi_X(t) dt \tag{25}$$

where $h > 0$ and $f(\cdot)$ and $\varphi(\cdot)$ are the density and characteristic functions, respectively. The pdf of the α -stable and CTS distributions can be computed by numerical evaluation of the integral above. A fast and computationally efficient method of numerical integration is the fast Fourier transform (FFT) algorithm.¹⁸ Consider the pdf computation in (25). The main idea of FFT is to evaluate the integral for a grid of equally-spaced values of the random variable X :

$$x_k = \left(k - 1 - \frac{N}{2}\right)h, \quad k = 1, \dots, N \tag{26}$$

That is, equation (25) can be expressed as

$$f_X(x_k) = \int_{-\infty}^{\infty} \exp\left(-i2\pi\omega\left(k - 1 - \frac{N}{2}\right)h\right) \varphi_X(2\pi\omega)d\omega$$

This integral can be approximated by the so-called Riemann sum, after choosing small enough lower and large enough upper bounds:

$$f_X(x_k) \approx s \sum_{n=1}^N \varphi\left(2\pi s\left(n - 1 - \frac{N}{2}\right)\right) \times \exp\left\{-i2\pi\left(k - 1 - \frac{N}{2}\right)\left(n - 1 - \frac{N}{2}\right)sh\right\} \tag{27}$$

for $k = 1, \dots, N$. Here, the lower and upper bounds equal $-\frac{sN}{2}$ and $\frac{sN}{2}$, respectively. The distance between the grid points $n - 1 - \frac{N}{2}$,

$n = 1, \dots, N$ is s . If $s = \frac{1}{hN}$, we arrive at the following expression for the density, after some algebraic rearrangement:

$$\begin{aligned}
 f_X(x_k) &\approx \frac{(-1)^{k-1+\frac{N}{2}}}{hN} \sum_{n=1}^N (-1)^{n-1} \varphi \\
 &\times \left(\frac{2\pi}{hN} \left(n-1 - \frac{N}{2} \right) \right) \\
 &\times \exp \left(-\frac{i2\pi(n-1)(k-1)}{N} \right), \\
 k &= 1, \dots, N \tag{28}
 \end{aligned}$$

To compute the sum above, one can use the FFT implemented by many numerical analysis software packages. The parameters of the FFT method are N , the number of summands in the Riemann sum, and h , the grid spacing. Their values can be chosen appropriately, so as to achieve a balance between approximation accuracy and computational burden.¹⁹ Finally, the maximum-likelihood estimates of the parameters of the α -stable and CTS distributions are obtained by numerical maximization of the log-likelihood function.

Simulations of α -stable distribution can be accomplished using an algorithm called the Chambers-Mallows-Stuck generator. To generate a random number from $S_\alpha(\sigma, \beta, \mu)$, the steps are as follows:

- Generate two independent random numbers from an exponential distribution with mean 1, $E \sim \exp(1)$, and from a uniform distribution, $U \sim U(-\frac{\pi}{2}, \frac{\pi}{2})$.
- If $\alpha \neq 1$, compute

$$\begin{aligned}
 Z &= s_{\alpha,\beta} \frac{\sin(\alpha(U + b_{\alpha,\beta}))}{(\cos U)^{1/\alpha}} \\
 &\times \left(\frac{\cos(U - \alpha(U + b_{\alpha,\beta}))}{E} \right)^{(1-\alpha)/\alpha} \tag{29}
 \end{aligned}$$

where

$$\begin{aligned}
 s_{\alpha,\beta} &= \left[1 + \beta^2 \tan^2 \frac{\pi\alpha}{2} \right]^{\frac{1}{2\alpha}} \\
 b_{\alpha,\beta} &= \frac{\arctan(\beta \tan \frac{\pi\alpha}{2})}{\alpha} \tag{30}
 \end{aligned}$$

- If $\alpha = 1$, compute

$$\begin{aligned}
 Z &= \frac{2}{\pi} \left[\left(\frac{\pi}{2} + \beta U \right) \tan U \right. \\
 &\quad \left. - \beta \log \left(\frac{E \cos U}{\frac{\pi}{2} + \beta U} \right) \right] \tag{31}
 \end{aligned}$$

- The random variable Z has a standardized stable distribution with location parameter equal to zero and scale parameter equal to one, $Z \sim S_\alpha(1, \beta, 0)$. To obtain an observation from $S_\alpha(\sigma, \beta, \mu)$ with arbitrary values of σ and μ , transform Z according to²⁰

$$S = \sigma Z + \mu \tag{32}$$

Conditional Parametric Fat-Tailed Models

A fat-tailed parametric model includes the following main components:

- An autoregressive component to capture autoregressive behavior.
- A volatility clustering component, usually a GARCH-type model.
- A fat-tailed distribution (stable Paretian or skewed Student's t) to explain the heavy tails and the skewness of the residuals from the ARMA-GARCH model.
- Tail thickness changing with time and across assets addressed.

INCORPORATING HEAVY TAILS AND SKEWNESS: SEMI-PARAMETRIC FAT-TAILED MODELS

In this section, we review semi-parametric models, which combine an empirical distribution for the body of the data distribution where plenty of observations are available and extend the tail by a parametric model based on extreme value theory (EVT). EVT has a long history of applications in modeling the occurrence of severe weather, earthquakes, and other extreme natural phenomena. In general terms, extreme value distributions are the asymptotic

distributions for the normalized largest observations of IID random variables. There are two main categories of models for extreme values: block maxima models and threshold exceedances models.

In the financial applications context, block maxima could refer to the maximal observations within certain predefined periods of time. For example, daily return data could be divided into quarterly (or semiannual or yearly) blocks and the largest daily observations within these blocks collected and analyzed. The distribution of the maximal values is generally not known. However, when the block size is large, so that block maxima are independent (irrespective of whether the underlying data are dependent), the limit distribution is given by EVT.²¹ The number of blocks determines the size of the data sample available for analysis and fitting. In contrast, in threshold exceedances models, the sample size is not predetermined but, naturally, depends on the a priori selected threshold level.

The first model category is represented by the so-called generalized extreme value (GEV) distribution. Its distribution function has the form

$$F_X(x | \xi, \mu, \sigma) = \begin{cases} \exp\left(-\left(1 + \xi \frac{x-\mu}{\sigma}\right)^{-1/\xi}\right), & \xi \neq 0 \\ \exp(-e^{-x}), & \xi = 0 \end{cases} \quad (33)$$

where $1 + \xi(x - \mu)/\sigma > 0$. The parameters $\xi \in \mathbb{R}$, $\mu \in \mathbb{R}$, and $\sigma > 0$ are the shape, location, and scale parameters, respectively. The value of ξ determines the three distributions encompassed by the parametric form above: the Weibull distribution ($\xi < 0$), the Gumbel distribution ($\xi = 0$), and the Fréchet distribution ($\xi > 0$). Of the three, the latter one has the heaviest tails,²² while the first one is short-tailed, with a finite right endpoint and, thus, not favored in modeling financial losses.²³

The block maxima method’s major drawback is its “wastefulness” of data: all but the largest observation within each block are discarded. For this reason, a more common approach

to EVT modeling is the threshold exceedance method. In it, the extreme events exceeding a predetermined high level (that is, events in the tail) are modeled with the generalized Pareto distribution (GPD). Its distribution function is given by

$$F_X(x | \xi, \sigma) = \begin{cases} 1 - \left(1 + \xi \frac{x}{\sigma}\right)^{-1/\xi}, & \xi \neq 0 \\ 1 - \exp\left(-\frac{x}{\sigma}\right), & \xi = 0 \end{cases} \quad (34)$$

where $\sigma > 0$ and $x \geq 0$ when $\xi \geq 0$ and $0 < x < -\sigma/\xi$ when $\xi < 0$. The parameters ξ and σ are the shape and scale parameters, respectively. Like the GEV, the GPD contains several special cases defined by the value of ξ . When $\xi > 0$, we get the Pareto distribution with parameters $\alpha = 1/\xi$ and $k = \sigma/\xi$, whose tails exhibit slow, power-law decay. The exponential distribution is obtained for $\xi = 0$; its tails decay at an exponential rate. A short (finite)-tailed distribution, called Pareto type II distribution, arises when $\xi < 0$.²⁴

Fitting and Simulations of the GPD

In empirical modeling, there is generally a perceived trade-off between fitting the bulk and the tails of the data. Data around the mode are numerous and relatively easy to fit, while data in the tails are sparse and present an estimation challenge. Most commonly, the choice of model is based on how well it fits the bulk of the data, with the tails relegated to a somewhat secondary role. The semiparametric approach we consider in this section is to describe the majority of the data in a nonparametric fashion and use the GPD to fit the tails. Since the GPD describes the excess distribution over a threshold, we now define formally this concept.

For a random variable with cumulative distribution function G , the excess distribution over the threshold u is denoted by G_u and is given by

$$G_u(x) = P(X - u \leq x | X > u) = \frac{G(x + u) - G(u)}{1 - G(u)}$$

for $0 \leq x \leq x_F - u$, where x_F is the right endpoint (a finite number or infinity) of X 's

distribution function G .²⁵ A statistical result known as the Pickand-Balkema-de Haan theorem implies that the excess distributions of a large class of underlying distributions converge to a GPD as the threshold level increases. That is, GPD is the limiting distribution as u increases to infinity.

Denote the available data sample by X_1, \dots, X_N and define an upper and a lower threshold level u_U and u_L , respectively. The data points beyond the threshold levels constitute the tails of the data distribution that are to be modeled with EVT. Naturally, separate modeling of the two tails has the purpose of accounting for the potential skewness in the data distribution. Let us define the exceedances of u_U by $Y_{k,U} = X_k - u_U$, where $X_k > u_U$ and the exceedances of u_L by $Y_{k,L} = u_L - X_k$, where $X_k < u_L$, $k = 1, \dots, K$.²⁶ The estimates of the scale and shape parameters are most conveniently obtained by maximizing the GPD log-likelihood function for each of the sets of data $Y_{k,U}$ and $Y_{k,L}$.²⁷ It is written as

$$\begin{aligned} \ln L(\xi, \sigma | Y_1, \dots, Y_K) &= \sum_{k=1}^K \ln f_Y(\xi, \sigma) \\ &= -K \ln \sigma - \left(1 + \frac{1}{\xi}\right) \sum_{k=1}^K \ln \left(1 + \xi \frac{Y_k}{\sigma}\right) \end{aligned} \quad (35)$$

where $f(\xi, \sigma)$ denotes the GPD density function.

The empirical distribution is usually estimated using kernel density estimation approach. The kernel density estimate can be roughly thought of as a smoothed-out histogram. A parameter, called bandwidth or window width, controls the degree of smoothness of the resulting density estimate. More formally, the kernel density estimate is defined as

$$f(x, x_i, h) = \frac{1}{hn} \sum_{i=1}^n K_h \left(\frac{x - x_i}{h} \right) \quad (36)$$

where $x_i = (x_1, x_2, \dots, x_n)$ is data sample coming from some unspecified distribution and assumed to be IID. The bandwidth, h , takes pos-

itive values and K is called the kernel, a symmetric function that integrates to one. The normal density is often chosen as the kernel in (36). The bandwidth's value can be selected in an optimal way.²⁸

The approach to scenario generation from a model based on GPD is also semiparametric—the body of the distribution is simulated from the empirical density and GPD tails are attached to it. Generating observations from a GPD with a given shape parameter ξ , a scale parameter σ , and a threshold level u can be accomplished in the following three steps:

- Generate an observation U from a uniform distribution on the interval $(0, 1)$.
- Compute the quantity

$$Z = \frac{U^{-\xi} - 1}{\xi} \quad (37)$$

- Compute the GPD realization as

$$Y = \xi + \sigma \times Z \quad (38)$$

Scenarios from the body of the distribution are generated nonparametrically, via historical simulation known as bootstrapping (or resampling, more generally). The procedure involves drawing randomly, with replacement, from the set of historically observed data points. The simulated tails of the distribution are then “attached” to the scenarios from the body to obtain semiparametric scenarios from the whole data distribution.

Threshold Selection

We consider two of the most popular tools for selection of the threshold level—the mean excess function plot and the Hill plot. Both of them rely on visual inspection to determine the threshold.

The mean excess function is closely related to the concept of excess distribution. It describes the average exceedance above a threshold u , as a function of u .²⁹ Formally, it is defined as

$$m(u) = E(X - u | X > u) \quad (39)$$

In the case of the GPD, $m(u)$ can be shown to equal

$$m(u) = \frac{\sigma}{1 - \xi} + \frac{\xi}{1 - \xi} u$$

where $0 \leq u < \infty$ if $0 \leq \xi < 1$ and $0 \leq u \leq -\beta/\xi$ if $\xi < 0$. The excess mean function does not exist for $\xi \geq 1$. The mean excess function is linear in the threshold level. This linearity is used to motivate a graphical check that the data conform to a GPD model: If the plot is approximately linear for high threshold values, the GPD may be employed to describe the distribution of the exceedances. The level above which linearity is evident may be taken as the threshold level.

Plots of the Hill estimator are another EVT model selection method. The Hill approach offers a way to estimate the tail index $\alpha = 1/\xi$. Denote the i th order statistics of the data sample by $X_{(i)}$.³⁰ The Hill estimator of α is defined as

$$H_{m,n} = \left(\frac{1}{m} \sum_{i=1}^m \ln X_{(i)} - \ln X_{(m)} \right)^{-1} \quad (40)$$

where $2 \leq m \leq n$ and m is a sufficiently high number. For $\xi > 0$, the Hill estimator is equal to α asymptotically, as the sample size n and the number of extremes m increase without bound. In practical applications, the Hill estimator is computed for different values of m and plotted against these values. The plot is expected to stabilize above a certain value of m , so that the Hill estimates constructed from a different number of order statistics remain approximately the same. The threshold level u is then estimated by $X_{(m)}$.

The semiparametric approach described in this section is a source of two major challenges. First, in order to obtain a sufficiently large number of observations in the tail, a large sample of historical data is needed. Second, even though the plots of the Hill estimator and the mean excess function provide a method for threshold identification, such identification is intrinsically subjective, as it is based on visual inspection.

Moreover, it is difficult to automate it for large-scale applications.³¹

Conditional GPD Approach

The semiparametric approach described above is unconditional, since it implicitly assumes that the observed data is IID. A typical conditional GPD approach involves the components:

- Autoregressive model to capture linear dependencies in the data.
- GARCH-type model to capture the volatility clustering in the data.
- Semi-parametric model applied to the standardized residuals (which are approximately IID) to explain the data's heavy-tailedness and asymmetry.

COMPARISON AMONG RISK MODELS

Using the DJIA daily returns from February 7, 1992 to June 30, 2011, we conduct a back-testing analysis to compare the three fat-tailed distribution models—stable Paretian, Student's t , and EVT—alongside the normal distribution model. The data used in all models are first filtered for autoregression and volatility clustering using ARMA-GARCH.

The particular models we use in this section are the univariate analogs of the typical approaches to modeling in the multivariate case. A short discussion will help clarify what this means. Earlier we explained that, in a multi-asset setting, taking into account the varying tail behavior of the returns of different assets is of principal importance for risk analysis and management. However, employing the classical Student's t distribution in the multivariate case necessarily implies the same value of the DOF parameter for all assets. That value would "average out" the tail-fatness of assets, so that the risk of some risk drivers will be underestimated, while the risk of others, overestimated. To reflect this typical multivariate application, in our backtesting analysis we

choose to fix the DOF of the Student's t distribution to four.

In the case of the stable Paretian model, similar considerations about the heterogeneity of tail behavior across risk drivers lead us to use the subordinated representation of the α -stable distribution. As mentioned in an earlier section, that representation allows for modeling the individual tail behavior of assets.

The backtesting analysis in this section, therefore, can be understood as a comparison among models with increasing degree of sophistication. We start with the classical parametric approach (the "Gaussian model"). Then, a "non-sophisticated" fat-tailed model, represented by the fixed-DOF Student's t model (the "T-model") is tested. Finally, a state-of-the-art fat-tailed model—the stable subordinated model (the "stable model")—is considered. For each of the four models, exceedances of *value-at-risk* (VaR)—the number of times the realized loss is larger than the predicted VaR level—are tracked.³² We run the backtest with the following settings:

- Backtest period: January 2, 2004, to June 30, 2011.
- VaR confidence level: 99%.
- Time window: 500 rolling days for normal, classical Student's t , and stable Paretian distributions and 3,000 rolling days for EVT.³³
- EVT threshold: 1.02% (as suggested by Goldberg, Miller, and Weinstein (2008)).

The number of exceedances of the daily 99% VaR in the backtesting analysis for the four models is summarized below:

Model	Number of Exceedances
Stable	21
Student's t	26
Gaussian (normal)	42
EVT	1

The number of exceedances is compared using a 95% confidence interval estimated to be [10, 27]. The results show that the Gaussian model is too optimistic—with 42 exceedances,

its VaR forecasts are too low. In contrast, the EVT approach is overly pessimistic: Its predicted VaR is only exceeded once in the backtesting period. The Student's t model and the stable model both produce exceedances within the confidence interval, with the latter model being very close to the upper bound.

The DJIA performance during the backtest period is presented in Figure 8. Figure 9 plots the daily 99% VaR forecast produced by the Gaussian model, the Student's t model, and the stable model against the daily DJIA returns for the full backtest period. Since the EVT model's VaR predictions are too conservative, we have excluded it from the exhibit for the sake of presentation clarity. It can be seen from the figure that in times of low market volatility, the VaR forecasts of the three models are almost indistinguishable. However, during periods of greater market turmoil, differences in predicted risk levels are substantial across models. This point is further elaborated in Figure 10, which shows the spreads between the 99% VaR forecasts for the Student's t Gaussian and the stable-Gaussian model pairs, along with the values and returns of DJIA. We observe that the stable-Gaussian VaR spread stays at zero for the period from 2004 to late-2006, suggesting "normal" market conditions. (The estimated tail index parameter of the α -stable distribution is close or equal to two during that period.) This is an essential feature of the stable model: Despite being a fat-tailed approach, it does not overpenalize the portfolio by assessing unnecessarily high risk estimates during calm market periods. On the other hand, even in times of severe market circumstances the number of exceedances of the stable VaR is within an acceptable range. For the period from June 1, 2008 to June 1, 2009, the stable VaR has one exceedance, which is within the 95% confidence interval for the number of exceedances ([0, 4]). By comparison, the Student's t model's VaR is exceeded four times, while the Gaussian model has seven exceedances.

It is interesting to analyze whether the VaR forecasts can anticipate the transition from a

Figure 8 Dow Jones Industrial Average Performance: January 2, 2004–June 30, 2011

calm market regime to a turbulent one. To investigate, we “zoom in” on the VaR spread dynamics for the two-year period leading up to the September 2008 crash. Figure 11 shows

the VaR spreads for the period September 1, 2006–September 1, 2008, relative to the Gaussian VaR forecast. We notice that the stable-Gaussian relative spread starts increasing in

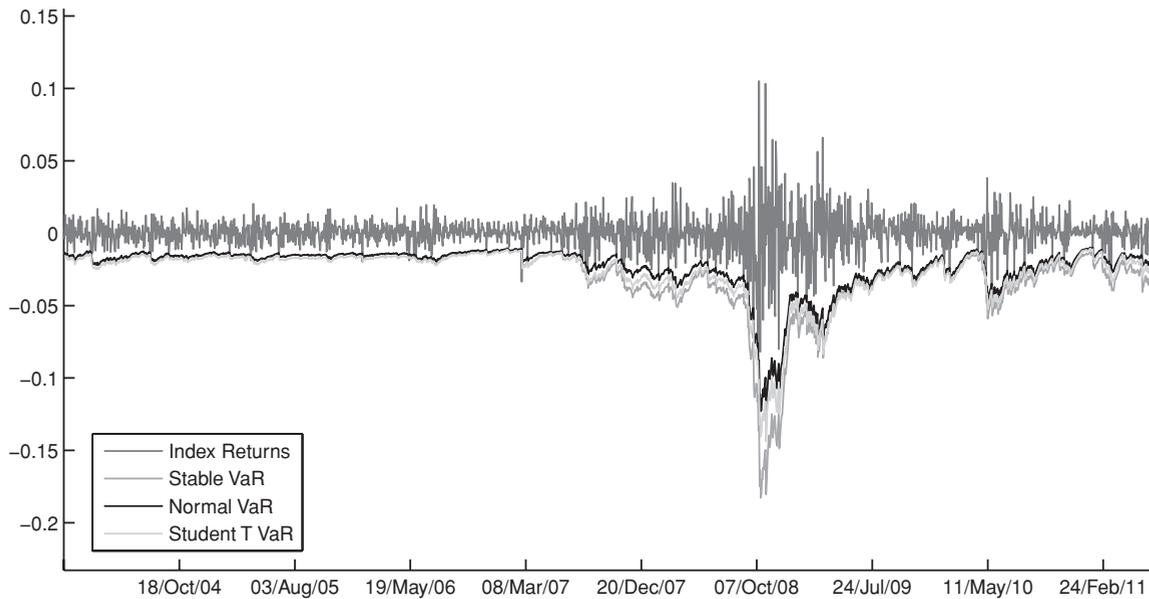

Figure 9 Backtest of the 99% Daily VaR Predicted by Different Distributional Methodologies

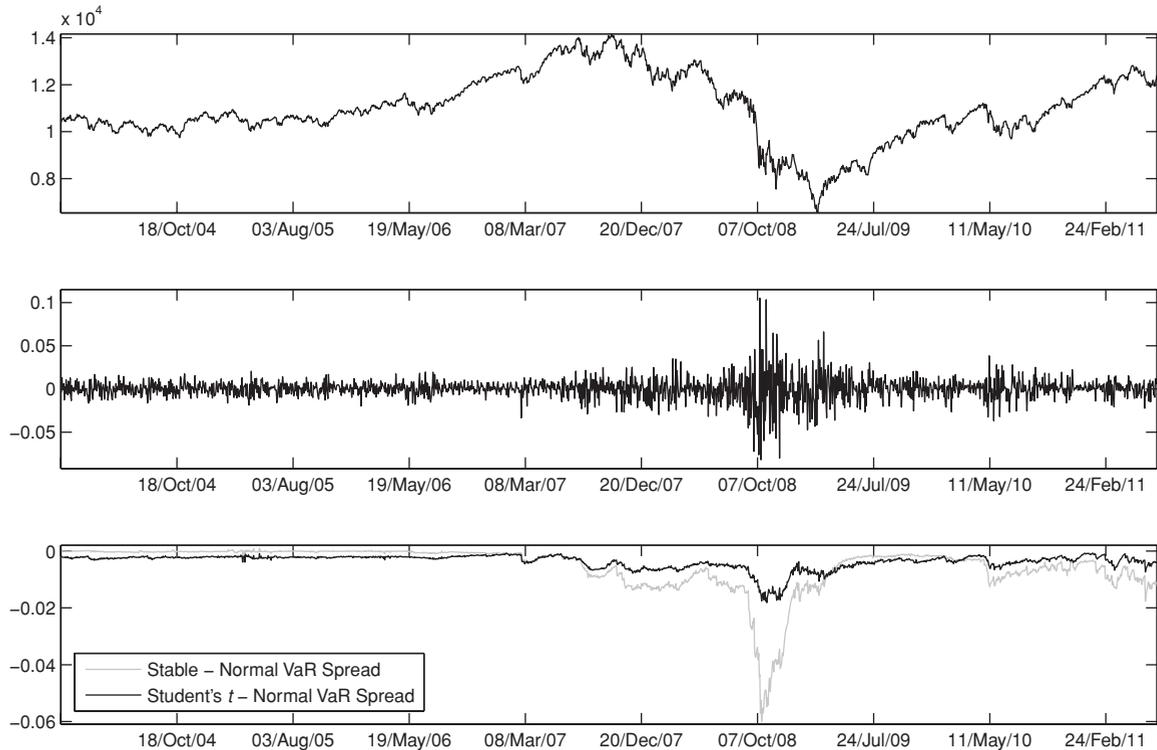

Figure 10 Spreads between 99% VaR Predictions for Student's t Gaussian and Stable-Gaussian Model Pairs: Full Period

late 2006. This is the result of the increased tail-fatness estimated by the stable model (α decreases). At the same time, the Student's t -Gaussian relative spread is fairly constant due to the fact that the DOF (and, therefore, the tail-fatness) is fixed.³⁴ Over the two-year period, we can see a pronounced increase in the stable-Gaussian VaR relative spread. There are two time segments (in spring 2007 and spring 2008) in which the spread actually decreases. Both are associated with periods following major negative news and market tremors.³⁵ In these periods, the Gaussian model's VaR "catches up" post factum due to the increase in the estimates of the conditional GARCH volatility.

In general, one can interpret the upward trend of the stable-Gaussian VaR relative spread as an indicator of markets accumulating higher probability of extreme events before the actual market volatility goes up. This predictive behavior is only possible due to the time-varying

estimates of the tail-fatness (the α parameter in the stable model). Thus, in the fixed-DOF Student's t model, such a predictive trend cannot be observed. During the two-year period, the number of exceedances is eight for the stable model, ten for the Student's t model, and 16 for the Gaussian model, while the 95% confidence interval is $[0, 9]$.

Finally, to test the significance of the stable-Gaussian VaR relative spread, we build a confidence interval for it. We do that by altering the tail index α at each point in time during the backtesting period with plus and minus one standard deviation of α and then re-computing the stable VaR and the associated stable-Gaussian relative spread. The standard deviation of α is estimated using parametric bootstrap, based on 200 bootstrap samples of 500 random draws each generated from an α -stable model with the corresponding α .³⁶ Figure 12 shows the confidence bounds of the

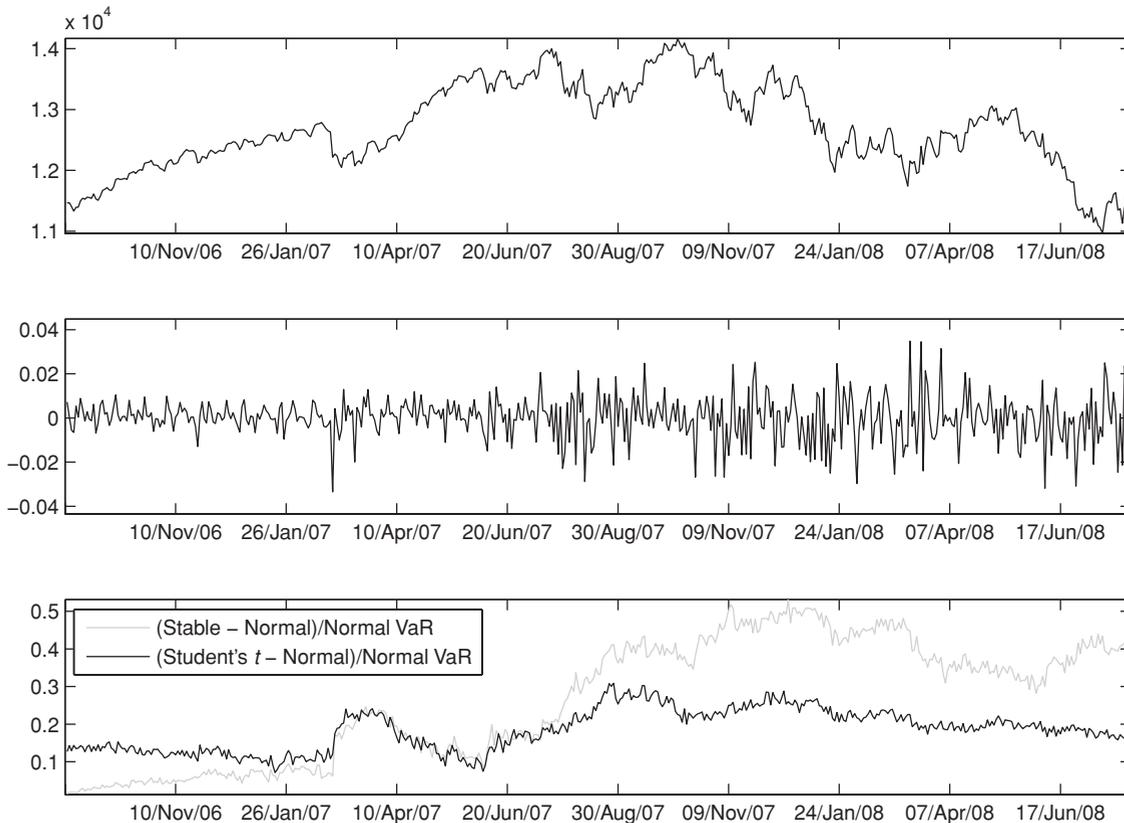

Figure 11 Relative Spreads between 99% VaR Predictions for Student's t Gaussian and Stable-Gaussian Model Pairs: September 1, 2006–September 1, 2008

stable-Gaussian VaR relative spread for the two-year period running up to September 2008, together with the Student's t -Gaussian VaR relative spread. Even the lower bound of the confidence interval of the stable-Gaussian VaR relative spread is more indicative than the Student's t -Gaussian relative spread over this time period. Although the upward trend of the lower confidence bound is not as strong as that of the upper confidence bound, the results support the conclusion that the stable model's VaR forecasts have the ability to anticipate a switch from a calm to a volatile market regime.

KEY POINTS

- The Gaussian distribution is not adequate to describe the empirical features of asset returns. The standardized residuals from a conditional Gaussian model exhibit heavy-tailedness and asymmetry.
- The Student's t distribution has fatter tails than the normal distribution. To account for skewness, however, the "classical" Student's t distribution needs to be modified.
- The skewed Student's t distribution can be represented as a mean-scale mixture of normal distributions; that is, normal distribution with random mean and variance.
- The tails of the stable Paretian distributions decay more slowly than the tails of the normal distribution and therefore better describe the extreme events present in the data.
- In the non-Gaussian case, a large sum of appropriately standardized IID random variables is distributed with the stable Paretian distribution in the limit.

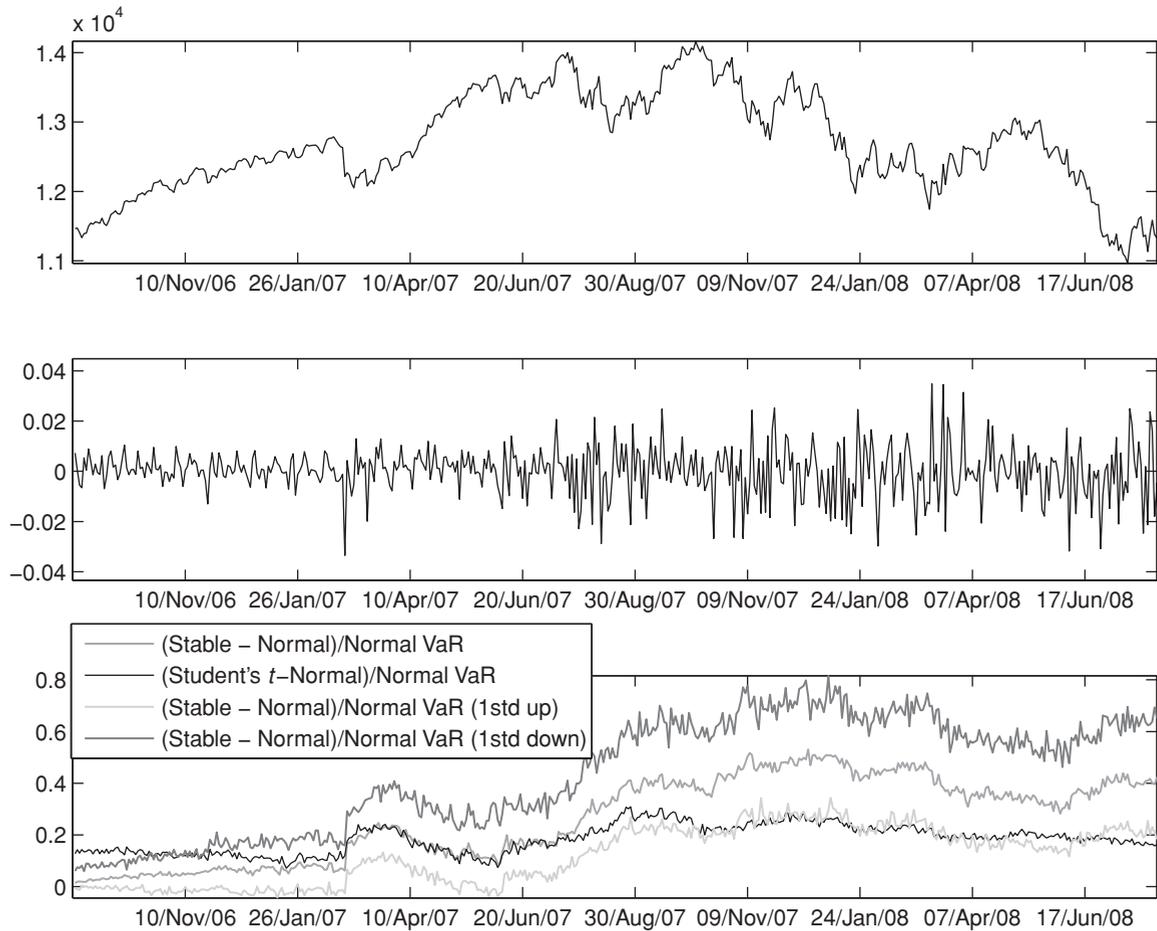

Figure 12 Relative Spreads between 99% VaR Predictions for Student's t Gaussian and Stable-Gaussian Model Pairs with Confidence Bounds: September 1, 2006–September 1, 2008

- To address the issue of infinite variance, the stable Paretian distribution may be modified by tempering of the distribution's tail. This gives rise to the tempered stable distributions.
- There are two main categories of distributions for extreme values—block maxima models and threshold exceedances models. The latter category is more often employed in risk modeling, since it is less “wasteful” of historical data than the former category.
- Selection of the threshold from where the tail of the data distribution starts is based on a subjective judgement and, together with data scarcity, is the main bottleneck in EVT applications.
- In all cases, before applying a fat-tailed model, an ARMA-GARCH filter should be

used to remove the temporal dependence in asset returns.

- A realistic distributional assumption for a model should allow for tail-fatness that changes over time and from asset to asset. Such models can serve as early warning indicators when moving to a new market regime (from calm to turbulent and vice versa) and can identify tail-risk contributors and tail-risk diversifiers.

NOTES

1. The Gaussian distribution's analytical tractability in the multivariate setting is an additional important factor behind its widespread use. See, for example, Kotz,

- Johnson, and Balakrishnan (2000) for details on the multivariate normal distribution.
2. However, later in this entry we provide an important clarification regarding a statistical result, called the central limit theorem.
 3. In general, the scale parameter does not always coincide with the standard deviation (volatility), as we will see, for instance, in our discussion of the scaled Student's t distribution later in the entry.
 4. See, for example, Rachev, Stoyanov, Biglova, and Fabozzi (2005).
 5. The conditional distribution of returns according to the model above is Gaussian. The unconditional distribution, however, is not normal but a mixture of normal distributions (due to the time-varying mean and variance). Its tails are fatter than those of the normal distribution but not fat enough to account for the empirically observed heavy tails.
 6. Note that this is not the same as "standardized," since the standard deviation of X is not one.
 7. Notice that the Student's t distribution defined in equation (8) has a location of zero and a scale of one.
 8. More precisely, we estimate a GARCH model on a 500-day rolling window of returns and then fit a t -distribution to the (standardized) GARCH residuals.
 9. Skewed Student's t models have been proposed by Fernandez and Steel (1998), Azzalini and Capitanio (2003), and Rachev and Rüschenendorf (1994), among others.
 10. The skewed Student's t distribution belongs to a more general class of distributions called generalized hyperbolic distributions and introduced by Barndorff-Nielsen (1978). It contains the Student's t and normal distributions as limiting cases.
 11. See Rachev and Mittnik (2000) and Samorodnitsky and Taqqu (1994). A detailed description of the stable methodology is available in Rachev, Martin, Racheva-Yotova, and Stoyanov (2009).
 12. For details on the statistical properties of subordinated processes, see Feller (1966) and Clark (1973). Rachev and Mittnik (2000) provide discussions of subordinated processes in financial applications.
 13. More generally, the family of infinitely divisible distributions to which the gamma, Poisson, inverse-Gaussian, and all stable Paretian distributions belong is a natural choice of distributions for the increments of the intrinsic time process $T(t)$.
 14. In a multivariate setting, Z would be distributed with a multivariate normal distribution and Y can be a vector whose components are stable subordinators with different tail-fatness. The resulting distribution is a generalization of the multivariate sub-Gaussian stable distribution.
 15. McCulloch (1986)'s estimation procedure generalized the quantile method for symmetric α -stable distributions of Fama and Roll (1971).
 16. See Press (1972). Kogon and Williams (1998) and Koutrouvelis (1980) suggested regression-type estimator algorithms, also based on the characteristic function.
 17. Comparison among the three types of estimation categories is provided in Stoyanov and Racheva-Yotova (2004).
 18. A detailed description of the stable fitting methodology is available in Rachev and Mittnik (2000).
 19. Rachev and Mittnik (2000) show that selecting $h = 0.01$ and $N = 2^{13}$ reduces the approximation error in computing the α -stable pdf to the satisfactory level of 10^{-6} .
 20. The algorithm for simulations from the CTS distribution is rather involved and described in detail in Rachev, Kim, Bianchi, and Fabozzi (2011).
 21. The role of EVT in modeling maxima of random variables is similar to the one the central limit theorem plays in modeling the sums of random variables. Both characterize the limiting distributions.

22. The tails of the Fréchet distribution decay like a power function at a rate $\alpha = 1/\xi$, the tail index parameter characterizing the α -stable distribution.
23. Comprehensive discussion of EVT is available in McNeil, Frey, and Embrechts (2005).
24. For more details on GPD, see Embrechts, Klüppelberg, and Mikosch (1997).
25. Notice that the threshold level u is in fact the location parameter in the GPD distribution.
26. The thresholds u_L and u_U are usually defined in terms of symmetric empirical quantiles, for example, the 5% and 95% quantiles. In that case, the number of observed data points in each tail is equal to K .
27. To be precise, when fitting the left tail, (35) is maximized over the absolute values of $Y_{k,L}$, $k = 1, \dots, K$.
28. See, for example, Silverman (1986).
29. $m(u)$ is also known as mean residual life function in survival analysis and characterizes the expected residual lifetime of a component that has function for u units of time already.
30. The i th order statistic is the i th largest observation in a data sample. The first order statistic is the maximum of the sample, while the n th order statistic is the minimum of a sample of size n .
31. See Rachev, Racheva-Yotova, and Stoyanov (2010) for a detailed discussion of these challenges.
32. Value-at-risk is defined as the minimum loss at a given confidence level for a pre-defined time horizon.
33. Goldberg, Miller, and Weinstein (2008) use time windows ranging from approximately 1,500 to 7,600 days.
34. The small variations are due to the variability in the estimates of the Student's t GARCH model.
35. In February 2007, Freddie Mac announced that it would no longer buy the most risky subprime mortgages and mortgage-related securities and in April 2007, New Century Financial Corporation, a leading subprime mortgage lender, filed for Chapter 11 bankruptcy protection. Then, in the spring of 2008, we observed the collapse of Bear Stearns and the associated events.
36. The bootstrap sample size is 500, since this is the length of the time window used to calibrate the model.

 example, input variables for, *II:379t*
 example, out-of-sample performance, *II:381t*
 fundamentals of, *II:376–377*
 in stock selection, *II:378–381*
 strengths and weaknesses of,
II:377–378
 uses of, *II:381*
- Cash-and-carry trade, *I:480, I:481, I:487*
- Cash concept, *II:567*
- Cash flows
 accounting for, *III:306*
 analysis of, *II:574–577, III:4–5*
 for bond class, *III:9t*
 of bonds, *I:211*
 cash flow at risk (CFaR), *III:376–378*
 classification of, *II:567*
 defined, *I:209–210, II:539, III:4*
 direct *vs.* indirect reporting method,
II:567
 discounted, *I:225*
 discrete, *I:429*
 distribution analysis *vs.* benchmark,
III:310
 estimation of, *I:209–210, II:21–23*
 expected, *I:211*
 factors in, *III:31–32, III:377*
 form residential mortgage loans,
III:62
 futures *vs.* forwards, *I:431t*
 future value of, *II:603f*
 influences on, *III:44*
 interest coverage ratio of, *II:561, II:575*
 interim, *I:482*
 for loan pool, *III:9t*
 measurement of, *II:565–566, III:14*
 monthly, *III:52–54, III:53t*
 net free (NFCF), *II:572–574, II:578*
 in OAS analysis, *I:259*
 perpetual stream of, *II:607–608*
 sources of, *II:540–541, II:569t*
 in state dependent models,
I:351–352
 statement of, *II:539–541, II:566–567*
 time patterns of, *II:607–611*
 and time value of money, *II:595–596*
 time value of series of, *II:602–607*
 for total return receivers, *I:542*
 for Treasuries, *I:219, III:564–565*
 types of in assessing liquidity risk,
III:378
 use of information on, *II:576–577*
 valuation of, *II:618–619*
vs. free cash flow, *II:22–23*
- Cash flow statements
 example of, *II:541*
 form of, *II:26t*
 information from, *II:577–578*
 reformatting of, *II:569t*
 restructuring of, *II:568*
 sample, *II:547t*
 use of, *II:24–26*
- Cash flow-to-debt ratio, *II:576*
- Cash-out refinancing, *III:66, III:69*
- Cash payments, *I:486–487, III:377*

 Reynolds-Syer study, III:117–118
 Rosenberg-Schuermann study, III:118
- Operational losses
 and bank size, III:83
 definitions of types, III:84*t*
 direct *vs.* indirect, III:84–85
 expected *vs.* unexpected, III:85
 histogram of, III:104*f*
 histogram of severity distribution, III:95*f*
 historical data on, III:96
 near-miss, III:84–85
 process of arriving at data, III:96–97
 process of occurrence, III:86*f*
 recording of, III:97
 severity of, III:104*f*
 time lags in, III:96–97
 types of, III:81, III:88
- Operational loss models
 approaches to, III:103–104
 assumptions in, III:104
 nonparametric approach, III:103–104, III:104–105, III:118
 parametric approach, III:104, III:105–110, III:118
 types of, III:118
- Operational risk
 classifications of, III:83–88, III:87–88, III:87*f*, III:88
 defined, III:81–83, III:88
 event types with descriptions, III:86*t*
 indicators of, III:83
 models of, III:91–96
 nature of, III:99
 and reputational risk, III:88
 sources of, III:82
- Operational risk/event/loss types, distinctions between, III:85–87
- Operational risk models
 actuarial (statistical) models, III:95
 bottom-up, III:92*f*, III:94–96, III:99
 causal, III:94
 expense-based, III:93
 income-based, III:93
 multifactor causal models, III:95
 operating leverage, III:93
 process-based, III:94–95
 proprietary, III:96
 reliability, III:94–95
 top down, III:92–94, III:99
 types of, III:91–92
- Operations
 addition, II:625, II:626
 defined, II:628
 inverse and adjoint, II:626–627
 multiplication, II:625–626, II:626
 transpose, II:625, II:626
 vector, II:625–626
- Operators in sets, defined, III:154
- Ophelimity, concept of, II:469
- Opportunity cost, I:435, I:438, I:439, II:596, III:623
- Optimal exercise, I:515–516
- Optimization
 algorithms for, III:124
 complexity of, II:82
 constrained, I:28–34
 defined, III:434–435
 local *vs.* global, II:378
 in MATLAB, III:434–444
 unconstrained, I:22–28
- Optimization theory, I:21
- Optimization Toolbox, in MATLAB, III:435–436, III:436*f*
- Optimizers, using, II:115–116, II:483
- Option-adjusted spread (OAS)
 calculation of, I:253–255
 defined, I:254, III:11
 demonstrated, I:254*f*
 determination of, I:259
 implementation of, I:257
 and market value, I:258
 results from example, III:617*t*
 and risk factors, III:599

 10-year data, I:279–280
 yield of, I:284
 yields from, I:278
- TLF model, strengths of, III:388–389
- Total asset turnover ratio, II:558
- Total return reports, II:237^t
- Total return swaps, I:540–542, I:541–542
- Trace test statistic, II:392
- Tracking error
 actual *vs.* predicted, II:69
 alternate definitions of, II:67–68
 defined, II:115, II:119
 estimates of future, II:69
 as measure of consistency, II:99–100
 reduction of, II:262–263
 standard definition, II:67
 with TIPS, I:293
- Tracking error volatility (TEV). *See* TEV (tracking error volatility)
- Trade optimizers, role of, II:116–117
- Trades
 amount needed for market impact, III:624
 cash-and-carry, I:487
 crossing of, II:75
 importance of execution of, III:623, III:631
 measurement of size, III:628
 in portfolio construction, II:104, II:116–117
 round-trip time of, II:451
 size effects of, III:372, III:630
 speed of, II:105
 timing of, III:628–629
- Trading costs, II:118, III:627–628, III:631–632
- Trading gains, defined, I:122, I:123
- Trading horizons, extending, III:624
- Trading lists, II:289^t
- Trading strategies
 backtesting of, II:236–237
 categories of, II:195
 in continuous-state, continuous-time, I:122
 development of factor-based, II:197–198, II:211
 factor-based, II:195, II:232–235
 factor weights in, II:233^f
 in multiperiod settings, I:105
 risk to, II:198–200
 self-financing, I:126–127, I:136
- Trading venues, electronic, II:57
- Training windows, moving, II:713–714
- Tranches, III:38, III:39^t, III:45
- Transaction costs
 in backtesting, II:235
 in benchmarking, II:67
 components of, II:119
 consideration of, II:64, II:85–86n
 dimensions of, III:631
 effect of, I:483
 figuring, II:85n
 fixed, II:72–73
 forecasting of, II:113–114
 incorporation of, II:69–73, II:84
 international, III:629
 linear, II:70
 and liquidity, III:624–625
 managing, III:146
 measurement of, III:626
 piecewise-linear, II:70–72, II:71^f

- quadratic, *II:72*
in risk modeling, *II:693*
types of, *III:623*
- Transformations, nonlinear,
III:630–631
- Transition probabilities, *I:368, I:381t*
- Treasuries
correlations of, *III:405t*
covariance matrix of, *III:406t*
curve risk, *II:277t*
discount function for, *III:564–565*
futures, *I:482*
inflation-indexed, *I:286*
movements of, *III:403f*
on-the-run, *I:227, III:7, III:560*
par yield curve, *I:218t*
spot rates, *I:220*
3-month, *II:415–416, II:416f*
volatility of, *III:404–406, III:406t*
- Treasury bill rates, weekly data, *I:89f*
- Treasury inflation-protected securities (TIPS). *See* TIPS (Treasury inflation-protected securities)
- Treasury Regulation T (Reg T), *I:67*
- Treasury securities, *I:210–211*
comparable, defined, *III:5*
in futures contracts, *I:483*
hypothetical, illustration of duration/convexity, *III:308–310, III:308t*
maturities of, *I:226*
options on, *I:490*
par rates for, *I:217*
prediction of 10-year yield, *II:322–328*
valuation of, *I:216*
yield of, *II:324–327t*
- Treasury strips, *I:218t, I:220–221, I:286, III:560*
- Treasury yield curves, *I:226, III:561*
- Trees/lattices
adjusted to current market price, *I:496f*
bushy trees, *I:265, I:266f*
calibrated, *I:495*
convertible bond value, *I:274–275*
extended pricing tree, *III:23f*
from historical data, *III:131f*
pruning of, *II:377*
stock price, *I:274*
three-period scenario, *III:131f*
trinomial, *I:81, I:273, I:495–496*
use of in modeling, *I:494–496*
- Trees/lattices, binomial
building of, *I:273*
for convertible bonds, *I:275f*
discussion of, *I:80–81*
interest rate, *I:244*
model of, *I:273–275*
- stock price model, *III:173*
- term structure evolution, *I:495f*
use of, *I:114–115, I:114f*
- Trends
deterministic, *II:383*
in financial time series, *II:504*
and integrated series, *II:512–514*
stochastic, *II:383, II:384*
- Treynor-Black model, *I:203n*
- Trinomial stochastic models, *II:11–12*
- Truncated Lévy flight (TLF), *III:382, III:384–386*
IDD in, *III:386*
time scaling of, *III:385f*
- Truncation, *III:385–386*
- Truth in Savings Act, *II:615*
- T*-statistic, *II:240n, II:336, II:350, II:390*
- Tuple, defined, *III:157*
- Turnover
assessment of, *III:68*
defined, *III:66*
in MBSs, *III:48*
in portfolios, *II:234, II:235*
- Two beta trap, *I:74–77*
- Two-factor models, *III:553–554*
- Two-stage growth model, *II:9*
- U.K. index-linked gilts, tax treatment of, *I:287*
- Uncertainties
and Bayesian statistics, *I:140*
in measurement processes, *II:367*
modeling of, *II:306, III:124, III:131–132*
and model risk, *II:729*
quantification of, *I:101*
representation of, *III:128*
time behavior of, *II:359*
- Uncertainty sets
effect of size of, *III:143*
in portfolio allocation, *II:80*
selection of, *III:140–141*
structured, *III:143–144*
in three dimensions, *II:81f*
use of, *III:138, III:140*
- Uncertain volatility model, *II:673–674*
- Underperformance, finding reasons for, *II:118*
- Underwater, on homeowner's equity, *III:73*
- Unemployment rate
as an economic measure, *II:398*
application of TAR models to, *II:405–406*
characteristics of series, *II:430*
forecasts from, *II:433*
performance of forecasting, *II:432–433, II:432t*
and risk, *II:292n*
- test of nonlinearity, *II:431, II:431t*
- time plot of, *II:406f, II:430f*
- Uniqueness, theorem of, *III:490*
- Unit root series, *II:385*
- Univariate linear regression model, *I:163–170*
- Univariate stationary series, *II:504*
- U.S. Bankruptcy Code. *See also* bankruptcy
Chapter 7, *I:350*
Chapter 11, *I:342, I:350*
Utility, *I:56, II:469, II:471, II:719–720*
- Validation, out of sample, *II:711*
- Valuation
arbitrage-free, *I:216–217, I:220–222, I:221t*
and cash flows, *I:223*
defined, *I:209*
effect of business cycle on, *I:303–304*
fundamental principle of, *I:209*
with Monte Carlo simulation, *III:6–12*
of natural gas/oil storage, *I:560–561*
of non-Treasury securities, *I:222–223*
relative, *I:225, II:34–40, II:44–45*
risk-neutral, *I:557, III:595–596, III:601*
total firm, *II:21–23*
uncertainty in, *II:15*
use of lattices for, *I:240*
- Value
absolute *vs.* relative basis of, *I:259–260*
analysis of relative, *I:225*
arbitrage-free, *I:221*
book *vs.* market of firms, *II:559–560*
determining present, *II:600–601*
formulas for analysis of, *II:238–239*
identification of relative, *I:405*
intrinsic, *I:484–485*
present, discounted, *II:601f*
relative, *I:405, II:37–38*
vs. price, *I:455n*
- Value at risk (VaR). *See also* CVaR (credit value at risk)

deficiencies in, *I:407, III:321, III:331–332, III:347*
defined, *II:754n, III:319–322*
density and distribution functions, *III:320f*

- Value at risk (VaR) (*Continued*)
determining from simulation, III:639f
distribution-free confidence intervals for, III:292–293
estimation of, II:366, III:289–290, III:373–376, III:644, III:644t
exceedances of, III:325–326
IDD in, III:290
interest rate covariance matrix in, III:403
levels of confidence with, III:290–291
liquidity-adjusted, III:374, III:376
in low market volatility, II:748
measurements by, II:354
methods of computation, III:323
modeling of, II:130–131, III:375–376
and model risk, II:695
normal against confidence level, III:294f
portfolio problem, I:193
in practice, III:321–325
relative spreads between predictions, II:750f, II:751f, II:752f
as safety-first risk measure, III:355
standard normal distribution of, III:324t
use of, II:365
vs. deviation measures, III:320–321
- Value of operations, process for finding, II:30t
- Values, lagged, II:130
- Van der Korput sequences, III:650
- Variables
antithetic, III:647–648
application of macro, II:193n
behavior of, III:152–153
categorical, II:333–334, II:350
classification, II:176
declaration of in VBL, III:457–458
dependence between, II:306–307
dependent categorical, II:348–350
dependent/independent in CAPM, I:67
dichotomous, II:350
dummy, II:334
exogenous *vs.* endogenous, II:692
fat-tailed, III:280
independent and identically distributed, II:125
independent categorical, II:333–348
interactions between, II:378
large numbers of, II:147
macroeconomic, II:54–55, II:177
in maximum likelihood calculations, II:312–313
mixing of categorical and quantitative, II:334–335
nonstationary, II:388–393
as observation or measurement, II:306
random, I:159n
in regression analysis, II:330
separable, II:647
slope, III:553
split formation of, III:130f
spread, II:336
standardization of, II:205
stationary, II:385, II:386
stationary/nonstationary, II:384–386
stochastic, III:159–164
use of dummy, II:335, II:343–344
- Variables, random, II:297
 α -stable, III:242–244, III:244–245
Bernoulli, III:169
continuous, III:200–201, III:205–206
on countable spaces, III:160–161, III:166
defined, III:162
discrete, III:165
infinitely divisible, III:253
in probability, III:159–164
sequences of, I:389
on uncountable spaces, III:161–162
use of, I:82
- Variance gamma process, III:499, III:504
- Variance matrix, II:370–371
- Variances
addressing inequality of, I:168
based on covariance matrix, II:161t, II:163t, II:164f
conditional, I:180
conditional/unconditional, II:361
in dispersion parameters, III:202–203
equal, I:164
as measure of risk, I:8
in probability, III:167–169
reduction in, III:647–651
unequal, I:167–168, I:172
- Variances/covariances, II:112–113, II:302–303, III:395–396
- Variance swaps, I:545–547, I:549, I:552
- Variational formulation, and finite element space, II:670–672
- Variation margins, I:478
- Vasicek model
with change of time, III:523–524
for coupon-bond call options, I:501–502
distribution of, I:493
in history, I:491
for short rates, III:545–546
use of, I:89, I:497
valuing zero-coupon bond calls with, I:499–500
- VBA (Visual Basic for Applications)
built-in numeric functions of, III:456
comments in, III:453
control flow statements, III:458–460
debugging in, III:461
debugging tools of, III:461, III:477
example programs, III:449–452, III:461–466
in Excel, III:449, III:450f
FactorialFun1, III:455–456
functions, user-defined, III:463f
functions in, III:477
generating Brownian motion paths in, III:463–465
If statements, III:459
For loops, III:458–459
methods (actions) in, III:452–453
modules, defined, III:455
as object-oriented language, III:452, III:466
objects in, III:452
operators in, III:459–460
Option Explicit command, III:458
pricing European call options, III:465–466
programing of input dialog boxes, III:460–461
programming tips for, III:454–461
properties in, III:453
random numbers in, III:464–465
subroutines and user-defined functions in, III:466–477
subroutines *vs.* user-defined functions in, III:455–457
use of Option Explicit command, III:458
user-defined functions, III:463f
user interaction with, III:460–461
variable declaration in, III:457–458
With/End structure in, III:453–454
writing code in, III:453–454
- Vech notation, II:371–372
- VEC model, II:372
- Vector autoregressive (VAR) model, II:393
- Vectors, II:621–622, II:625–626, II:628
- Vega, I:521
- Vichara Technology, III:41–42, III:43t
- Visual Basic for Applications (VBA). *See* VBA
- Volatilities
absolute *vs.* relative, III:404–405
actual, I:514
aim of models of, I:176
analysis of, II:270–272
and ARCH models, II:409

- assumptions about, *III:7*
 calculation of, *II:272, III:534t*
 calculation of daily, *III:533–534*
 calibration of local, *II:681–685*
 clustering of, *II:359, II:716, III:402*
 confidence intervals for, *III:399–400*
 constant, *III:653*
 decisions for measuring, *III:403–404*
 defined, *III:533, III:653*
 with different mean reversions,
III:538f
 of the diffusion, *I:125*
 effect of local, *III:609*
 effect on hedging, *I:517–518*
 of energy commodities, *I:556–557*
 estimation of, *II:368–369*
 in EWMA estimates, *III:410–411*
 exposure to, *II:252f, II:252t*
 forecasts of, *I:179–180, II:172,*
II:367–368
 in FTSE 100, *III:412–413*
 historical, *I:513, III:534, III:654*
 hypothetical modelers of, *III:408*
 implied, *I:513–514, II:282, II:662,*
III:654
 in interest rate structure models,
I:492
 jump-diffusion, *III:657*
 level-dependent, *III:654–655,*
III:656
 local, *II:681, II:682–683, III:655*
 as a measure, *I:545, II:373*
 measurement of, *I:393, III:403–406*
 minimization of, *II:179*
 in models, *II:302*
 models of, *II:428*
 in option pricing, *I:513–514*
 patterns in, *I:395*
 in random walks, *I:84*
 and risk, *II:270*
 in risk-neutral measures, *III:587*
 smile of, *III:557*
 and the smoothing constant,
III:409–410
 states of, *I:180–181*
 stochastic, *I:94, I:547, I:548,*
III:655–658, III:656, III:658
 stochastic models, *II:681*
 time increments of, *I:83*
 of time series, *I:80*
 time-varying, *II:733–734*
 types of, *III:658*
 vs. annual standard deviation,
III:534
 Volatility clustering, *III:242, III:388*
 Volatility curves, *III:534–535,*
III:535t
- Volatility measures, nonstochastic,
III:654–655
 Volatility multiples, use of,
III:536
 Volatility risk, *I:509*
 Volatility skew, *III:550, III:551f,*
III:555–556, III:654
 measuring, *III:550*
 Volatility smile, *II:681, III:555–557,*
III:556f, III:654, III:656
 Volatility swaps, *I:545–547, I:552*
 for S&P Canada index (example),
I:550–552
 valuing of, *I:549*
 Volume-weighted average price
 (VWAP), *II:117, III:626–627*
 VPRs (voluntary prepayment rates)
 calculation of, *III:76*
 in cash flow calculators, *III:34*
 defined, *III:30*
 impacts of, *III:38*
- W. T. Grant, cash flows of, *II:576*
 Waldrop, Mitchell, *II:699*
 Wal-Mart, *II:569, II:570f*
 Walras, Leon, *II:467, II:468–469,*

About the Editor

Frank J. Fabozzi is Professor of Finance at EDHEC Business School and a member of the EDHEC Risk Institute. Prior to joining EDHEC in August 2011, he held various professorial positions in finance at Yale University's School of Management from 1994 to 2011 and from 1986 to 1992 was a visiting professor of finance and accounting at MIT's Sloan School of Management. From 2008 to 2011, he was an affiliated professor in the Institute of Statistics, Econometrics, and Mathematical Finance at the University of Karlsruhe in Germany. Prior to 1986 he held professorial positions at Lafayette College, Fordham University, Queens College (CUNY), and Hofstra University. From 2003 to 2011, he served on Princeton University's Advisory Council for the Department of Operations Research and Financial Engineering and since then has been a visiting fellow in that department.

Professor Fabozzi is the editor of the *Journal of Portfolio Management*, as well as on the editorial board of the *Journal of Fixed Income*, *Journal of Asset Management*, *Quantitative Finance*, *Review of Futures Markets*, *Journal of Mathematical Finance*, *Journal of Structured Finance*, *Annals of Financial Economics*, and *Theoretical Economic Letters*.

He has authored and edited a number of books in asset management and quantitative finance. His coauthored books in quantitative finance include *A Probability Metrics Approach to Financial Risk Measures* (2011), *Financial Modeling with Lévy Processes and Volatility Clustering* (2011), *Quantitative Equity Investing: Techniques and Strategies* (2010), *Probability and Statistics for Finance* (2010), *Simulation and Optimization Modeling in Finance* (2010), *Bayesian Methods in Finance* (2008), *Advanced Stochastic Models, Risk Assessment, and Portfolio Optimization: The Ideal Risk* (2008), *Financial Econometrics: From Basics to Advanced Modeling Techniques* (2007), *Robust Portfolio Optimization and Management* (2007), and *Mathematics of Financial Modeling and Investment Management* (2004). His books in applied mathematics include *The Methods of Distances in the Theory of Probability and Statistics* (2013) and *Robust and Non-Robust Models in Statistics* (2009). He coauthored three monographs for the Research Foundation of the CFA Institute: *The Impact of the Financial Crisis on the Asset Management Industry* (2010), *Challenges in Quantitative Equity Management* (2008), and *Trends in Quantitative Finance* (2006).

Professor Fabozzi's research papers have appeared in numerous journals, including *Journal of Finance*, *Journal of Finance and Quantitative Analysis*, *Econometric Theory*, *Operations Research*, *Journal of Banking and Finance*, *Journal of Economic Dynamics and Control*, *Studies in Nonlinear Dynamics and Econometrics*, *European Journal of Operational Research*, *Annals of Operations Research*, *Quantitative Finance*, *European Financial Management*, and *The Econometric Journal*. His 2010 article published in *European Financial Management* with Professors Robert Shiller, and Radu Tunaru, "Property Derivatives for Managing European Real-Estate Risk," received the Best Paper Award and his paper with the same coauthors entitled "A Pricing Framework for Real Estate Derivatives" was awarded

Best Research Paper at the 10th Research Conference Campus for Finance held annually at WHU Otto Beisheim School of Management, Vallendar, Germany. An article coauthored with Dr. Sergio Focardi, "An Autoregressive Conditional Duration Model of Credit Risk Contagion," published in 2005 in *Journal of Risk Finance* was the winner of the 2006 Outstanding Paper by Emerald Literati Network.

He has received several awards and honors for his body of work. In 1994 he was awarded an Honorary Doctorate of Humane Letters from Nova Southeastern University. In 2002 he was inducted into the Fixed Income Analysts Society's Hall of Fame, established by the society "to recognize the lifetime achievements of outstanding practitioners in the advancement of the analysis of fixed-income securities and portfolios." In 2007 he was the recipient of the C. Stewart Sheppard Award given by the CFA Institute "in recognition of outstanding contribution to continuing education in the CFA profession." He was the cover story in the July 1999 issue of *Bloomberg Magazine* entitled "The Boswell of Bonds."

Professor Fabozzi was the co-founder of Information Management Network (now a subsidiary of Euromoney), a conference company specializing in financial topics. He is a trustee for the BlackRock family of closed-end funds where he is the chair of the performance committee and a member of the audit committee. He was a director of Guardian Mutual Funds and Guardian Annuity Funds.

He earned both an M.A. and B.A. in economics and statistics in June 1970 from the City College of New York and elected to Phi Beta Kappa in 1969. He earned a Ph.D. in Economics in September 1972 from the City University of New York. Professor Fabozzi holds two professional designations: Chartered Financial Analyst (1977) and Certified Public Accountant (1982).

Preface

It is often said that investment management is an art, not a science. However, since the early 1990s the market has witnessed a progressive shift toward a more industrial view of the investment management process. There are several reasons for this change. First, with globalization the universe of investable assets has grown many times over. Asset managers might have to choose from among several thousand possible investments from around the globe. Second, institutional investors, often together with their consultants, have encouraged asset management firms to adopt an increasingly structured process with documented steps and measurable results. Pressure from regulators and the media is another factor. Finally, the sheer size of the markets makes it imperative to adopt safe and repeatable methodologies.

In its modern sense, financial modeling is the design (or engineering) of financial instruments and portfolios of financial instruments that result in predetermined cash flows contingent upon different events. Broadly speaking, financial models are employed to manage investment portfolios and risk. The objective is the transfer of risk from one entity to another via appropriate financial arrangements. Though the aggregate risk is a quantity that cannot be altered, risk can be transferred if there is a willing counterparty.

Financial modeling came to the forefront of finance in the 1980s, with the broad diffusion

of derivative instruments. However, the concept and practice of financial modeling are quite old. The notion of the diversification of risk (central to modern risk management) and the quantification of insurance risk (a requisite for pricing insurance policies) were already understood, at least in practical terms, in the 14th century. The rich epistolary of Francesco Datini, a 14th-century merchant, banker, and insurer from Prato (Tuscany, Italy), contains detailed instructions to his agents on how to diversify risk and insure cargo.

What is specific to modern financial modeling is the quantitative management of risk. Both the pricing of contracts and the optimization of investments require some basic capabilities of statistical modeling of financial contingencies. It is the size, diversity, and efficiency of modern competitive markets that makes the use of financial modeling imperative.

This three-volume encyclopedia offers not only coverage of the fundamentals and advances in financial modeling but provides the mathematical and statistical techniques needed to develop and test financial models, as well as the practical issues associated with implementation. The encyclopedia offers the following unique features:

- The entries for the encyclopedia were written by experts from around the world. This diverse collection of expertise has created the most definitive coverage of established and

cutting-edge financial models, applications, and tools in this ever-evolving field.

- The series emphasizes both technical and managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding of the topics and the necessary background to deal with issues related to financial modeling.
- Each entry follows a format that includes the author, entry abstract, introduction, body, listing of key points, notes, and references. This enables readers to pick and choose among various sections of an entry, and creates consistency throughout the entire encyclopedia.
- The numerous illustrations and tables throughout the work highlight complex topics and assist further understanding.
- Each volume includes a complete table of contents and index for easy access to various parts of the encyclopedia.

TOPIC CATEGORIES

As is the practice in the creation of an encyclopedia, the topic categories are presented alphabetically. The topic categories and a brief description of each topic follow.

VOLUME I

Asset Allocation

A major activity in the investment management process is establishing policy guidelines to satisfy the investment objectives. Setting policy begins with the asset allocation decision. That is, a decision must be made as to how the funds to be invested should be distributed among the major asset classes (e.g., equities, fixed income, and alternative asset classes). The term “asset allocation” includes (1) policy asset allocation, (2) dynamic asset allocation, and (3) tactical asset allocation. Policy asset allocation decisions can loosely be characterized as long-term asset allocation decisions, in which the investor seeks to assess an appropriate long-term “normal” asset mix that represents an ideal blend of controlled risk and enhanced return. In dynamic asset allocation the asset mix (i.e., the

allocation among the asset classes) is mechanically shifted in response to changing market conditions. Once the policy asset allocation has been established, the investor can turn his or her attention to the possibility of active departures from the normal asset mix established by policy. If a decision to deviate from this mix is based upon rigorous objective measures of value, it is often called tactical asset allocation. The fundamental model used in establishing the policy asset allocation is the mean-variance portfolio model formulated by Harry Markowitz in 1952, popularly referred to as the theory of portfolio selection and modern portfolio theory.

Asset Pricing Models

Asset pricing models seek to formalize the relationship that should exist between asset returns and risk if investors behave in a hypothesized manner. At its most basic level, asset pricing is mainly about transforming asset payoffs into prices. The two most well-known asset pricing models are the arbitrage pricing theory and the capital asset pricing model. The fundamental theorem of asset pricing asserts the equivalence of three key issues in finance: (1) absence of arbitrage; (2) existence of a positive linear pricing rule; and (3) existence of an investor who prefers more to less and who has maximized his or her utility. There are two types of arbitrage opportunities. The first is paying nothing today and obtaining something in the future, and the second is obtaining something today and with no future obligations. Although the principle of absence of arbitrage is fundamental for understanding asset valuation in a competitive market, there are well-known limits to arbitrage resulting from restrictions imposed on rational traders, and, as a result, pricing inefficiencies may exist for a period of time.

Bayesian Analysis and Financial Modeling Applications

Financial models describe in mathematical terms the relationships between financial random variables through time and/or across assets. The fundamental assumption is that the

model relationship is valid independent of the time period or the asset class under consideration. Financial data contain both meaningful information and random noise. An adequate financial model not only extracts optimally the relevant information from the historical data but also performs well when tested with new data. The uncertainty brought about by the presence of data noise makes imperative the use of statistical analysis as part of the process of financial model building, model evaluation, and model testing. Statistical analysis is employed from the vantage point of either of the two main statistical philosophical traditions—frequentist and Bayesian. An important difference between the two lies with the interpretation of the concept of probability. As the name suggests, advocates of the frequentist approach interpret the probability of an event as the limit of its long-run relative frequency (i.e., the frequency with which it occurs as the amount of data increases without bound). Since the time financial models became a mainstream tool to aid in understanding financial markets and formulating investment strategies, the framework applied in finance has been the frequentist approach. However, strict adherence to this interpretation is not always possible in practice. When studying rare events, for instance, large samples of data may not be available, and in such cases proponents of frequentist statistics resort to theoretical results. The Bayesian view of the world is based on the subjectivist interpretation of probability: Probability is subjective, a degree of belief that is updated as information or data are acquired. Only in the last two decades has Bayesian statistics started to gain greater acceptance in financial modeling, despite its introduction about 250 years ago. It has been the advancements of computing power and the development of new computational methods that have fostered the growing use of Bayesian statistics in financial modeling.

Bond Valuation

The value of any financial asset is the present value of its expected future cash flows. To value

a bond (also referred to as a fixed-income security), one must be able to estimate the bond's remaining cash flows and identify the appropriate discount rate(s) at which to discount the cash flows. The traditional approach to bond valuation is to discount every cash flow with the same discount rate. Simply put, the relevant term structure of interest rate used in valuation is assumed to be flat. This approach, however, permits opportunities for arbitrage. Alternatively, the arbitrage-free valuation approach starts with the premise that a bond should be viewed as a portfolio or package of zero-coupon bonds. Moreover, each of the bond's cash flows is valued using a unique discount rate that depends on the term structure of interest rates and when in time the cash flow is. The relevant set of discount rates (that is, spot rates) is derived from an appropriate term structure of interest rates and when used to value risky bonds augmented with a suitable risk spread or premium. Rather than modeling to calculate the fair value of its price, the market price can be taken as given so as to compute a yield measure or a spread measure. Popular yield measures are the yield to maturity, yield to call, yield to put, and cash flow yield. Nominal spread, static (or zero-volatility) spread, and option-adjusted spread are popular relative value measures quoted in the bond market. Complications in bond valuation arise when a bond has one or more embedded options such as call, put, or conversion features. For bonds with embedded options, the financial modeling draws from options theory, more specifically, the use of the lattice model to value a bond with embedded options.

Credit Risk Modeling

Credit risk is a broad term used to refer to three types of risk: default risk, credit spread risk, and downgrade risk. Default risk is the risk that the counterparty to a transaction will fail to satisfy the terms of the obligation with respect to the timely payment of interest and repayment of the amount borrowed. The counterparty could be the issuer of a debt obligation or an entity on

the other side of a private transaction such as a derivative trade or a collateralized loan agreement (i.e., a repurchase agreement or a securities lending agreement). The default risk of a counterparty is often initially gauged by the credit rating assigned by one of the three rating companies—Standard & Poor’s, Moody’s Investors Service, and Fitch Ratings. Although default risk is the one that most market participants think of when reference is made to credit risk, even in the absence of default, investors are concerned about the decline in the market value of their portfolio bond holdings due to a change in credit spread or the price performance of their holdings relative to a bond index. This risk is due to an adverse change in credit spreads, referred to as credit spread risk, or when it is attributed solely to the downgrade of the credit rating of an entity, it is called downgrade risk. Financial modeling of credit risk is used (1) to measure, monitor, and control a portfolio’s credit risk, and (2) to price credit risky debt instruments. There are two general categories of credit risk models: structural models and reduced-form models. There is considerable debate as to which type of model is the best to employ.

Derivatives Valuation

A derivative instrument is a contract whose value depends on some underlying asset. The term “derivative” is used to describe this product because its value is derived from the value of the underlying asset. The underlying asset, simply referred to as the “underlying,” can be either a commodity, a financial instrument, or some reference entity such as an interest rate or stock index, leading to the classification of commodity derivatives and financial derivatives. Although there are close conceptual relations between derivative instruments and cash market instruments such as debt and equity, the two classes of instruments are used differently: Debt and equity are used primarily for raising funds from investors, while derivatives are primarily

used for dividing up and trading risks. Moreover, debt and equity are direct claims against a firm’s assets, while derivative instruments are usually claims on a third party. A derivative’s value depends on the value of the underlying, but the derivative instrument itself represents a claim on the “counterparty” to the trade. Derivatives instruments are classified in terms of their payoff characteristics: linear and nonlinear payoffs. The former, also referred to as symmetric payoff derivatives, includes forward, futures, and swap contracts while the latter include options. Basically, a linear payoff derivative is a risk-sharing arrangement between the counterparties since both are sharing the risk regarding the price of the underlying. In contrast, nonlinear payoff derivative instruments (also referred to as asymmetric payoff derivatives) are insurance arrangements because one party to the trade is willing to insure the counterparty of a minimum or maximum (depending on the contract) price. The amount received by the insuring party is referred to as the contract price or premium. Derivative instruments are used for controlling risk exposure with respect to the underlying. Hedging is a special case of risk control where a party seeks to eliminate the risk exposure. Derivative valuation or pricing is developed based on no-arbitrage price relations, relying on the assumption that two perfect substitutes must have the same price.

Difference Equations and Differential Equations

The tools of linear difference equations and differential equations have found many applications in finance. A difference equation is an equation that involves differences between successive values of a function of a discrete variable. A function of such a variable is one that provides a rule for assigning values in sequences to it. The theory of linear difference equations covers three areas: solving difference equations, describing the behavior

of difference equations, and identifying the equilibrium (or critical value) and stability of difference equations. Linear difference equations are important in the context of dynamic econometric models. Stochastic models in finance are expressed as linear difference equations with random disturbances added. Understanding the behavior of solutions of linear difference equations helps develop intuition for the behavior of these models. In nontechnical terms, differential equations are equations that express a relationship between a function and one or more derivatives (or differentials) of that function. The relationship between difference equations and differential equations is that the latter are invaluable for modeling situations in finance where there is a continually changing value. The problem is that not all changes in value occur continuously. If the change in value occurs incrementally rather than continuously, then differential equations have their limitations. Instead, a financial modeler can use difference equations, which are recursively defined sequences. It would be difficult to overemphasize the importance of differential equations in financial modeling where they are used to express laws that govern the evolution of price probability distributions, the solution of economic variational problems (such as intertemporal optimization), and conditions for continuous hedging (such as in the Black-Scholes option pricing model). The two broad types of differential equations are ordinary differential equations and partial differential equations. The former are equations or systems of equations involving only one independent variable. Another way of saying this is that ordinary differential equations involve only total derivatives. Partial differential equations are differential equations or systems of equations involving partial derivatives. When one or more of the variables is a stochastic process, we have the case of stochastic differential equations and the solution is also a stochastic process. An assumption must be made about what is driving noise in a stochastic differential

equation. In most applications, it is assumed that the noise term follows a Gaussian random variable, although other types of random variables can be assumed.

Equity Models and Valuation

Traditional fundamental equity analysis involves the analysis of a company's operations for the purpose of assessing its economic prospects. The analysis begins with the financial statements of the company in order to investigate the earnings, cash flow, profitability, and debt burden. The fundamental analyst will look at the major product lines, the economic outlook for the products (including existing and potential competitors), and the industries in which the company operates. The result of this analysis will be the growth prospects of earnings. Based on the growth prospects of earnings, a fundamental analyst attempts to determine the fair value of the stock using one or more equity valuation models. The two most commonly used approaches for valuing a firm's equity are based on discounted cash flow and relative valuation models. The principal idea underlying discounted cash flow models is that what an investor pays for a share of stock should reflect what is expected to be received from it—return on the investor's investment. What an investor receives are cash dividends in the future. Therefore, the value of a share of stock should be equal to the present value of all the future cash flows an investor expects to receive from that share. To value stock, therefore, an investor must project future cash flows, which, in turn, means projecting future dividends. Popular discounted cash flow models include the basic dividend discount model, which assumes a constant dividend growth, and the multiple-phase models, which include the two-stage dividend growth model and the stochastic dividend discount models. Relative valuation methods use multiples or ratios—such as price/earnings, price/book, or price/free cash flow—to determine whether a stock is trading at higher or lower multiples than its peers.

There are two critical assumptions in using relative valuation: (1) the universe of firms selected to be included in the peer group are in fact comparable, and (2) the average multiple across the universe of firms can be treated as a reasonable approximation of “fair value” for those firms. This second assumption may be problematic during periods of market panic or euphoria. Managers of quantitative equity firms employ techniques that allow them to identify attractive stock candidates, focusing not on a single stock as is done with traditional fundamental analysis but rather on stock characteristics in order to explain why one stock outperforms another stock. They do so by statistically identifying a group of characteristics to create a quantitative selection model. In contrast to the traditional fundamental stock selection, quantitative equity managers create a repeatable process that utilizes the stock selection model to identify attractive stocks. Equity portfolio managers have used various statistical models for forecasting returns and risk. These models, referred to as predictive return models, make conditional forecasts of expected returns using the current information set. Predictive return models include regressive models, linear autoregressive models, dynamic factor models, and hidden-variable models.

Factor Models and Portfolio Construction

Quantitative asset managers typically employ multifactor risk models for the purpose of constructing and rebalancing portfolios and analyzing portfolio performance. A multifactor risk model, or simply factor model, attempts to estimate and characterize the risk of a portfolio, either relative to a benchmark such as a market index or in absolute value. The model allows the decomposition of risk factors into a systematic and an idiosyncratic component. The portfolio’s risk exposure to broad risk factors is captured by the systematic risk. For equity portfolios these are typically fundamental factors (e.g., market capitalization and value

vs. growth), technical (e.g., momentum), and industry/sector/country. For fixed-income portfolios, systematic risk captures a portfolio’s exposure to broad risk factors such as the term structure of interest rates, credit spreads, optionality (call and prepayment), credit, and sectors. The portfolio’s systematic risk depends not only on its exposure to these risk factors but also the volatility of the risk factors and how they correlate with each other. In contrast to systematic risk, idiosyncratic risk captures the uncertainty associated with news affecting the holdings of individual issuers in the portfolio. In equity portfolios, idiosyncratic risk can be easily diversified by reducing the importance of individual issuers in the portfolio. Because of the larger number of issuers in bond indexes, however, this is a difficult task. There are different types of factor models depending on the factors. Factors can be exogenous variables or abstract variables formed by portfolios. Exogenous factors (or known factors) can be identified from traditional fundamental analysis or from economic theory that suggests macroeconomic factors. Abstract factors, also called unidentified or latent factors, can be determined with the statistical tool of factor analysis or principal component analysis. The simplest type of factor models is where the factors are assumed to be known or observable, so that time-series data are those factors that can be used to estimate the model. The four most commonly used approaches for the evaluation of return premiums and risk characteristics to factors are portfolio sorts, factor models, factor portfolios, and information coefficients. Despite its use by quantitative asset managers, the basic building blocks of factor models used by model builders and by traditional fundamental analysts are the same: They both seek to identify the drivers of returns for the asset class being analyzed.

Financial Econometrics

Econometrics is the branch of economics that draws heavily on statistics for testing and

analyzing economic relationships. The economic equivalent of the laws of physics, econometrics represents the quantitative, mathematical laws of economics. Financial econometrics is the econometrics of financial markets. It is a quest for models that describe financial time series such as prices, returns, interest rates, financial ratios, defaults, and so on. Although there are similarities between financial econometric models and models of the physical sciences, there are two important differences. First, the physical sciences aim at finding immutable laws of nature; econometric models model the economy or financial markets—artifacts subject to change. Because the economy and financial markets are artifacts subject to change, econometric models are not unique representations valid throughout time; they must adapt to the changing environment. Second, while basic physical laws are expressed as differential equations, financial econometrics uses both continuous-time and discrete-time models.

Financial Modeling Principles

The origins of financial modeling can be traced back to the development of mathematical equilibrium at the end of the nineteenth century, followed in the beginning of the twentieth century with the introduction of sophisticated mathematical tools for dealing with the uncertainty of prices and returns. In the 1950s and 1960s, financial modelers had tools for dealing with probabilistic models for describing markets, the principles of contingent claims analysis, an optimization framework for portfolio selection based on mean and variance of asset returns, and an equilibrium model for pricing capital assets. The 1970s ushered in models for pricing contingent claims and a new model for pricing capital assets based on arbitrage pricing. Consequently, by the end of the 1970s, the frameworks for financial modeling were well known. It was the advancement of computing power and refinements of the theories to take into account real-world market imperfections and

conventions starting in the 1980s that facilitated implementation and broader acceptance of mathematical modeling of financial decisions. The diffusion of low-cost high-performance computers has allowed the broad use of numerical methods, the landscape of financial modeling. The importance of finding closed-form solutions and the consequent search for simple models has been dramatically reduced. Computationally intensive methods such as Monte Carlo simulations and the numerical solution of differential equations are now widely used. As a consequence, it has become feasible to represent prices and returns with relatively complex models. Nonnormal probability distributions have become commonplace in many sectors of financial modeling. It is fair to say that the key limitation of financial modeling is now the size of available data samples or training sets, not the computations; it is the data that limit the complexity of estimates. Mathematical modeling has also undergone major changes. Techniques such as equivalent martingale methods are being used in derivative pricing, and cointegration, the theory of fat-tailed processes, and state-space modeling (including ARCH/GARCH and stochastic volatility models) are being used in financial modeling.

Financial Statement Analysis

Much of the financial data that are used in constructing financial models for forecasting and valuation purposes draw from the financial statements that companies are required to provide to investors. The four basic financial statements are the balance sheet, the income statement, the statement of cash flows, and the statement of shareholders' equity. It is important to understand these data so that the information conveyed by them is interpreted properly in financial modeling. The financial statements are created using several assumptions that affect how to use and interpret the financial data. The analysis of financial statements involves the selection, evaluation, and

interpretation of financial data and other pertinent information to assist in evaluating the operating performance and financial condition of a company. The operating performance of a company is a measure of how well a company has used its resources—its assets, both tangible and intangible—to produce a return on its investment. The financial condition of a company is a measure of its ability to satisfy its obligations, such as the payment of interest on its debt in a timely manner. There are many tools available in the analysis of financial information. These tools include financial ratio analysis and cash flow analysis. Cash flows are essential ingredients in valuation. Therefore, understanding past and current cash flows may help in forecasting future cash flows and, hence, determine the value of the company. Moreover, understanding cash flow allows the assessment of the ability of a firm to maintain current dividends and its current capital expenditure policy without relying on external financing. Financial modelers must understand how to use these financial ratios and cash flow information in the most effective manner in building models.

Finite Mathematics and Basic Functions for Financial Modeling

The collection of mathematical tools that does not include calculus is often referred to as “finite mathematics.” This includes matrix algebra, probability theory, and statistical analysis. Ordinary algebra deals with operations such as addition and multiplication performed on individual numbers. In financial modeling, it is useful to consider operations performed on ordered arrays of numbers. Ordered arrays of numbers are called vectors and matrices while individual numbers are called scalars. Probability theory is the mathematical approach to formalize the uncertainty of events. Even though a decision maker may not know which one of the set of possible events may finally occur, with probability theory a decision maker has the means of providing each event with

a certain probability. Furthermore, it provides the decision maker with the axioms to compute the probability of a composed event in a unique way. The rather formal environment of probability theory translates in a reasonable manner to the problems related to risk and uncertainty in finance such as, for example, the future price of a financial asset. Today, investors may be aware of the price of a certain asset, but they cannot say for sure what value it might have tomorrow. To make a prudent decision, investors need to assess the possible scenarios for tomorrow’s price and assign to each scenario a probability of occurrence. Only then can investors reasonably determine whether the financial asset satisfies an investment objective included within a portfolio. Probability models are theoretical models of the occurrence of uncertain events. In contrast, statistics is about empirical data and can be broadly defined as a set of methods used to make inferences from a known sample to a larger population that is in general unknown. In finance, a particular important example is making inferences from the past (the known sample) to the future (the unknown population). There are important mathematical functions with which the financial modeler should be acquainted. These include the continuous function, the indicator function, the derivative of a function, the monotonic function, and the integral, as well as special functions such as the characteristic function of random variables and the factorial, the gamma, beta, and Bessel functions.

Liquidity and Trading Costs

In broad terms, liquidity refers to the ability to execute a trade or liquidate a position with little or no cost or inconvenience. Liquidity depends on the market where a financial instrument is traded, the type of position traded, and sometimes the size and trading strategy of an individual trade. Liquidity risks are those associated with the prospect of imperfect market liquidity and can relate to risk of loss or

risk to cash flows. There are two main aspects to liquidity risk measurement: the measurement of liquidity-adjusted measures of market risk and the measurement of liquidity risks per se. Market practitioners often assume that markets are liquid—that is, that they can liquidate or unwind positions at going market prices—usually taken to be the mean of bid and ask prices—without too much difficulty or cost. This assumption is very convenient and provides a justification for the practice of marking positions to market prices. However, it is often empirically questionable, and the failure to allow for liquidity can undermine the measurement of market risk. Because liquidity risk is a major risk factor in its own right, portfolio managers and traders will need to measure this risk in order to formulate effective portfolio and trading strategies. A considerable amount of work has been done in the equity market in estimating liquidity risk. Because transaction costs are incurred when buying or selling stocks, poorly executed trades can adversely impact portfolio returns and therefore relative performance. Transaction costs are classified as explicit costs such as brokerage and taxes, and implicit costs, which include market impact cost, price movement risk, and opportunity cost. Broadly speaking, market impact cost is the price that a trader has to pay for obtaining liquidity in the market and is a key component of trading costs that must be modeled so that effective trading programs for executing trades can be developed. Typical forecasting models for market impact costs are based on a statistical factor approach where the independent variables are trade-based factors or asset-based factors.

VOLUME III

Model Risk and Selection

Model risk is the risk of error in pricing or risk-forecasting models. In practice, model risk arises because (1) any model involves simpli-

fication and calibration, and both of these require subjective judgments that are prone to error, and/or (2) a model is used inappropriately. Although model risk cannot be avoided, there are many ways in which financial modelers can manage this risk. These include (1) recognizing model risk, (2) identifying, evaluating, and checking the model's key assumption, (3) selecting the simplest reasonable model, (4) resisting the temptation to ignore small discrepancies in results, (5) testing the model against known problems, (6) plotting results and employing nonparametric statistics, (7) back-testing and stress-testing the model, (8) estimating model risk quantitatively, and (9) reevaluating models periodically. In financial modeling, model selection requires a blend of theory, creativity, and machine learning. The machine-learning approach starts with a set of empirical data that the financial modeler wants to explain. Data are explained by a family of models that include an unbounded number of parameters and are able to fit data with arbitrary precision. There is a trade-off between model complexity and the size of the data sample. To implement this trade-off, ensuring that models have forecasting power, the fitting of sample data is constrained to avoid fitting noise. Constraints are embodied in criteria such as the Akaike information criterion or the Bayesian information criterion. Economic and financial data are generally scarce given the complexity of their patterns. This scarcity introduces uncertainty as regards statistical estimates obtained by the financial modeler. It means that the data might be compatible with many different models with the same level of statistical confidence. Methods of probabilistic decision theory can be used to deal with model risk due to uncertainty regarding the model's parameters. Probabilistic decision making starts from the Bayesian inference process and involves computer simulations in all realistic situations. Since a risk model is typically a combination of a probability distribution model and a risk measure, a critical assumption is the probability distribution assumed for

the random variable of interest. Too often, the Gaussian distribution is the model of choice. Empirical evidence supports the use of probability distributions that exhibit fat tails such as the Student's t distribution and its asymmetric version and the Pareto stable class of distributions and their tempered extensions. Extreme value theory offers another approach for risk modeling.

Mortgage-Backed Securities Analysis and Valuation

Mortgage-backed securities are fixed-income securities backed by a pool of mortgage loans. Residential mortgage-backed securities (RMBS) are backed by a pool of residential mortgage loans (one-to-four family dwellings). The RMBS market includes agency RMBS and nonagency RMBS. The former are securities issued by the Government National Mortgage Association (Ginnie Mae), Fannie Mae, and Freddie Mac. Agency RMBS include passthrough securities, collateralized mortgage obligations, and stripped mortgage-backed securities (interest-only and principal-only securities). The valuation of RMBS is complicated due to prepayment risk, a form of call risk. In contrast, nonagency RMBS are issued by private entities, have no implicit or explicit government guarantee, and therefore require one or more forms of credit enhancement in order to be assigned a credit rating. The analysis of nonagency RMBS must take into account both prepayment risk and credit risk. The most commonly used method for valuing RMBS is the Monte Carlo method, although other methods have garnered favor, in particular the decomposition method. The analysis of RMBS requires an understanding of the factors that impact prepayments.

Operational Risk

Operational risk has been regarded as a mere part of a financial institution's "other" risks. However, failures of major financial entities

have made regulators and investors aware of the importance of this risk. In general terms, operational risk is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. This risk encompasses legal risks, which includes, but is not limited to, exposure to fines, penalties, or punitive damages resulting from supervisory actions, as well as private settlements. Operational risk can be classified according to several principles: nature of the loss (internally inflicted or externally inflicted), direct losses or indirect losses, degree of expectancy (expected or unexpected), risk type, event type or loss type, and by the magnitude (or severity) of loss and the frequency of loss. Operational risk can be the cause of reputational risk, a risk that can occur when the market reaction to an operational loss event results in reduction in the market value of a financial institution that is greater than the amount of the initial loss. The two principal approaches in modeling operational loss distributions are the nonparametric approach and the parametric approach. It is important to employ a model that captures tail events, and for this reason in operational risk modeling, distributions that are characterized as light-tailed distributions should be used with caution. The models that have been proposed for assessing operational risk can be broadly classified into top-down models and bottom-up models. Top-down models quantify operational risk without attempting to identify the events or causes of losses. Bottom-up models quantify operational risk on a micro level, being based on identified internal events. The obstacle hindering the implementation of these models is the scarcity of available historical operational loss data.

Optimization Tools

Optimization is an area in applied mathematics that, most generally, deals with efficient algorithms for finding an optimal solution among a set of solutions that satisfy given constraints. Mathematical programming, a management

science tool that uses mathematical optimization models to assist in decision making, includes linear programming, integer programming, mixed-integer programming, nonlinear programming, stochastic programming, and goal programming. Unlike other mathematical tools that are available to decision makers such as statistical models (which tell the decision maker what occurred in the past), forecasting models (which tell the decision maker what might happen in the future), and simulation models (which tell the decision maker what will happen under different conditions), mathematical programming models allow the decision maker to identify the “best” solution. Markowitz’s mean-variance model for portfolio selection is an example of an application of one type of mathematical programming (quadratic programming). Traditional optimization modeling assumes that the inputs to the algorithms are certain, but there are also branches of optimization such as robust optimization that study the optimal decision under uncertainty about the parameters of the problem. Stochastic programming deals with both the uncertainty about the parameters and a multiperiod decision-making framework.

Probability Distributions

In financial models where the outcome of interest is a random variable, an assumption must be made about the random variable’s probability distribution. There are two types of probability distributions: discrete and continuous. Discrete probability distributions are needed whenever the random variable is to describe a quantity that can assume values from a countable set, either finite or infinite. A discrete probability distribution (or law) is quite intuitive in that it assigns certain values, positive probabilities, adding up to one, while any other value automatically has zero probability. Continuous probability distributions are needed when the random variable of interest can assume any value inside of one or more

intervals of real numbers such as, for example, any number greater than zero. Asset returns, for example, whether measured monthly, weekly, daily, or at an even higher frequency are commonly modeled as continuous random variables. In contrast to discrete probability distributions that assign positive probability to certain discrete values, continuous probability distributions assign zero probability to any single real number. Instead, only entire intervals of real numbers can have positive probability such as, for example, the event that some asset return is not negative. For each continuous probability distribution, this necessitates the so-called probability density, a function that determines how the entire probability mass of one is distributed. The density often serves as the proxy for the respective probability distribution. To model the behavior of certain financial assets in a stochastic environment, a financial modeler can usually resort to a variety of theoretical distributions. Most commonly, probability distributions are selected that are analytically well known. For example, the normal distribution (a continuous distribution)—also called the Gaussian distribution—is often the distribution of choice when asset returns are modeled. Or the exponential distribution is applied to characterize the randomness of the time between two successive defaults of firms in a bond portfolio. Many other distributions are related to them or built on them in a well-known manner. These distributions often display pleasant features such as stability under summation—meaning that the return of a portfolio of assets whose returns follow a certain distribution again follows the same distribution. However, one has to be careful using these distributions since their advantage of mathematical tractability is often outweighed by the fact that the stochastic behavior of the true asset returns is not well captured by these distributions. For example, although the normal distribution generally renders modeling easy because all moments of the distribution exist, it fails to reflect stylized facts commonly encountered in

asset returns—namely, the possibility of very extreme movements and skewness. To remedy this shortcoming, probability distributions accounting for such extreme price changes have become increasingly popular. Some of these distributions concentrate exclusively on the extreme values while others permit any real number, but in a way capable of reflecting market behavior. Consequently, a financial modeler has available a great selection of probability distributions to realistically reproduce asset price changes. Their common shortcoming is generally that they are mathematically difficult to handle.

Risk Measures

The standard assumption in financial models is that the distribution for the return on financial assets follows a normal (or Gaussian) distribution and therefore the standard deviation (or variance) is an appropriate measure of risk in the portfolio selection process. This is the risk measure that is used in the well-known Markowitz portfolio selection model (that is, mean-variance model), which is the foundation for modern portfolio theory. Mounting evidence since the early 1960s strongly suggests that return distributions do not follow a normal distribution, but instead exhibit heavy tails and, possibly, skewness. The “tails” of the distribution are where the extreme values occur, and these extreme values are more likely than would be predicted by the normal distribution. This means that between periods where the market exhibits relatively modest changes in prices and returns, there will be periods where there are changes that are much higher (that is, crashes and booms) than predicted by the normal distribution. This is of major concern to financial modelers in seeking to generate probability estimates for financial risk assessment. To more effectively implement portfolio selection, researchers have proposed alternative risk measures. These risk measures fall into

two disjointed categories: dispersion measures and safety-first measures. Dispersion measures include mean standard deviation, mean absolute deviation, mean absolute moment, index of dissimilarity, mean entropy, and mean colog. Safety-first risk measures include classical safety first, value-at-risk, average value-at-risk, expected tail loss, MiniMax, lower partial moment, downside risk, probability-weighted function of deviations below a specified target return, and power conditional value-at-risk. Despite these alternative risk measures, the most popular risk measure used in financial modeling is volatility as measured by the standard deviation. There are different types of volatility: historical, implied volatility, level-dependent volatility, local volatility, and stochastic volatility (e.g., jump-diffusion volatility). There are risk measures commonly used for bond portfolio management. These measures include duration, convexity, key rate duration, and spread duration.

Software for Financial Modeling

The development of financial models requires the modeler to be familiar with spreadsheets such as Microsoft Excel and/or a platform to implement concepts and algorithms such as the Palisade Decision Tools Suite and other Excel-based software (mostly @RISK1, Solver2, VBA3), and MATLAB. Financial modelers can choose one or the other, depending on their level of familiarity and comfort with spreadsheet programs and their add-ins versus programming environments such as MATLAB. Some tasks and implementations are easier in one environment than in the other. MATLAB is a modeling environment that allows for input and output processing, statistical analysis, simulation, and other types of model building for the purpose of analysis of a situation. MATLAB uses a number-array-oriented programming language, that is, a programming language in which vectors and matrices

are the basic data structures. Reliable built-in functions, a wide range of specialized toolboxes, easy interface with widespread software like Microsoft Excel, and beautiful graphing capabilities for data visualization make implementation with MATLAB efficient and useful for the financial modeler. Visual Basic for Applications (VBA) is a programming language environment that allows Microsoft Excel users to automate tasks, create their own functions, perform complex calculations, and interact with spreadsheets. VBA shares many of the same concepts as object-oriented programming languages. Despite some important limitations, VBA does add useful capabilities to spreadsheet modeling, and it is a good tool to know because Excel is the platform of choice for many finance professionals.

Stochastic Processes and Tools

Stochastic integration provides a coherent way to represent that instantaneous uncertainty (or volatility) cumulates over time. It is thus fundamental to the representation of financial processes such as interest rates, security prices, or cash flows. Stochastic integration operates on stochastic processes and produces random variables or other stochastic processes. Stochastic integration is a process defined on each path as the limit of a sum. However, these sums are different from the sums of the Riemann-Lebesgue integrals because the paths of stochastic processes are generally not of bounded variation. Stochastic integrals in the sense of Itô are defined through a process of approximation by (1) defining Brownian motion, which is the continuous limit of a random walk, (2) defining stochastic integrals for elementary functions as the sums of the products of the elementary functions multiplied by the increments of the Brownian motion, and (3) extending this definition to any function through approximating sequences. The major application of integration to financial modeling involves stochastic

integrals. An understanding of stochastic integrals is needed to understand an important tool in contingent claims valuation: stochastic differential equations. The dynamic of financial asset returns and prices can be expressed using a deterministic process if there is no uncertainty about its future behavior, or, with a stochastic process, in the more likely case when the value is uncertain. Stochastic processes in continuous time are the most used tool to explain the dynamic of financial assets returns and prices. They are the building blocks to construct financial models for portfolio optimization, derivatives pricing, and risk management. Continuous-time processes allow for more elegant theoretical modeling compared to discrete time models, and many results proven in probability theory can be applied to obtain a simple evaluation method.

Statistics

Probability models are theoretical models of the occurrence of uncertain events. In contrast, statistics is about empirical data and can be broadly defined as a set of methods used to make inferences from a known sample to a larger population that is in general unknown. In finance, a particular important example is making inferences from the past (the known sample) to the future (the unknown population). In statistics, probabilistic models are applied using data so as to estimate the parameters of these models. It is not assumed that all parameter values in the model are known. Instead, the data for the variables in the model to estimate the value of the parameters are used and then applied to test hypotheses or make inferences about their estimated values. In financial modeling, the statistical technique of regression models is the workhorse. However, because regression models are part of the field of financial econometrics, this topic is covered in that topic category. Understanding dependences or functional links between variables is a key theme in

financial modeling. In general terms, functional dependencies are represented by dynamic models. Many important models are linear models whose coefficients are correlation coefficients. In many instances in financial modeling, it is important to arrive at a quantitative measure of the strength of dependencies. The correlation coefficient provides such a measure. In many instances, however, the correlation coefficient might be misleading. In particular, there are cases of nonlinear dependencies that result in a zero correlation coefficient. From the point of view of financial modeling, this situation is particularly dangerous as it leads to substantially underestimated risk. Different measures of dependence have been proposed, in particular copula functions. The copula overcomes the drawbacks of the correlation as a measure of dependency by allowing for a more general measure than linear dependence, allowing for the modeling of dependence for extreme events, and being indifferent to continuously increasing transformations. Another essential tool in financial modeling, because it allows the incorporation of uncertainty in financial models and consideration of additional layers of complexity that are difficult to incorporate in analytical models, is Monte Carlo simulation. The main idea of Monte Carlo simulation is to represent the uncertainty in market variables through scenarios, and to evaluate parameters of interest that depend on these market variables in complex ways. The advantage of such an approach is that it can easily capture the dynamics of underlying processes and the otherwise complex effects of interactions among market variables. A substantial amount of research in recent years has been dedicated to making scenario generation more accurate and efficient, and a number of sophisticated computational techniques are now available to the financial modeler.

Term Structure Modeling

The arbitrage-free valuation approach to the valuation of option-free bonds, bonds with em-

bedded options, and option-type derivative instruments requires that a financial instrument be viewed as a package of zero-coupon bonds. Consequently, in financial modeling, it is essential to be able to discount each expected cash flow by the appropriate interest rate. That rate is referred to as the spot rate. The term structure of interest rates provides the relationship between spot rates and maturity. Because of its role in valuation of cash bonds and option-type derivatives, the estimation of the term structure of interest rates is of critical importance as an input into a financial model. In addition to its role in valuation modeling, term structure models are fundamental to expressing value, risk, and establishing relative value across the spectrum of instruments found in the various interest-rate or bond markets. The term structure is most often specified for a specific market such as the U.S. Treasury market, the bond market for double-A rated financial institutions, the interest rate market for LIBOR, and swaps. Static models of the term structure are characterizations that are devoted to relationships based on a given market and do not serve future scenarios where there is uncertainty. Standard static models include those known as the spot yield curve, discount function, par yield curve, and the implied forward curve. Instantiations of these models may be found in both a discrete- and continuous-time framework. An important consideration is establishing how these term structure models are constructed and how to transform one model into another. In modeling the behavior of interest rates, stochastic differential equations (SDEs) are commonly used. The SDEs used to model interest rates must capture the market properties of interest rates such as mean reversion and/or a volatility that depends on the level of interest rates. For a one-factor model, the SDE is used to model the behavior of the short-term rate, referred to as simply the "short rate." The addition of another factor (i.e., a two-factor model) involves extending the SDE to represent the behavior of the short rate and a long-term rate (i.e., long rate).

- Quantitative asset management
- Asset and derivative pricing
- Risk management

Frank J. Fabozzi
Editor, *Encyclopedia of Financial Models*

Guide to the *Encyclopedia of Financial Models*

The *Encyclopedia of Financial Models* provides comprehensive coverage of the field of financial modeling. This reference work consists of three separate volumes and 127 entries. Each entry provides coverage of the selected topic intended to inform a broad spectrum of readers ranging from finance professionals to academicians to students to fiduciaries. To derive the greatest possible benefit from the *Encyclopedia of Financial Models*, we have provided this guide. It explains how the information within the encyclopedia can be located.

ORGANIZATION

The *Encyclopedia of Financial Models* is organized to provide maximum ease of use for its readers.

Table of Contents

A complete table of contents for the entire encyclopedia appears in the front of each volume. This list of titles represents topics that have been carefully selected by the editor, Frank J. Fabozzi. The Preface includes a more detailed description of the volumes and the topic categories that the entries are grouped under.

Index

A Subject Index for the entire encyclopedia is located at the end of each volume. The sub-

jects in the index are listed alphabetically and indicate the volume and page number where information on this topic can be found.

Entries

Each entry in the *Encyclopedia of Financial Models* begins on a new page, so that the reader may quickly locate it. The author's name and affiliation are displayed at the beginning of the entry. All entries in the encyclopedia are organized according to a standard format, as follows:

- Title and author
- Abstract
- Introduction
- Body
- Key points
- Notes
- References

Abstract

The abstract for each entry gives an overview of the topic, but not necessarily the content of the entry. This is designed to put the topic in the context of the entire *Encyclopedia*, rather than give an overview of the specific entry content.

Introduction

The text of each entry begins with an introductory section that defines the topic under

discussion and summarizes the content. By reading this section, the reader gets a general idea about the content of a specific entry.

Body

The body of each entry explains the purpose, theory, and math behind each model.

Key Points

The key points section provides in bullet point format a review of the materials discussed in

each entry. It imparts to the reader the most important issues and concepts discussed.

Notes

The notes provide more detailed information and citations of further readings.

References

The references section lists the publications cited in the entry.

Mortgage-Backed Securities Analysis and Valuation

Valuing Mortgage-Backed and Asset-Backed Securities

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC School of Business

MARK B. WICKARD
Senior Vice President/Corporate Cash Investment Advisor, Morgan Stanley Smith Bamey

Abstract: The valuing (or pricing) of a bond without an embedded option (that is, an option-free bond) is straightforward. The value is equal to the present value of the expected cash flows. Ignoring defaults, for an option-free bond the cash flows are known and consist of the periodic interest payments and principal at the maturity date. The interest or discount rates for computing the present value of the cash flows begin with the spot rates for a benchmark security and to those rates an appropriate spread is added. Moving from valuing option-free bonds to corporate bonds and agency debentures with embedded options is not simple. The interest rate-sensitive options that can be embedded into these bonds are call options, put options, accelerated sinking provisions, and, for floating-rate securities, caps on the interest rate. The reason valuation is complicated is that the embedded options must be taken into account and the theoretical option-free value of the bond must be adjusted accordingly. The technique typically used for valuing corporate bonds and agency debentures with embedded options is the lattice method. Mortgage-backed securities also have embedded options: the right of the borrowers in a loan pool to prepay their mortgage loan. However, because future cash flows for a loan pool are sensitive to not only the current interest rate but the history of rates since the loans were originated, the lattice method which is solved using backward induction cannot be employed. Instead, the most common methodology used for valuing mortgage-backed securities and mortgage-related asset-backed securities is the Monte Carlo simulation model. Other types of asset-backed securities are straightforward to value. In addition to the complications in valuing mortgage-backed securities and mortgage-related asset-backed securities, there is the difficulty in estimating their price sensitivity to changes in interest rates (that is, duration and convexity). The Monte Carlo simulation model can be used to compute the effective duration of these securities. This duration measure takes into consideration how a change in interest rates can impact a security's cash flow.

In this entry we will explain the methodology for valuing asset-backed securities (ABS) and mortgage-backed securities (MBS) and measures of relative value.¹ We begin by reviewing cash-flow yield analysis and the limitations

of the spread measure that is a result of that analysis—the nominal spread. We then look at a better spread measure called the zero-volatility spread, but point out its limitation as a measure of relative value for MBS products because

of the borrower's prepayment option and for ABS products where the prepayment option has value. Finally, we look at the methodology for valuing MBS and for ABS products where the prepayment option has value—the *Monte Carlo simulation model*. A by-product of this model is a spread measure called the option-adjusted spread (OAS). This measure is superior to the nominal spread and the zero-volatility spread for ABS products where the prepayment option has a value because it takes into account how cash flows may change when interest rates change. That is, it recognizes the borrower's prepayment option and how that affects prepayments when interest rates may change in the future. While the OAS is superior to the two other spread measures, it is based on assumptions that must be understood by an investor and the sensitivity of the security's value and OAS to changes in those assumptions must be investigated.

CASH-FLOW YIELD ANALYSIS

The yield on any financial instrument is the interest rate that makes the present value of the expected cash flow equal to its market price plus accrued interest. For ABS and MBS, the yield calculated is called a *cash-flow yield*. The problem in calculating the cash-flow yield of MBS and ABS is that because of prepayments the cash flow is unknown. A prepayment is the amount of the payment made by the obligor in the loan pool that is in excess of the scheduled principal payment. Prepayments can be voluntary such as for refinancing the loan or involuntary such as for a default by the obligor. Consequently, to determine a cash-flow yield some assumption about the prepayment rate and recovery rate in the case of defaults must be made.²

The cash flow for MBS and ABS is typically monthly. The convention is to compare the yield on MBS and ABS to that of a Treasury coupon security by calculating the security's bond-

equivalent yield. The bond-equivalent yield for a Treasury coupon security is found by doubling the semiannual yield. However, it is incorrect to do this for MBS and ABS because the investor has the opportunity to generate greater interest by reinvesting the more frequent cash flows. The market practice is to calculate a yield so as to make it comparable to the yield to maturity on a bond-equivalent yield basis. The formula for annualizing the monthly cash-flow yield for MBS and ABS is as follows:

$$\text{Bond-equivalent yield} = 2[(1 + i_M)^6 - 1]$$

where i_M is the monthly interest rate that will equate the present value of the projected monthly cash flow to the market price (plus accrued interest) of the security.

All yield measures suffer from problems that limit their use in assessing a security's potential return. The yield to maturity for a Treasury, agency, or corporate bond has two major shortcomings as a measure of a bond's potential return. To realize the stated yield to maturity, the investor must: (1) reinvest the coupon payments at a rate equal to the yield to maturity and (2) hold the bond to the maturity date. The reinvestment of the coupon payments is critical and for long-term bonds can comprise as much as 80% of the bond's return. The risk of having to reinvest the interest payments at less than the computed yield is called *reinvestment risk*. The risk associated with a decline in the value of a security due to a rise in interest rates is called *interest rate risk* and in practice is quantified by computing the security's duration and convexity.

These shortcomings are equally applicable to the cash-flow yield measure for ABS and MBS: (1) the projected cash flows are assumed to be reinvested at the computed cash-flow yield and (2) the security is assumed to be held until the final payout based on some prepayment assumption. The importance of reinvestment risk—the risk that the cash flow will be reinvested at a rate less than the calculated cash-flow yield—is particularly important for amortizing MBS and

ABS products, because payments are monthly and both interest and principal must be reinvested. Moreover, an additional assumption is that the projected cash flow is actually realized. If the prepayment experience and the recovery rate realized differ from that assumed, the cash-flow yield will not be realized.

Given the computed cash-flow yield and the average life for a security based on some prepayment assumption and default/recovery assumption, the next step is to compare the yield to the yield for a comparable Treasury security. "Comparable" is typically defined as a Treasury security with the same maturity as the (weighted) average life or the duration of the security. The difference between the cash-flow yield and the yield on a comparable Treasury security is called the *nominal spread*.

Unfortunately, it is the nominal spread that investors will too often use as a measure of relative value for ABS and MBS. However, this spread masks the fact that a portion of the nominal spread may be compensation for accepting prepayment risk. Instead of nominal spread, investors need a measure that indicates the compensation after adjusting for prepayment risk for all MBS and for ABS where the prepayment option has value. This measure is called the option-adjusted spread. Before discussing this measure, we describe another spread measure commonly quoted for MBS and ABS called the zero-volatility spread. This measure takes into account another problem with the nominal spread. Specifically, the nominal spread is computed assuming that all the cash flows for a security should be discounted at only one interest rate. That is, it fails to recognize the term structure of interest rates.

ZERO-VOLATILITY SPREAD

The proper procedure to compare ABS and MBS to a Treasury is to compare it to a portfolio of Treasury securities that have the same cash flow. The value of the security is then equal to the present value of all of the cash flows. The secu-

rity's value, assuming the cash flows are default free, will equal the present value of the replicating portfolio of Treasury securities. In turn, these cash flows are valued at the Treasury spot rates.

The *zero-volatility spread* is a measure of the spread that the investor would realize over the entire Treasury spot rate curve if the non-Treasury security being analyzed is held to maturity. It is not a spread off one point on the Treasury yield curve, as is the nominal spread. The zero-volatility spread (also called the *Z-spread* and the *static spread*) is the spread that will make the present value of the cash flows from the non-Treasury security when discounted at the Treasury spot rate plus the spread equal to the market price plus accrued interest of the non-Treasury security. A trial-and-error procedure (or search algorithm) is required to determine the zero-volatility spread.

In general, the shorter the average life of the ABS/MBS, the less the zero-volatility spread will deviate from the nominal spread. The magnitude of the difference between the nominal spread and the zero-volatility spread also depends on the shape of the yield curve. The steeper the yield curve, the greater the difference.

If borrowers in the underlying loan pool have the right to prepay but do not typically take advantage of a decline in interest rates below the loan's rate to refinance, then the zero-volatility spread is the appropriate measure of relative value and it should be used in valuing cash flows to determine the value of ABS. This is the case, for example, for automobile loan ABS. While borrowers have the right to refinance when rates decline below the loan rate, they typically do not. In contrast, for standard residential mortgage loans, home equity loan ABS, and manufactured housing ABS, the borrowers in the underlying pool do refinance when interest rates decline below the loan rate. The next methodology and spread measure are used for products with this characteristic. Basically, they are used for all residential MBS and mortgage-related ABS.

VALUATION USING MONTE CARLO SIMULATION AND OAS ANALYSIS

In fixed income valuation modeling, there are two methodologies commonly used to value securities with embedded options—the Monte Carlo simulation model and the lattice model. The Monte Carlo simulation model involves simulating a large number of potential interest rate paths in order to assess the value of a security on those different paths. This model is the most flexible of the two valuation methodologies for valuing interest rate-sensitive instruments where the history of interest rates is important. MBS and mortgage-related ABS are commonly valued using this model. As explained below, a by-product of this valuation model is the OAS. (An alternative model for valuing agency passthrough securities that does not require a prepayment model is provided in Kalotay, Yang, and Fabozzi, 2004.)

A lattice model is used to value callable agency debentures and corporate bonds. This valuation model accommodates securities in which the decision to exercise a call option is not dependent on how interest rates evolved over time. That is, the decision of an issuer to call a bond will depend on the prevailing interest rate at which the issue can be refunded relative to the issue's coupon rate and the costs associated with refunding, and not the path interest rates took to get to that rate. MBS and mortgage-related ABS which allow prepayments have periodic cash flows that are interest rate path dependent. This means that the cash flow received in one period is determined not only by the current interest rate level, but also by the path that interest rates took to get to the current level.

Prepayments for MBS and mortgage-related ABS are interest rate path dependent because this month's prepayment rate depends on whether there have been prior opportunities to refinance since the underlying loans were originated. Moreover, the cash flows to be received

in the current month by investors in a bond class of MBS and mortgage-related ABS transaction depend on the outstanding balances of the other bond classes in the transaction. For example, in the case of a planned amortization class (PAC) bond in a collateralized mortgage obligation structure, all prepayments from the time the security was issued up to the valuation date affect the amount of support bonds outstanding and therefore the cash flow at the valuation date for the PAC bond.³ Thus, we need the history of prepayments to calculate the balances of bond classes in a structure.

Conceptually, valuation using the Monte Carlo simulation model is simple. In practice, however, it is very complex. The simulation involves generating a set of cash flows based on simulated future refinancing rates, which in turn imply simulated prepayment and default/recovery rates. The objective is to figure out how the value of the collateral gets transmitted to the bond classes in the structure. More specifically, modeling is used to identify where the value in a transaction has been allocated and where the risk (prepayment risk and credit risk) has been distributed in order to identify the bond classes with low risk and high value.

Simulating Interest Rate Paths and Cash Flows

Monte Carlo simulation is a management science/operations research technique that is commonly employed in finance.⁴ The purpose of Monte Carlo simulation is to generate a probability distribution for the outcome of some random variable of interest. In its application to valuing securities, it is used to generate interest rate paths so that potential cash flows on those paths can be determined and then each path is valued. (In the parlance of simulation, an interest rate path is referred to as a trial.) The value for the security on each of those interest rate paths is then one value in determining the estimated probability distribution for the security's value.

The procedure for generating the interest rate paths begins with a benchmark term structure of interest rates and associated with this benchmark are market prices for benchmark securities. Given the benchmark term structure of interest rates, the interest rate paths are adjusted (that is, calibrated) so that the average price produced by the model for each benchmark security will equal the market price for the benchmark security.

Most models use the on-the-run Treasury issues in this calibration process. Other model developers use off-the-run Treasury issues as well. The argument for using off-the-run Treasury issues is that the price/yield of on-the-run Treasury issues will not reflect their true economic value because the market price reflects their value for financing purposes (that is, an issue may be on special in the repo market). Some models use the London Interbank Offered Rate (LIBOR) curve instead of the Treasury curve. The reason is that some investors are interested in spreads that they can earn relative to their funding costs and LIBOR, for many investors, is a better proxy for that cost than Treasury rates.

To generate the interest rate paths, an assumption about the evolution of future interest rates is required. Most Monte Carlo simulation models use some form of one-factor interest rate model. The one factor used is the short-term interest rate. When using a particular one-factor interest rate model, several further assumptions must be made. The first, and the most important, is the assumption about the volatility of the short-term interest rate. The volatility assumption determines the dispersion of future interest rates in the simulation. Many model developers do not use one volatility number for the yield volatility of all maturities for the benchmark curve. Instead, they use either a short/long yield volatility or a term structure of yield volatility. A short/long yield volatility means that volatility is specified for maturities up to a certain number of years (short yield volatility) and a different yield volatility for greater maturities (long yield volatility). The

short yield volatility is assumed to be greater than the long yield volatility. A term structure of yield volatilities means that a yield volatility is assumed for each maturity. (In practice, interest rate volatility is extracted from interest rate cap market prices.) From these prices, a term structure of yield volatility is obtained. Differences in the assumption about volatility of short-term interest rates can have a material impact on the resulting value derived for the security.

Another assumption relates to the speed of mean reversion of the short-term interest rate. Mean reversion in an interest rate model has to do with not allowing interest rates to fall below a lower barrier and not exceed an upper barrier before rates revert back to some average interest rate specified by the model developer or user.

The random paths of interest rates should be generated from an arbitrage-free model of the future term structure of interest rates. By arbitrage free it is meant that the model replicates today's term structure of interest rates, an input of the model, and that for all future dates there is no possible arbitrage within the model.

The simulation works by generating many scenarios of future interest rate paths. In each month of a given scenario (that is, path), a monthly interest rate and a refinancing rate are generated. The monthly interest rates are used to discount the projected cash flows in the scenario. The refinancing rate is needed to determine the cash flows because it represents the opportunity cost the borrower is facing at that time.

If the refinancing rates are high relative to the borrower's loan rate, the borrower will have no incentive to refinance. For MBS and mortgage-related ABS, there is a disincentive to prepay (that is, the homeowner may avoid moving in order to avoid refinancing). If the refinancing rate is low relative to the borrower's loan rate, the borrower has an incentive to refinance.

Prepayments (voluntary and involuntary) and recoveries are projected by feeding the refinancing rate and loan characteristics into a

Table 1 Simulated Paths of One-Month Future Interest Rates

Month	Interest Rate Path Number

M	$f_M(1)$	$f_M(2)$	$f_M(3)$...	$f_M(n)$...	$f_M(N)$

Notation: $f_t(n)$ = one-month future interest rate for month t on path n , N = total number of interest rate paths; M = number of months for the loan pool.

prepayment model and default model. (In the case of agency MBS [Ginnie Mae, Fannie Mae, and Freddie Mac] no assumption about defaults is required.) Given the projected prepayments, the cash flows along an interest rate path can be determined. To be able to do this, the entire deal must be reverse engineered. That is, the deal's waterfall (that is, the rules for distribution of interest, principal repayment, and loss allocation) must be specified so that the cash flow for the bond class being valued can be determined. Model developers do not reverse engineer the deals. Rather, there are vendors who provide the waterfall for deals that are used in conjunction with the Monte Carlo simulation model.

To make this more concrete, consider a newly issued loan pool with a maturity of M months

that is the collateral for an MBS or mortgage-related ABS. Table 1 shows N simulated interest rate path scenarios. Each scenario consists of a path of M simulated 1-month future interest rates. (The determination of the number of paths generated is based on a variance-reduction method.⁵) So, the first assumption made to generate the short-term interest rate paths in Table 1 is the volatility of short-term interest rates.

Table 2 shows the paths of simulated refinancing rates corresponding to the scenarios shown in Table 1. In going from Table 1 to Table 2, an assumption must be made about the relationship between the benchmark short-term interest rate and the refinancing rate. The assumption is that there is a constant spread relationship between the refinancing rate and the interest rate for a

maturity that is the best proxy for the borrowing rate. Typically, it is the 10-year rate that is used as a proxy.

Given the refinancing rates, the collateral's cash flows on each interest rate path can be generated. This requires a prepayment and default/recovery model. So our next assumption is that the prepayment and default/recovery models used to generate the loan pool's cash flows are correct. The resulting cash flows are depicted in Table 3.

Given the loan pool's cash flow for each month on each interest rate path, the next step is to use the waterfall for the structure to determine how the cash flow is distributed to the bond class being valued. Let us use BCC to denote the cash flow for that bond class. Table 4 shows the simulated cash flows on each of

the interest rate paths for the bond class being valued.

Calculating the Present Value of a Bond Class for a Scenario Interest Rate Path

Given the cash flows for the bond class on an interest rate path, the path's present value can be calculated. The discount rate for determining the present value is the simulated spot rate for each month on the interest rate path plus an appropriate spread. The spot rate on a path can be determined from the simulated future monthly rates. The relationship that holds between the simulated spot rate for month t on path n and the simulated future one-month rates is:

$$z_t(n) = \{[1 + f_1(n)][1 + f_2(n)] \cdots [1 + f_t(n)]\}^{1/t} - 1$$

Table 4 Simulated Cash Flows for the Bond Class Being Valued

Notation: $BCC_t(n)$ = bond class's cash flow for month t on path n ; N = total number of interest rate paths; M = number of months for the loan pool.

Table 5 Simulated Paths of Monthly Spot Rates

Month	Interest Rate Path Number						
	1	2	3	...	n	...	N
1	$z_1(1)$	$z_1(2)$	$z_1(3)$...	$z_1(n)$...	$z_1(N)$
2	$z_2(1)$	$z_2(2)$	$z_2(3)$...	$z_2(n)$...	$z_2(N)$
3	$z_3(1)$	$z_3(2)$	$z_3(3)$...	$z_3(n)$...	$z_3(N)$
...
t	$z_t(1)$	$z_t(2)$	$z_t(3)$...	$z_t(n)$...	$z_t(N)$
...
$M-2$	$z_{M-2}(1)$	$z_{M-2}(2)$	$z_{M-2}(3)$...	$z_{M-2}(n)$...	$z_{M-2}(N)$
$M-1$	$z_{M-1}(1)$	$z_{M-1}(2)$	$z_{M-1}(3)$...	$z_{M-1}(n)$...	$z_{M-1}(N)$
M	$z_M(1)$	$z_M(2)$	$z_M(3)$...	$z_M(n)$...	$z_M(N)$

Notation: $z_t(n)$ = spot rate for month t on path n ; N = total number of interest rate paths; M = number of months for the loan pool.

where

$$z_t(n) = \text{simulated spot rate for month } t \text{ on path } n$$

$$f_j(n) = \text{simulated future one-month rate for month } j \text{ on path } n$$

Consequently, the interest rate path for the simulated future one-month rates can be converted to the interest rate path for the simulated monthly spot rates as shown in Table 5. Therefore, the present value of the cash flows for month t on interest rate path n discounted at the simulated spot rate for month t plus some spread is:

$$PV[BCC_t(n)] = \frac{BCC_t(n)}{[1 + z_t(n) + K]^t} \quad (1)$$

where

$$PV[BCC_t(n)] = \text{present value of the cash flow for the bond class for month } t \text{ on path } n$$

$$BCC_t(n) = \text{cash flow for the bond class for month } t \text{ on path } n$$

$$z_t(n) = \text{spot rate for month } t \text{ on path } n$$

$$K = \text{spread}$$

The present value for path n is the sum of the present value of the cash flows for each month

on path n . That is,

$$PV[\text{Path}(n)] = PV[BCC_1(n)] + PV[BCC_2(n)] + \dots + PV[BCC_M(n)] \quad (2)$$

where $PV[\text{Path}(n)]$ is the present value of interest rate path n .

Determining the Theoretical Value

The present value of a given interest rate path is treated as the *theoretical value* of a bond class if that path is realized. The theoretical value of the bond class using the Monte Carlo simulation model is determined by calculating the average of the theoretical values of all the interest rate paths. That is, the theoretical value is equal to

$$\text{Theoretical value} = \frac{PV[\text{Path}(1)] + \dots + PV[\text{Path}(N)]}{N} \quad (3)$$

where N is the number of interest rate paths.

Notice that the results of the Monte Carlo simulation model produce one value, the average value, and that value is taken as the theoretical value. However, as noted earlier, the purpose of a Monte Carlo simulation model is to estimate the probability distribution for the variable of interest. While a probability distribution can easily be obtained from the values for each path and summary information in addition to the mean such as dispersion and skewness

measures can be computed, it is rare if that information is provided. Basically, the reason is that investors rarely seek that information because too often they do not understand the Monte Carlo simulation process.

Moreover, it should be apparent how the Monte Carlo simulation model is driven by assumptions. Hence, a user of a model such as the one described here is subject to *modeling risk*. To mitigate modeling risk, an investor can test the sensitivity of the value produced by the model to alternative assumptions. For example, regarding the volatility assumption, the model can be rerun assuming both proportionality lower and higher volatility than initially assumed. The sensitivity to prepayments can be analyzed in the same way. From the sensitivity analysis, an investor can determine which assumptions appear to be more important for the security being considered for purchase.⁶

Option-Adjusted Spread

Thus far we have seen how the theoretical value of a security can be determined using the Monte Carlo simulation model. Recall that in the model, a spread (K) is added to the monthly spot rates on all the interest rate paths in Table 5 in order to determine the discount rate used for calculating the present value of the cash flows. The spread should reflect the risk associated with the security as required by the market. However, the reverse can be done. Given (1) the cash flows in Table 4 for the bond class being valued, (2) the spot rates in Table 5, and (3) the market price of the security being valued, one can determine the spread that will make the average value for the interest rate paths equal to the market price (plus accrued interest). That spread is what is referred to as the *option-adjusted spread* (OAS). Mathematically, OAS is the spread that will make

$$\text{Market price} + \text{Accrued interest} = \frac{\text{PV}[\text{Path}(1)] + \dots + \text{PV}[\text{Path}(N)]}{N} \quad (4)$$

where N is the number of interest rate paths.

Basically, the OAS is used to reconcile the model's value [that is, the value determined by the Monte Carlo simulation model given by equation (3)] with the market price. On the left-hand side of equation (4) is the market's valuation of the security as represented by the market price. On the right-hand side of the equation is the model's evaluation of the security (that is, the theoretical value), which is the average present value over all the interest rate paths. Basically, the OAS was developed as a measure of the spread that can be used to convert dollar differences between model value and market price. But what is it a "spread" over? In describing the model above, we can see that the OAS is measuring the average spread over the benchmark spot rate. It is an average spread since the OAS is found by averaging over the interest rate paths for the possible future benchmark spot rate curves.

This spread measure is superior to the nominal spread, which gives no recognition to the prepayment risk. The OAS is "option adjusted" because the cash flows on the interest rate paths are adjusted for the option of the borrowers to prepay.

Option Cost

The implied cost of the option embedded in a security can be obtained by calculating the difference between the OAS and the zero-volatility spread. That is,

$$\text{Option cost} = \text{Zero-volatility spread} - \text{OAS}$$

The *option cost* measures the prepayment (or option) risk embedded in MBS and ABS. Note that the cost of the option is a by-product of the OAS analysis, not valued explicitly with some option pricing model.

When the option cost is zero because the borrower tends not to exercise the prepayment option when interest rates decline below the loan rate or when there is no prepayment option, then substituting zero for the OAS in the previous equation and solving for the zero-volatility

spread, we get:

$$\text{Zero-volatility spread} = \text{OAS}$$

Consequently, when the value of the option is zero (that is, the option cost is zero) for a particular ABS, simply computing the zero-volatility spread for relative value purposes or for valuing that ABS is sufficient. Even if there is a small value for the option, the zero-volatility spread should be adequate rather than calculating an OAS using the Monte Carlo simulation model.

Simulated Average Life

The average life of a security when using the Monte Carlo simulation model is the weighted average time to receipt of principal payments (scheduled payments and projected prepayments). The average life reported in a Monte Carlo model is the average of the average lives along the interest rate paths. That is, for each interest rate path, there is an average life. The average of these average lives is the average life reported by the model.

Additional information is conveyed by the distribution of the average life. The greater the range and standard deviation of the average life, the more uncertainty there is about the security's average life.

MEASURING INTEREST RISK

There are two measures of interest rate risk that are commonly used: duration and convexity.⁷ Duration is a first approximation as to how the value of an individual security or the value of a portfolio will change when interest rates change. Convexity measures the change in the value of a security or portfolio that is not explained by duration. How these measures are computed when using the Monte Carlo simulation model is described in this section.

Duration

The most obvious way to measure a bond's price sensitivity as a percentage of its current

price to changes in interest rates is to change rates by a small number of basis points and calculate how its price will change. To do this, we introduce the following notation. Let

V_0 = initial value or price of the security

Δy = change in the yield of the security (in decimal)

V_- = the estimated value of the security if the yield is decreased by Δy

V_+ = the estimated value of the security if the yield is increased by Δy

There are two key points to keep in mind in the foregoing discussion. First, the change in yield referred to above is the same change in yield for all maturities. This assumption is commonly referred to as a "parallel yield curve shift assumption." Thus, the foregoing discussion about the price sensitivity of a security to interest rate changes is limited to parallel shifts in the yield curve. Second, the notation refers to the estimated value of the security. This value is obtained from a valuation model. Consequently, the resulting measure of the price sensitivity of a security to interest rate changes is only as good as the valuation model employed to obtain the estimated value of the security.

Now let's focus on the measure of interest. We are interested in the percentage change in the price of a security when interest rates change. This measure is referred to as duration. It can be demonstrated that duration can be estimated using the following formula:

$$\text{Duration} = \frac{V_- - V_+}{2V_0(\Delta y)} \quad (5)$$

The duration of a security can be interpreted as the approximate percentage change in price for a 100 basis point parallel shift in the yield curve. Thus, a bond with a duration of 5 will change by approximately 5% for a 100 basis point parallel shift in the yield curve. For a 50 basis point parallel shift in the yield curve, the bond's price will change by approximately 2.5%; for a 25 basis point parallel shift in the yield curve, 1.25%, and so on.

What this means is that in calculating the values of V_- and V_+ in the duration formula, the same cash flows used to calculate V_0 are used. Therefore, the change in the bond's price when the yield curve is shifted by a small number of basis points is due solely to discounting at the new yields. This assumption makes sense for option-free bonds such as Treasury securities and nonmortgage ABS such as credit card ABS and auto loan-backed ABS. However, the same cannot be said for MBS and mortgage-related ABS because for these products the cash flows are sensitive to changes in interest rates. Rather, for these products a change in yield will alter the expected cash flows because it will change expected payments.

The Monte Carlo simulation model takes into account how parallel shifts in the yield curve will affect the cash flows. Thus, when V_- and V_+ are the values produced from the valuation model, the resulting duration takes into account both the discounting at different interest rates and how the cash flows can change. When duration is calculated in this manner, it is referred to as *effective duration* or *option-adjusted duration*.

To calculate effective duration, the value of a security must be estimated when interest rates are shocked (that is, changed) up and down a given number of basis points. In terms of the Monte Carlo simulation model, the yield curve used is shocked up and down and the new curve is used to generate the values to be used in equation (5) to obtain effective duration.

There are two important aspects of this process of generating the values when the rates are shocked that are critical to understand. First, the assumption is that the relationships assumed do not change when rates are shocked up and down. Specifically, (1) the interest rate volatility is assumed to be unchanged to derive the new interest rate paths for a given shock (that is, the new Table 1), as well as the other assumptions made to generate the new Table 2 from the newly constructed Table 1, and (2) the OAS is assumed to be constant. The constancy of the OAS comes into play because when discount-

ing the new cash flows (that is, the cash flows in the new Table 4), the current OAS that was computed is assumed to be the same and is added to the new rates in the new Table 1.

Convexity

The duration measure indicates that regardless of whether interest rates increase or decrease, the approximate percentage price change is the same. However, this does not agree with the price volatility property of a bond. Specifically, while for small changes in yield the percentage price change will be the same for an increase or decrease in yield, for large changes in yield this is not true. This suggests that duration is only a good approximation of the percentage price change for a small change in yield.

The reason for this result is that duration is in fact a first approximation for a small change in yield. The approximation can be improved by using a second approximation. This approximation is referred to as "convexity." (The use of this term in the industry is unfortunate since the term "convexity" is also used to describe the shape or curvature of the price/yield relationship.) The convexity measure of a security can be used to approximate the change in price that is not explained by duration.

The convexity measure of a bond can be approximated using the following formula:

$$\text{Convexity measure} = \frac{V_+ + V_- - 2V_0}{2V_0(\Delta y)^2} \quad (6)$$

where the notation is the same as used earlier for duration. When the values for the inputs in the convexity measure as given in equation (6) are obtained from a Monte Carlo simulation model, the resulting convexity is referred to as *effective convexity*. Note that dealers often quote convexity by dividing the convexity measure by 100.

When the convexity measure is positive, we have the situation where the gain is greater than the loss for a given large change in rates. That is, the security exhibits *positive convexity*. Most nonmortgage ABS have positive convexity.

However, if the convexity measure is negative, we have the situation where the loss will be greater than the gain. A security with this characteristic is said to have *negative convexity* and it occurs with MBS and mortgage-related ABS.

KEY POINTS

- Valuing securities with interest rate-sensitive options requires the employment of a model that recognizes how future interest rates can change and how that impacts the expected cash flows.
- For bonds with embedded options such as callable bonds and puttable bonds, as well as bonds that have an accelerated sinking fund provision, the lattice method can be used. Unfortunately, the lattice model cannot be used for MBS and mortgage-related ABS because these securities have path-dependent cash flows and thus how interest rates have evolved prevents solving a lattice model.
- Instead of the lattice model, the Monte Carlo simulation model is used to value MBS and mortgage-related ABS. There are many assumptions in the model and therefore, sensitivity analysis should be used to test the sensitivity of the model's value to changes in the major assumptions.
- For ABS that do not have an embedded option (that is, no prepayment option) or where there is a prepayment option but for all intents and purposes the prepayment option is unlikely to be exercised, valuation is fairly straightforward—assuming a good model for estimating defaults and recoveries. It is simply the present value of the expected cash flow discounted at the benchmark spot rates plus an appropriate spread.
- The cash-flow yield measure for MBS and ABS is a flawed measure of value. The corresponding nominal spread is therefore similarly flawed. A better measure for ABS where the prepayment option has little value is the zero-volatility spread. For MBS and mortgage-related ABS, the commonly used

measure is the OAS. This measure adjusts the spread for the embedded option by adjusting the cash flows in the Monte Carlo simulation model (as well as in the lattice model).

- Because the OAS is derived from the Monte Carlo simulation model, it is also an assumption-driven product and therefore subject to modeling risk.
- The appropriate interest risk measures for MBS and mortgage-related ABS are effective duration and effective convexity. These measures require, as inputs, the estimated value of the security obtained by shocking the Monte Carlo simulation model.

The Active-Passive Decomposition Model for MBS

ALEXANDER LEVIN, PhD

Director, Financial Engineering, Andrew Davidson & Co., Inc.

Abstract: Even a simple mortgage pass-through is a path-dependent financial instrument, valuation of which depends on prepayment “burnout.” The burnout is caused by observed or unobserved heterogeneity of borrowers; as a result, a mortgage pool’s composition changes in the presence of refinancing incentives. An attractive modeling approach for dealing with this is to split a mortgage pool into mutually exclusive “active” and “passive” groups. Not only does such a method explain the burnout, it effectively decomposes the path-dependent valuation problem into two easy-to-solve path-independent ones. The method is faster than the traditional Monte Carlo sampling approach while delivering the full set of interest rate risk measures at no additional cost of computing time. The method can be applied to an attractive prepayment model specification where the speed is a function of the pool’s objective price, and not an interest rate. This makes universal refinancing modeling feasible as the same curve or curves can apply to both fixed- and adjustable-rate mortgages.

The *active-passive decomposition (APD) method* of mortgage-backed securities (MBS) modeling and valuation was introduced in Levin (2001, 2002, 2003). An efficient alternative to brute-force Monte Carlo simulation, the APD method splits a mortgage pass-through into two path-independent components, the active (refinanceable) and the passive (nonrefinanceable). Once this is done, the most time-efficient pricing structures operating backwards on probability trees or finite-difference grids could be employed. This valuation method runs faster than Monte Carlo simulation while deliver-

ing a much richer outcome—all stressed values required by mandatory risk assessments—at no additional cost. Risk managers and traders of unstructured mortgage instruments such as agency pass-through MBS, whole loans, stripped (IO/PO) derivatives, and mortgage servicing rights (MSRs) are immediate beneficiaries of the method.

The APD approach simulates the *burnout* effect in a natural and explicit way through modeling the heterogeneity of the collateral. Hence, it presents an analytical advantage over any other approach that requires ad hoc judgments

The extended APD model and its implementation presented here has greatly benefited from joint work with Andrew Davidson and Dan Szakallas.

about the achieved degree of burnout. Structured instruments—such as a collateralized mortgage obligation (CMO) and asset-backed security (ABS)—though they retain heavy sources of path-dependence (other than the burnout) and still rely on Monte Carlo pricing, can benefit from better, more robust prepay modeling.

The multi-population view of mortgage collateral is a known approach used to explain the burnout effect. In one of the earliest modeling attempts, Davidson (1987) and Davidson et al. (1988) proposed the *refinancing* threshold model, in which collateral is split into three or more American option bonds having differing strikes. A conceptually similar approach proposed by Kalotay and Young (2002) divides collateral into bonds differing by their exercise timing. Such structures naturally call for the *backward induction* pricing, but they fall short in replicating actually observed, probabilistically smoothed, prepayment behavior—even if many constituent bonds are used. On the other hand, analytical systems used in practice often employ multi-population mortgage models (see Hayre, 1994, 2000), but do not seek any computational benefits as they rely heavily on Monte Carlo simulation pricing anyway.

The APD is a “mortgage-like” model with refinancing S-curve, aging, and other ad hoc features, which are meant to capture nonefficient, empirical option exercise. Therefore, the APD model is capable of generating realistic prepayment behavior with only two constituent components, the active and the passive. This entry introduces an extended APD model and its applications.

PATH-DEPENDENCE AND PRICING PARTIAL DIFFERENTIAL EQUATION

Let us consider a hypothetical dynamic asset (“mortgage”) market price of which $P(t, x)$ depends on time t and one market factor x . The latter can be formally anything and does not

necessarily have to be the short market rate or the yield on the security analyzed. We treat $x(t)$ as a random process having a (generally, variable) drift rate μ and a volatility rate σ , and being disturbed by a standard Brownian motion $z(t)$, that is,

$$dx = \mu dt + \sigma dz \quad (1)$$

We assume further that the asset continuously pays the $c(t, x)$ coupon rate and its balance B is amortized at the $\lambda(t, x)$ rate, that is, $\partial B/\partial t = -\lambda B$. Then one can prove that the price function $P(t, x)$ should solve the following *partial differential equation* (PDE):

$$\underbrace{\frac{r + OAS}{P}}_{\text{expected return}} = \underbrace{\frac{1}{P} \frac{\partial P}{\partial t} + \frac{1}{P}(c + \lambda) - \lambda}_{\text{time return}} + \underbrace{\frac{1}{P} \frac{\partial P}{\partial x} \mu}_{\text{return}} + \underbrace{\frac{1}{2P} \frac{\partial^2 P}{\partial x^2} \sigma^2}_{\text{return}} \quad (2)$$

A derivation of this PDE can be found in Levin (1998), but it goes back at least to Fabozzi and Fong (1994). A notable feature of the above written PDE is that it does not contain the balance variable, B . The entire effect of possibly random prepayments is represented by the amortization rate function, $\lambda(t, x)$. Although the total cash flow observed for each accrual period does depend on the beginning-period balance, construction of a finite-difference scheme and the backward induction will require the knowledge of $\lambda(t, x)$, not the balance. This observation agrees with a trivial practical rule stating that the relative price is generally independent of the investment size.

Another interesting observation comes as follows. If we transform the economy having shifted all the rates, $r(t, x)$ and $c(t, x)$, by amortization rate $\lambda(t, x)$, then PDE (2) will be reduced to the constant-par asset’s pricing PDE. It means that a probability tree or finite difference *pricing grid* built in the “ λ -shifted” economy should, in principle, have as many dimensions as the total number of factors or state variables that affect r , c , and λ . In particular, if the coupon rate is fixed, and the amortization

rate λ depends only on current time (loan age) and the immediate market factor x , the entire valuation problem can be solved backwards on a two-dimensional (x, t) lattice. To implement this method, we would start our valuation process from maturity T when we surely know that the price is par, $P(T, x) = 1$, regardless the value of factor x .

Working backwards, we derive prices at age $t - 1$ from prices already found at age t . In doing so, we replace derivatives in PDE (2) by finite difference approximations, or weigh branches of the lattice by explicitly computed probabilities. If the market is multifactor, then x should be considered a vector; the lattice will require more dimensions. Generally, the efficiency of finite-difference methods deteriorates quickly on high-dimensional grids because the number of nodes and cash flows grows geometrically; probability trees may maintain their speed, but at the cost of accuracy, if the same number of emanating nodes is used to capture multifactor dynamics. If we decide to operate on a probability tree instead of employing a finite-difference grid, then, for every branch,

$$P_k = \frac{c_k + P_{k+1} + \lambda_k(1 - P_{k+1})}{1 + r_k + OAS} \quad (3)$$

where P_k is the previous-node value deduced from the next-node value P_{k+1} . Of course, probability weighting of thus obtained values applies to all emanating branches.

EXTENDED ACTIVE-PASSIVE DECOMPOSITION MODEL

Even for a simple fixed-rate mortgage pass-through, total amortization speed λ cannot be modeled as a function of time and the immediate market. Prepayment burnout is a strong source of path-dependence because the future refinancing activity is affected by the past incentives. One can think of a mortgage pool as of a heterogeneous population of participants having different refinancing propensities. Some borrowers have higher rate, better credit,

larger loans, or perhaps they face smaller state-enforced transaction costs. Once they leave the pool, the future prepayment activity gradually declines.

Instead of considering pricing PDE for the entire collateral, we propose decomposing it first into two components, "active" and "passive," differing in refinancing activity. Under the following two conditions, mortgage path-dependent collateral can be deemed a simple portfolio of two path-independent instruments:

1. Active and passive components prepay differently, but follow the immediate market and loan age.
2. Any migration between components is prohibited.

The Details

Here is a permissible example:

$$\begin{aligned} \text{ActiveSMM} &= \text{RefiSMM} + \text{TurnoverSMM} \\ \text{PassiveSMM} &= \beta^* \text{RefiSMM} + \text{TurnoverSMM} \end{aligned} \quad (4)$$

where RefiSMM denotes refinancing speed measured in terms of the single monthly mortality rate (SMM), TurnoverSMM is the turnover speed, and both are assumed to depend on market rates and loan age only. Parameter β quantifies relative refinancing activity for the passive component; it takes values between 0 and 1.

In order to find the total speed, we have to know the collateral composition. Denote ψ the ratio of active group to total, then

$$\begin{aligned} \lambda \equiv \text{TotalSMM} &= \psi^* \text{ActiveSMM} \\ &+ (1 - \psi)^* \text{PassiveSMM} \end{aligned} \quad (5)$$

All variables are time-dependent, but we omitted subscript t for simplicity. The initial value of ψ describes the composition of collateral at origination; both ψ_0 and β are parameters for the particular prepay model. The dynamic evolution of ψ from one time moment (t) to the next ($t + 1$) is as follows

$$\psi_{t+1} = \psi_t \frac{1 - \text{ActiveSMM}_t}{1 - \text{TotalSMM}_t} \quad (6)$$

It is worth considering a few trivial special cases. First, if ψ is zero at any instance of time, it will remain zero for life. Second, if ψ is 1 at any time, then it will retain this value as well because TotalSMM is identical to ActiveSMM from equation (5). Indeed, if the mortgage pool is either totally passive ($\psi = 0$) or totally active ($\psi = 1$), it will retain its status due to the complete absence of migration. In either of these two special cases, variables ψ and TotalSMM are path-independent, leading us to a key conclusion: The separate consideration of active and passive components avoids the problem of path-dependence altogether.

How the Model Works Forward

If $0 < \psi < 1$, then TotalSMM < ActiveSMM, the fraction in the right-hand side of formula (6) is less than 1, and ψ gradually falls. If we employed the APD model for prepay modeling while using Monte Carlo simulation for valuation, we could innovate compositional variable ψ month after month. First, we would compute refinancing and turnover speeds at time t from their respective models. Then, we would produce active, passive, and total speeds, all still at time t , from formulas (4) and (5). This information is not only sufficient to generate the t -month cash flow, but it also allows for finding the next-month composition, ψ_{t+1} , from formula (6), and proceeding forward.

Note that prepay speeds RefiSMM and TurnoverSMM depend only on current market rates and time, that is, they are path-independent. Naturally, ActiveSMM and PassiveSMM found from (4) will be path-independent as well. In contrast, variables ψ and TotalSMM are generally path-dependent except when ψ is either 0 or 1.

Let us visualize how the APD model works. Suppose we have a pool with $\psi_0 = 0.8$, that is, the active part constitutes 80% of the total at origination. Consider two possible scenarios:

Scenario A: Rates drop and remain low, inducing refinancing activity.

Scenario B: Rates rise and remain high.

Figures 1A and 1B show how the pool composition will evolve in these two cases. For scenario A, pool balance is amortized quickly due to the refinancing wave, but, more importantly, the active group (darker bars) evaporates much faster than the passive group (lighter bars). As the result, variable ψ drops from the original 80% to under 30% and, correspondingly, the total speed (as measured by conditional prepayment rate and denoted by CPR) declines—in the complete absence of any rate dynamics. A sizable speed reduction from 45 CPR to 30 CPR is caused exclusively by the burnout effect and reflected by ψ . This effect is not seen in scenario B where the active and the passive groups retire at similar rates. Pool composition barely changes, as does the total prepayment speed.

We could give prepayment behaviors depicted in Figures 1A and 1B another interesting practical interpretation. Let us assume that we wish to compare a regular fixed-rate pool (Figure 1A) with a prepayment-penalty pool (Figure 1B) under the same low-rate market conditions. The regular pool burns out—unlike the prepay-penalty one, which faces additional refinancing barriers. At the end of its penalty window (assume 60 months), this pool retains a relatively high level of ψ (71.7%). Looking at a matching speed level in Figure 1A, we conclude that, once the penalty window is over, the prepay speed will jump above 40 CPR (compared to 29 CPR of the regular pool). Therefore, the APD model naturally explains the “catch-up” effect actually known for prepay-penalty mortgages.

Above, we assumed a newly originated pool, the population of which is determined by parameter ψ_0 . In practice, a pool may be already seasoned, and today’s value of ψ , denote it $\psi(t_0)$, needs to be determined first. We will cover this task shortly.

How the Model Works in Backward Induction

If we decide to employ the APD model for backward valuation, we do not need to innovate path-dependent variables, ψ , and TotalSMM,

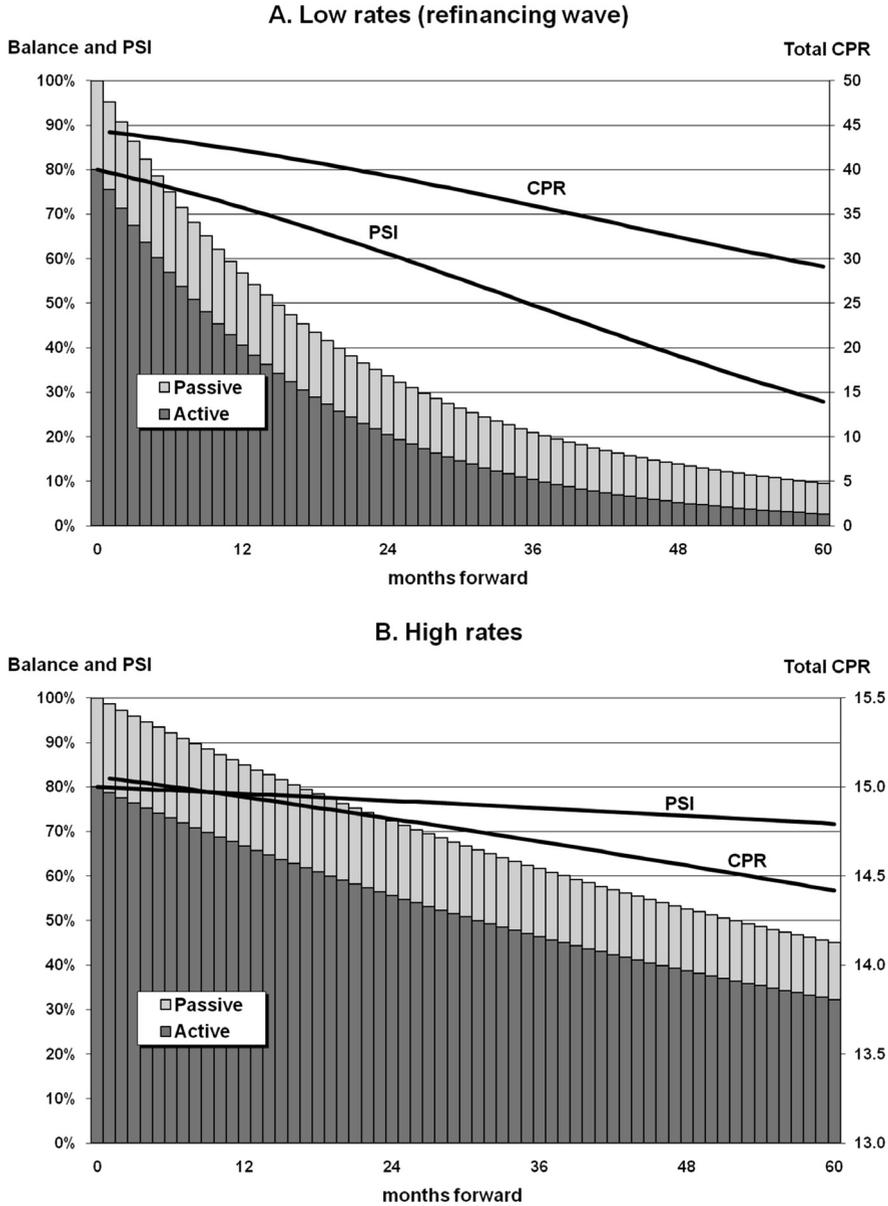

Figure 1 Simple APD Model: How It Works Forward

or keep track of their dynamics. Here are few simple steps to perform:

Step 1: Recover today’s value of the population variable, $\psi(t_0)$.

Step 2 Active: Generate cash flows on each node of a pricing grid (tree) for the active part

only and value it using a backward inducting scheme that solves pricing equation (2).

Step 2 Passive: Do the same for the passive part.

Step 3: Combine thus obtained values as

$$P = \psi(t_0)P_{active} + [1 - \psi(t_0)]P_{passive} \quad (7)$$

Interestingly enough, formula (7) applies to today’s prices obtained for all interest rate

levels of the pricing grid. As we mentioned above, computing prices on the entire grid is an inseparable part of backward valuation. Therefore, the total price can be also found on the grid, at no additional cost. In particular, the measures representing the sensitivities of an MBS price to the interest rates are found immediately, without any repetitive efforts with a stressed market (compare to Monte Carlo simulation). However, we can't apply formula (7) for future nodes because we know only $\psi(t_0)$ —today's value of ψ .

Initializing the Burnout Factor

If the pool is already seasoned, we have to assess $\psi(t_0)$ first before we can employ the APD model either for forward simulation or backward induction. There exist two main approaches to solve this problem: an analytical closed-form method and historical simulation.

Suppose that we know the pool's age, t_0 , factor, $F(t_0)$, and a constant turnover rate,¹ $\lambda_{turnover}$. Then, we can assess the turnover factor $F_{turnover}(t_0) = \exp(-\lambda_{turnover}t_0)$ along with the scheduled factor, $F_{scheduled}(t_0)$. Since the entire pool's amortization is driven by refinancing, turnover, and the scheduled payoff, the knowledge of two out of three factors along with the total pool's factor is enough to restore the entire time t_0 composition. It is easy to show that unknown $\psi(t_0)$ satisfies the following, generally transcendental, algebraic equation:

$$x + \alpha x^\beta = 1 \quad (8)$$

where α is a known parameter:

$$\alpha = \frac{1 - \psi_0}{\psi_0^\beta} \left[\frac{F_{turnover}(t_0)F_{scheduled}(t_0)}{F(t_0)} \right]^{1-\beta}$$

and β is the same speed-reducing multiplier that enters the APD model (4).

Of course, no numerical iterations are needed if β is 0, 1, or 0.5. For instance, $\beta = 1$ is a trivial case when the pool is homogeneous and is not subject to burnout, $\psi(t_0) \equiv \psi_0$. Case $\beta = 0$ was considered in Levin (2001, 2002); it leads to

$\psi(t_0) = 1 - (1 - \psi_0) \frac{F_{turnover}(t_0)F_{scheduled}(t_0)}{F(t_0)}$. A simple quadratic equation for $\psi(t_0)$ arises when $\beta = 0.5$, with only one meaningful positive solution. For all other values of β , numerical methods will suffice.

Solving equation (8) is an attractive way to initialize the burnout stage, as it does not require historical simulation of past refinancing incentives. However, it is valid only for very specific forms of the APD model, presented by formulas (4) and (5). Any possible extension of the model (such as discussed below) will make it impossible to recover the burnout stage using the pool's factor and age information only. An alternative method to estimate $\psi(t_0)$ would be a historical simulation of all prepayment components, that is, running the APD model forward from a pool origination until today. A relevant historical interest rate dataset will be required to facilitate this process.

EXTENSIONS AND NUANCES

In this section, we discuss several possibilities of exploring and extending the APD framework. We complete the section by disclosing its expected accuracy and limitations.

Computing Interest Rate Sensitivities Directly Off a Pricing Tree

Let us illustrate how interest rate exposures can be efficiently computed using prices produced on a pricing tree. The idea is to augment the tree with "ghost nodes" as shown in Figure 2; for simplicity and clarity, we illustrate the idea with a recombining binomial tree.²

The tree contains the usual nodes and links (solid lines) that refer to market conditions (interest rates) and their changes. The root node refers to today's market. We assume application of the pricing formula (3) for every transition. We carry this process from maturity backward until we reach the root. This process is carried out separately for Active and Passive

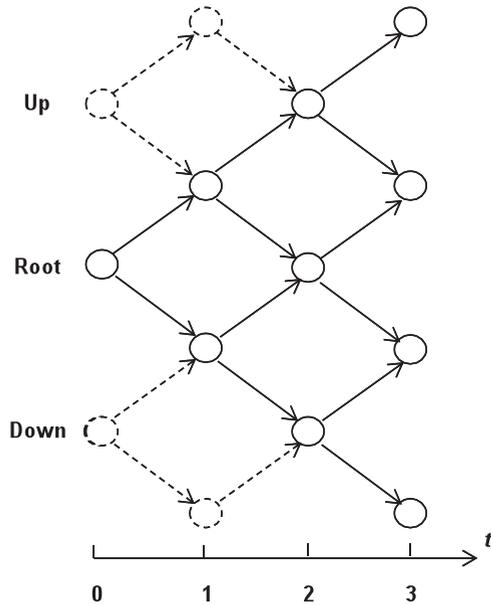

Figure 2 Extended Pricing Tree

components of the mortgage pool; at the root, we combine prices using formula (7).

Let us augment the actual tree with some nodes marked by “Up” and “Down” in Figure 2. Those nodes cannot be reached from the root, but can be perceived theoretically as results of immediate market shocks. We can add as many nodes at time $t = 0$ as we would like. These nodes and the emanating transitions are marked by dashed lines in Figure 2. If we assign transitional probabilities according to the law of our interest rate models and carry out the backward valuation process, we will end up with prices of Active, Passive, and Total prices at time $t = 0$. We can now measure duration and convexity using up and down shifts in the interest rate factor; we can also compile a risk report covering a substantial range on interest rate moves. These calculations will require carrying out the backward induction algorithm on a somewhat expanded tree, but otherwise, no extra computing efforts.

One practical question a user may have is whether interest rate shocks that are reflected in the up, the down, and other nodes are, in fact, parallel moves. In most cases, they are not. Each

node of the valuation tree represents the full set of market conditions altered by a single factor (e.g., the short rate). The entire yield curve becomes known via the relevant law of the term structure model. For example, long rates move less than the short rate if the single-factor model is mean reverting; the rate’s move may be comparable on a relative, not absolute, basis if the model is lognormal, and so on. These examples illustrate nonparallel moves in the yield curve. In these cases, it would be practically advisable to measure the Greeks with respect to the “most important” rate, such as the MBS current coupon rate or the 10-year reference rate.

Among a vast family of known short-rate models, there exists one special model whose internal law is consistent with the notion of parallel shocks. This is the Hull-White model with a zero mean reversion, also known as the Ho-Lee model³ (see, for example, Hull, 2005). When the short rate moves by x basis point, every zero-coupon rate will move by the same amount, regardless of its maturity.

If the Ho-Lee model is not employed and the sensitivity to parallel shocks of interest rates is a must (no approximation accepted), the tree-based valuation will have to be repeated using user-defined parallel moves of the yield curve. Whereas some advantages of the backward induction’s superior speed will be forfeited, the method will still stand as a viable alternative to the Monte Carlo method.

More Components, More Prepay Sources

The APD model given by (4), (5), and (6) is a two-component pool model exposed to two sources of prepayment, refinancing and turnover. Each of these features can be generalized. A mortgage pool can be thought of as a blend of many prepayment patterns (super-active, active, moderately active, and so on). On the other hand, there may exist prepayment sources that contribute to each of the groups, but are distinctly different from refinancing and

turnover. Let us briefly discuss both ways to extend the model.

As we already pointed out, even a two-component model ensures smooth prepayment behavior if each component does so. Within the APD framework, a refinancing model may include the traditional S-like curve, aging, and perhaps some other known empirical mortgage effects that can be attributed to a nonoptimal option exercise. The total prepayment speed is proven to be between RefiSMM and TurnoverSMM, being continuously weighted as controlled by variable $\psi(t)$. Adding more components into the model does not alter this fact nor does it add any smoothness in the prepay model. It is also more difficult to fit a three- or four-component model than the APD model presented here. We believe that even a simple, but dynamic, APD model captures the main prepayment factors, including burnout.

The APD model (4) assumes that the active and passive components share the same turnover rate, and their refinancing speeds relate to one another as 1 to β . We can consider some other prepayment source that is not propagated to the active and passive components identically, or with the 1 to β ratio. For example, we may introduce both default termination and credit cure prepay sources, additive to refinancing and turnover, but likely having a higher effect on the passive part than on the active part.⁴

Of course, additional prepayment sources can be formally included in the refinancing without assuming any more that active and passive refinancing models relate to one another. We will not be able to initialize $\psi(t_0)$ by solving equation (8), and we must use historical simulation for this purpose as discussed above. Principally, we may assume unrelated refinancing models built for the active and passive components, gaining generality with little sacrifice of convenience.

Residual Sources of Path-Dependence

The APD model takes care of the burnout effect, the major source of path-dependence for

fixed-rate mortgages. After the decomposition is done, we need to review residual sources of path-dependence and arrange the numerical valuation procedure to reduce or eliminate potential pricing errors.

Prepayment lag, a lookback option feature, is such a source. Applications to obtain a new mortgage replacing an old one enter the origination pipeline 30 to 90 days before the loan is actually closed and the existing debt is paid off. Even if the prepayment model features a lag, but the backward valuation scheme is unaware of its existence, the pricing results can be somewhat inaccurate. This ignorance of the lag by the backward induction scheme usually causes small errors for pass-through securities. However, mortgage strip derivatives are highly prepayment sensitive, and the lag may change their values in a sizable way.

It is generally known that lookbacks with fairly short lag periods can be accounted for in the course of a backward induction process. Let us assume, for example, that, on a trinomial monthly tree, speed λ_k actually depends on market rates lagging one month. Hence, the MBS value will also depend on both the current market and 1-month lagged market. This is to say that each valuation node of the tree should be “sliced” into three subnodes keeping track of prices matching three possible historical nodes, one month back. Of course, this costs computational time; efficiency may deteriorate quickly for deeper lags and more complex trees.

Approximate alternatives do exist and it is feasible to reduce pricing errors without much trouble. AD&Co employs a progressively sparse recombining pentagonal tree, which does not branch off every month. Branches of the tree are made from two to 12 months long so that the lagged market rates are explicitly known for most monthly steps. The lookback correction can also be adapted for the “fractional” prepayment lag that almost always exists due to the net payment delay between the accrued-month-end and the actual cash flow date. In such a case, λ_k could be interpolated

between the current-month and the previous-month values. Thus, the total lag processing should account for both prepay lookback and payment delay.

Another example of path-dependence not cured by pool decomposition is the coupon reset for adjustable-rate mortgages (ARMs). Both reset caps and nonlinear relationships between prepayments and coupons make it difficult for a backward induction scheme to account for this feature. One possible solution is to extend the state space and create an additional dimension that would keep track of the coupon rate for an ARM (Dorigan et al., 2001). This state-space extension will come at a cost of both computational efficiency and memory consumption. Levin (2002) suggests that the reset provisions found in typical ARMs allow for backward valuation with a practically acceptable accuracy, without any special measures on curing this path-dependence.

Modeling Prepayments Universally: Refinancing Speed as a Function of Price

We finish the entry with a rather interesting, if not unique, application of the APD idea where backward valuation of MBS is not an option, but a necessity. The academic literature contains quite a few works on the rational prepayment exercise models.⁵ Our APD model is not of that sort as it is a “mortgage-like” approach that can accommodate empirical features such as an S-curve or aging. Yet, it can address some shortcomings typically known for purely ad hoc empirical models. As we have already asserted, the APD model can value MBS backward provided that its refinancing and turnover constituents depend only on the current market. A likely implementation of this rule would rely on some experimental relationship between the SMMs and a relevant mortgage index. Although this is the way most mortgage practitioners envision *prepayment modeling*, it is not the only possible approach. In fact, the refinancing be-

havior of homeowners also depends on the type of mortgage in hand. Given coupon and market, the economic incentive to prepay vanishes when maturity, balloon, or ARM reset date approach. Hence, each type of mortgage and each seasoning stage call for its own refinancing model.

An attractive alternative would be linking the refinancing speed of a mortgage (still measured on the grid nodes, separately for the active and passive pieces) directly to its price appreciation, using path-independent specification $\text{RefiSMM}(\text{Price})$ instead of $\text{RefiSMM}(\text{Rate})$. This is the same hint as the one used for valuation of American option bonds except the refinancing model can still be an exogenous S-curve, not the “optimal” or “rational” exercise rule. This model would state the refinancing speed, RefiSMM , as a function of the pool’s price, for example, 15 CPR if collateral is priced at 102, 30 CPR for 105, and so on, asymptotically approaching its “ultimate” speed. Formulas (4), (5) still allow computing the active, passive, and total speeds. In particular, the passive component will still run off at a beta-reduced speed for the same price premium as the active component.

In essence, variable λ in the pricing PDE (2) becomes a function of the unknown P . Such an equation will still be path-independent, presenting no theoretical or computational issues for the backward solution. Moreover, if the refinancing behavior is indeed driven by price appreciation and such a universal relationship can be experimentally established, then the APD modeling approach and its backward implementation becomes a natural, if not the only, way to price an MBS. Any Monte-Carlo-based valuation method simply would not allow assessing future prices and, hence, prepayment speeds.

Arguably, the $\text{RefiSMM}(\text{Price})$ function can be viewed as one universal refinancing rule that can serve many collateral types. Furthermore, such a model can directly account for additional loan-specific transaction costs and cost saving

opportunities. For example, the knowledge of prepayment penalties, average loan sizes, or state-imposed taxes can easily be used to modify the S-curve.

Furthermore, the RefiSMM(Price) formulation can be used for modeling collateral behavior for CMOs as well. Although a typical CMO is path-dependent well beyond its collateral and necessitates Monte Carlo sampling, it is the prepayment modeling stage that can be done via the APD scheme. We will start with valuing collateral first on the grid or a tree, and then compute and store ActiveSMM and PassiveSMM for every node of the tree as a result of the backward inducting process described in this entry. We then run Monte Carlo simulations for the CMO in question and apply precomputed SMMs. As we pointed out, the key compositional variable $\psi(t)$ is known going forward (but not backward), thereby enabling construction of the full prepayment rate, hence, the cash flow, for every node and every path.

This approach's details and an illustration of how the same S-curve can "serve" both fixed-rate and adjustable-rate ARMs are given in Levin (2006). Pricing PDE (2) with $\lambda = \lambda(P)$ has been given mathematical consideration by Goncharov (2003, 2006), who studied the existence and uniqueness of its solution.

KEY POINTS

- The prices of mortgage-backed securities follow a partial differential equation that includes interest rates, coupon rates, and prepayment rates. Even for a simple mortgage pass-through security, this valuation PDE is path-dependent as it depends on the attained stage of burnout (hence, on past refinancing incentives).
- The active-passive decomposition model splits a pool into two path-independent, mutually exclusive borrower groups. APD naturally simulates the burnout effect.
- For mortgage pass-through securities (and their strip derivatives), APD splits valuation

into two quick backward induction steps and produces the entire pricing grid for risk measurement at no additional cost (unlike Monte Carlo simulation).

- Whereas CMOs will still rely on Monte Carlo simulation as being heavily path-dependent beyond the burnout, they will benefit from better prepay modeling.
- The backward induction pricing technique makes future values accessible and new valuation and modeling tasks feasible. For example, one can assume that the refinancing curve is a function of a loan's objective price rather than interest rates. Such an approach can be viewed as a universal model that applies to both fixed and adjustable rate pools.

NOTES

1. We can relax this condition just assuming that the historical turnover rate is known, not necessarily constant.
2. When using finite difference grids for solving the pricing PDE, the ghost nodes are part of the grid.
3. Historical calibration of the Hull-White model to the swaption volatility surface often reveals a small-to-zero level of the mean reversion constant.
4. One reason a borrower is "passive" can be due to credit-related issues.
5. See Longstaff (2003) and Stanton (1995).

Abstract: The transformation of groups of mortgage loans with common attributes into tradable and liquid MBS occurs using one of two mechanisms. Loans that meet the guidelines of the agencies (i.e., Fannie Mae, Freddie Mac, and Ginnie Mae) in terms of credit quality, underwriting standards, and balance are assigned an insurance premium (called a guaranty fee) by the agency in question and securitized as an agency pool. Loans that either do not qualify for agency treatment, or for which agency pooling execution is not efficient, can be securitized in nonagency or “private-label” transactions when such transactions are economically feasible. These types of securities do not have an agency guaranty, and must therefore be issued under the registration entity or “shelf” of the issuer. Although the analysis of private-label mortgage-backed securities utilizes many of the techniques employed to assess agency securities, the analysis must be extended in order to incorporate credit risk and adjust returns for expected principal losses, requiring additional analysis and metrics.

While the evaluation of private-label mortgage-backed securities (MBS) utilizes many of the techniques used in the evaluation of agency MBS (i.e., Ginnie Mae, Fannie Mae, and Freddie Mac MBS), the need to incorporate credit risk and adjust returns for expected principal losses requires additional analysis and metrics. The fact that the credit risk in these securities is not

assumed by the government, either explicitly or implicitly, forces investors to evaluate and judge both the timing of the return of principal as well as the amount of principal, if any, that investors can expect to receive. Moreover, credit analysis has moved up what is called the credit stack. A major change stemming from the subprime mortgage crisis is that investors

The authors acknowledge the contributions in one section of this entry by Paul Jacob.

can no longer assume that senior private-label mortgage-backed securities have virtually the same credit risk as agency MBS. Any bond that does not have agency credit support must be treated as a “credit piece” requiring the analysis of a variety of internal and external factors.

In this entry, we outline the various elements that drive the performance of nonagency MBS, and also examine the interactions of these factors.¹ We then examine a useful framework for understanding the evolution of a population’s credit profile and discuss a variety of techniques used to evaluate the credit risk and expected returns of private-label securities.

FACTORS IMPACTING RETURNS FROM NONAGENCY MBS

The analysis of agency MBS is focused on estimating the timing of principal cash flows since the government backing of these securities eliminates investors’ exposure to principal writedowns. Private-label securities require layers of additional analysis. This is because of the introduction of a series of additional factors that determine the bond’s cash flows and thus their projected returns. These factors can be broadly characterized as:

- The amount of principal expected to be returned.
- The timing of principal returns.
- The allocation of principal within the transaction.

Before proceeding, it will be helpful to review a few concepts. Prepayments on nonagency securities must be classified based on their causation. Unlike agency securities, the return of principal to the securitization (or, more specifically, the investment trust) must be treated differently depending on whether it resulted from a voluntary action by the borrower or is forced by credit-related difficulties. Modeling the impact of voluntary prepayments is relatively straightforward; investors can assume

that 100% of principal being prepaid will be returned on the next payment date. By contrast, projecting the impact of involuntary prepayments requires an estimate of both how much of every principal dollar prepaid will actually be paid to the investor, as well as when principal payments will be received by the trust.

The Amount and Timing of Principal Return

Before proceeding, a brief discussion of terminology will be helpful. For private-label securities *voluntary prepayments* encompass traditional prepayment activity. *Involuntary prepayments* are credit-related prepayments that result from defaults or other events specifically related to credit events (such as short sales of homes), while also accounting for the likelihood that less than the full amount of principal will be returned to the transaction (or, more accurately, the trust holding the deal’s collateral). Voluntary prepayments are typically quoted as VPRs, which stands for *voluntary prepayment rate*. They are calculated similar to a conditional prepayment rate (CPR), in which a monthly percentage of prepaid principal (sometimes denoted by VMM) is annualized. Involuntary prepayment speeds are quoted as *conditional default rates* (CDRs)², which are the annualized rate of default. CDRs are calculated by annualizing the monthly rate of default as a percentage of the current balance, or the MDR. The sum of the monthly VMMs and MDRs equals the total deal single monthly mortgage (SMM) rate for any particular month.

The issue of how much principal is projected to be received as a result of involuntary prepayments is a straightforward function of the assumed default rate and *loss severity*. Loss severities are simply the percentage of the defaulted principal that ultimately will not be returned to the investment trust. The inverse of loss severity is the *recovery percentage*.

The issues associated with the timing of principal return are more complex. Since the CDR is

by definition the involuntary prepayment rate, a higher default rate assumes the faster return of at least some principal to investors. As a result, the faster return of principal to the trust due to higher default rates can offset the effects of principal loss. This effect is a function of the price of the security, the loss severity, and the tranche's position in the transaction's structure (i.e., under what circumstances the security will absorb losses).

In addition, the amount of time between when a default occurs and recovered principal is received by the trust (the *lag*) can have a major influence on investor returns, especially for bonds that are more junior in priority. A longer lag between the time of default and the receipt of recovered principal delays the write-down of the junior bond's principal value. This means that the investor may receive interest payments for a longer period of time, improving the value of securities for which the interest payments comprise the bulk of expected cash flows. In fact, lower-priority subordinates are sometimes referred to as credit IOs, since investors assume that no principal will be returned, and the only cash flows that they expect to receive are coupon payments. Since the outstanding principal is written off more slowly, investors holding the tranche receive a larger and longer stream of interest payments as the lag extends.

There are a variety of factors that influence the lag. Both the amount of seriously delinquent loans at a point in time and the actions of servicers play major roles in the timing of defaults and principal recoveries. The period after 2007, for example, saw a huge increase in the number of seriously delinquent loans outstanding. At the same time, servicers (i.e., the entities that process borrower payments and manage the foreclosure process) were unable to effectively manage the huge surge in problem loans. This resulted in an enormous backup in the foreclosure pipeline, and led to long lags between the time when loans stopped performing and the properties were liquidated.

Legal and political factors also impact lag times. Since real estate transactions are governed by state and local laws, there are differences in the timing of principal returns based on the state in which a loan resides. Some states, which are referenced as judicial states, require that a foreclosure be approved by a judge, which typically slows the foreclosure process. Foreclosures in nonjudicial states can be processed faster, resulting in shorter lags. Also, the foreclosure process itself can become a matter of controversy. In 2010, for example, problems with the legal documentation of foreclosure filings led to the suspension of foreclosure proceedings in some states, as well as calls for a national foreclosure moratorium.

Generally speaking, the amount and timing of cash flows to the trust are impacted by a variety of actions and decisions taken by both borrowers and servicers, and are also influenced by exogenous factors. We discuss how these behaviors can be understood and modeled later in this entry.

Deal-Specific Factors

There are also a series of other subtle and obscure factors that can impact the cash flows and returns of nonagency securities. Some of these factors result from decisions by the servicer, while others vary depending on how an individual transaction's governing documents were written. These factors include (but are not limited to) the following:

- Servicers are required to advance principal and interest on delinquent loans. However, the governing documents of most deals state that the servicer is not required to advance any amount it deems "nonrecoverable" through the foreclosure process. The interpretation of "recoverability" depends on servicers' policies with respect to how long they will advance against seriously delinquent loans, along with the loan-to-value ratios (LTVs) of properties backing these loans. (Since expected recoveries are a function of

the current LTV, servicers often will stop advancing on loans where the current LTV exceeds a certain threshold.)

- The treatment of “modified” loans (i.e., loans for which the terms were altered in order to help borrowers meet their obligations) within individual transactions was rarely outlined in deals issued prior to the mortgage crisis. For example, there have been controversies regarding whether “forborne” (i.e., deferred) principal resulting from loan modifications should be written off immediately (which typically benefits the senior bondholders in a transaction) or deferred until the point where principal losses are realized by the trust, which would result in more interest flowing to the subordinates.
- The allocation of losses due to principal and interest “shortfalls” can become highly complex and deal-specific, particularly once the subordinate bonds in an overcollateralization structure are paid off. For example, some deals (typically those issued before mid-2005) only allow for the balances of senior bonds to be reduced by payments actually made by borrowers. These structures can experience a phenomenon called “negative overcollateralization,” which means that losses for the seniors are “implied.” As a result, losses on the senior tranches are only realized when the collateral pool is entirely paid off and the trust is terminated with some bond balances still outstanding.

One conclusion that can be drawn is that investors in private-label MBS must have the will-

ingness and ability to read and understand the documents governing their holdings. Events and factors that were either not contemplated or were viewed as highly improbable can, under adverse conditions, become important in determining investor returns.

UNDERSTANDING THE EVOLUTION OF CREDIT PERFORMANCE WITHIN A TRANSACTION

As discussed previously, the actions and decisions taken by both borrowers and servicers, along with outside environmental factors, determine both the amount and timing of cash flows received by the trust. This behavior can be conceptualized through the use of transition matrices. Such matrices show the probability of loans moving from one credit status (or “state”) to another in any month. This technique is often used as a foundation for formally modeling voluntary and involuntary speeds. We address it here, however, to help conceptualize the “life cycle” of a transaction’s credit profile. The methodology offers useful techniques for demonstrating how the credit problems of obligors evolve into delinquencies and defaults and flow through a transaction over time. It is also useful in describing and quantifying how changes in the overall credit environment might impact the performance of a loan population.

Table 1 contains a hypothetical example of a roll matrix for a loan population, which can be defined either narrowly (e.g., for a single

transaction) or more broadly (to represent a particular product and vintage). The vertical axis of the matrix shows the current (or "from") states of the population, while the horizontal axis shows the future (i.e., "to") states of the loans, typically one month hence. The horizontal axis also allows for two additional states, which would represent termination of the loans either through "payoff" (i.e., prepaid voluntarily) or "liquidation" (involuntarily prepaid). Each row must sum to 100%, as every loan in the population at time zero must transition to some state in the following month.

The matrix itself can be created through a variety of techniques. In some cases, the matrix simply represents historical experience (over either a short- or long-term horizon), while other analysts use loan-level simulations to generate the matrix. Note that not all cells have values greater than zero, as some transitions are impossible; for example, a loan cannot go from current to 60-days delinquent without first residing in the 30-days delinquent bucket.

Once a transition matrix is created, it can be applied to the population's current profile (i.e., at time T_0) as a means of projecting the population's credit performance in a future month. Table 2 illustrates the matrix math involved in generating the population's profile in month T_1 , treating the T_0 profile as a 1×7 matrix shown in Table 2(A) to be multiplied times the 7×9 transition matrix in Table 1.³ Table 2(B) shows the resulting profile one month hence (i.e., at time T_1) after summing each column, along with the percentage of loans that drop out of the population through voluntary or involuntary prepayment. The remaining population profile is then normalized by dividing the percentages of remaining loans in each credit state (i.e., excluding loans that are paid off or liquidated) by the remaining percentage in the pool. (In the exhibit, 98.8% represents the portion of the population that remains active; the 59.2% of loans expected to be current in month T_1 is divided by this percentage to get the 59.9% normalized total.)

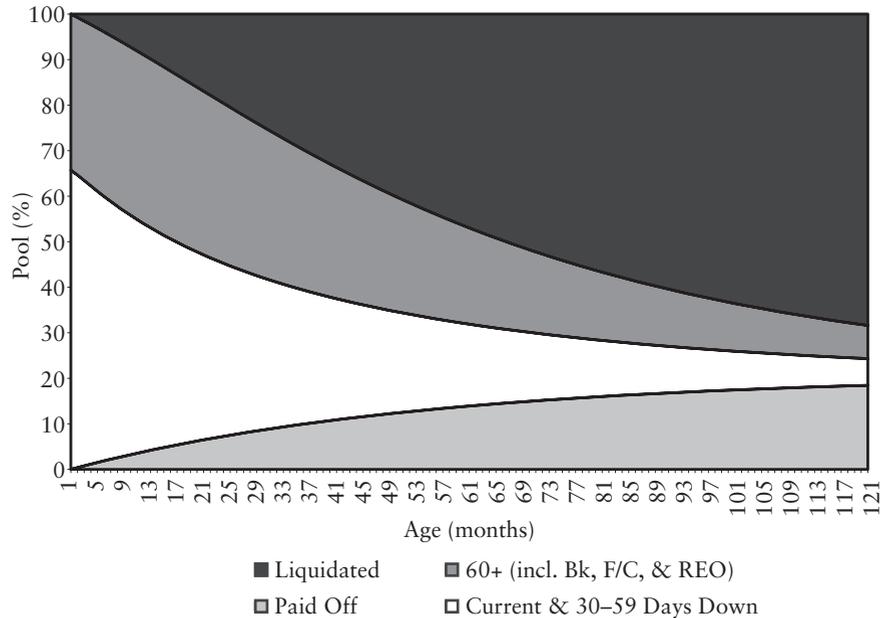

Figure 1 Projected Long-Term Performance Trends for Subject Deal

The process can be performed iteratively in order to show how the population's profile can, given unchanged transition behavior, be expected to evolve over time. (This means that the profile at T_1 can be multiplied by the transition matrix to generate a profile for time T_2 , etc.) Figure 1 shows the projected profile of the population over the next 10 years by iteratively applying the transition matrix in Table 1 to the evolving population. The chart indicates that liquidated loans (i.e., loans that go into default and are removed from the pool through the foreclosure process) will comprise the largest single cohort in around three years if current transition probabilities hold. Moreover, two-thirds of the current population can be expected to be liquidated in 10 years.

The iterative calculation can also be used to generate projections for voluntary and involuntary prepayment speeds. VPR and CDR vectors can then be utilized in yield and cash flow calculators.⁴ Figure 2 shows the vectors generated by the analysis over 120 months.

Interestingly, the vectors are neither constant nor linear; note that the CDR vector increases

fairly steadily for the first few years before leveling off around month 60. This pattern highlights the intrinsic nature of population transitions. Loans flow through the different credit states at varying rates that are a function of transition probabilities captured by the matrix. Therefore, the levels of VPRs and CDRs over time will vary even if transition activity is assumed to remain stable.

However, transition patterns normally do vary over time, reflecting changes in the economic and lending landscape as well as in the actions of servicers. The impact of changing behaviors can be captured by altering the transition matrix at a point in time. For example, a move on the part of servicers to more aggressively clean up the foreclosure pipeline would be captured in a transition framework by increasing the percentages in "late-stage" transitions (i.e., D90+ to FC, FC to REO, and REO to Liq) at a point in the future. Conversely, a full foreclosure moratorium (which was discussed in 2010) would be taken into account by changing all probabilities "from" the D90+, FC and REO buckets to zero for the expected length

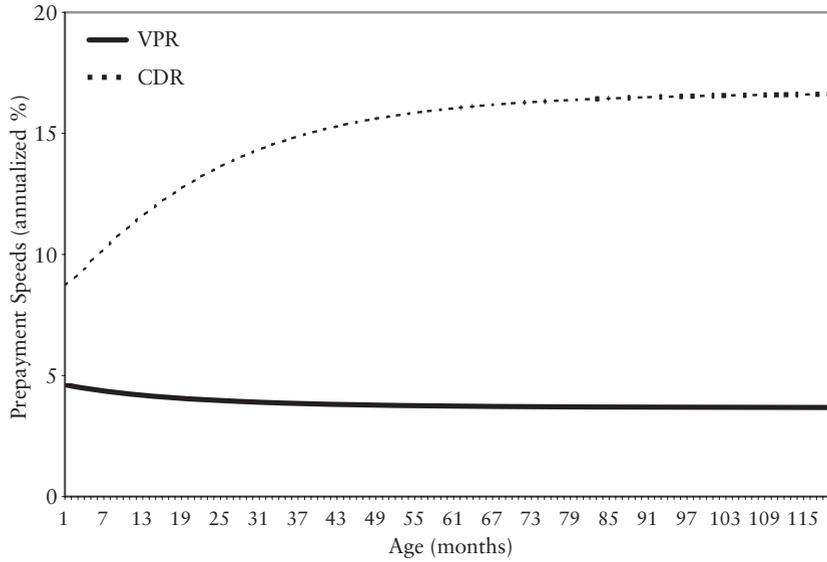

Figure 2 VPRs and CDRs for Subject Deal Using Unchanged Transition Matrix

of the moratorium. Finally, improved borrower performance would be captured by increasing “cures,” (i.e., D30 and D60 to Current) while decreasing the Current to D30 percentage. The updated matrix would be utilized at the point when the changes in behavior were expected to go into effect.

Incorporating such changes in servicer and/or borrower behavior would result in discontinuities in the VPR and CDR vectors. Along with the base vector, Figure 3 shows the projected CDRs for the subject population if the vectors are calculated using transition matrices after month 12 that reflect the “Foreclosure

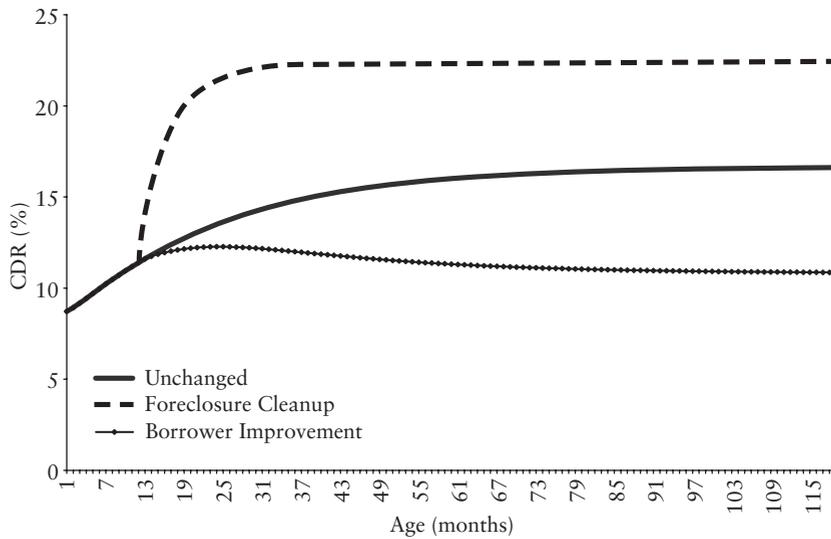

Figure 3 CDR Projections for Different Scenarios after 12 Months

Cleanup” and “Borrower Improvement” scenarios described above.

THE PROCESS OF ESTIMATING PRIVATE-LABEL MBS RETURNS

The analysis and valuation of private-label MBS is complicated by the need to project and account for a number of variables over and above those required to evaluate agency securities. As noted previously, the analysis requires additional metrics necessary to project the principal and interest cash flows paid to the trust, as well as how they will be allocated to the different tranches under a variety of scenarios.

The additional complexity associated with private-label MBS means that the dominant metric used to assess expected returns is *loss-adjusted yield*. This represents the internal rate of return (IRR) for a security’s projected cash flows using the additional factors and variables discussed previously after adjusting for the normal MBS-specific issues such as payment frequency and delay. The increased complexity associated with the product means that some methodologies, such as total return analysis, are infrequently utilized in evaluating credit pieces. For example, total return requires the estimation of a terminal value at the horizon for each scenario being analyzed. The complexity involved in projecting future prices makes them, and thus the analysis, quite subjective.

In the following sections, we illustrate the technique described in this entry using a series of tranches, as well as the collateral, from a representative 2007-vintage hybrid ARM transaction.⁵ The three tranches examined include a super-senior (SS) tranche with 24.2% original credit support; a senior mezzanine (SM) tranche (i.e., a bond originally rated triple-A but junior in priority to the SS) with original credit support of 5.25%; and a subordinate (“sub”) bond or tranche that originally had 3.85% credit enhancement.

Differentiating between Collateral and Tranche Losses

The various factors outlined above have interesting effects and interactions within individual transactions with respect to losses. For one thing, it is important to differentiate between losses on a deal’s collateral pool (i.e., at the trust level) and those impacting individual bonds within a transaction. Private-label MBS have a variety of internal mechanisms that allocate cash flows and principal losses within the structure to tranches having different degrees of seniority. Therefore, losses absorbed by individual bonds are a function of both the losses absorbed by the trust and the amount of credit support available to them.

Figure 4 shows projected losses, as a percentage of original face, for both the overall collateral pool of the deal as well as the three tranches described above. Losses were calculated using different loss severity assumptions while assuming a constant 4% VPR and CDR. (These levels are hypothetical and used for illustrative purposes only.) While the line showing projected losses on the collateral has a linear upward slope, the profile of projected losses for the tranches are quite different. For example, the SS tranche suffers no losses until severities are greater than 50%, while the SM begins to experience losses at severities greater than 40%. The sub tranche, however, has a unique loss profile. It experiences no losses until severities exceed 30%, but at that point losses spike higher; virtually the entire principal value of the bond is written off once the assumed loss severity reaches 45%. The chart highlights a critical conclusion; in addition to being different from the collateral, each bond’s exposure to losses is a function of its place in the transaction’s capital structure.

The Interaction of Credit Inputs

There are also a series of interesting observations that can be made by comparing the yields of the three bonds under a variety of scenarios.

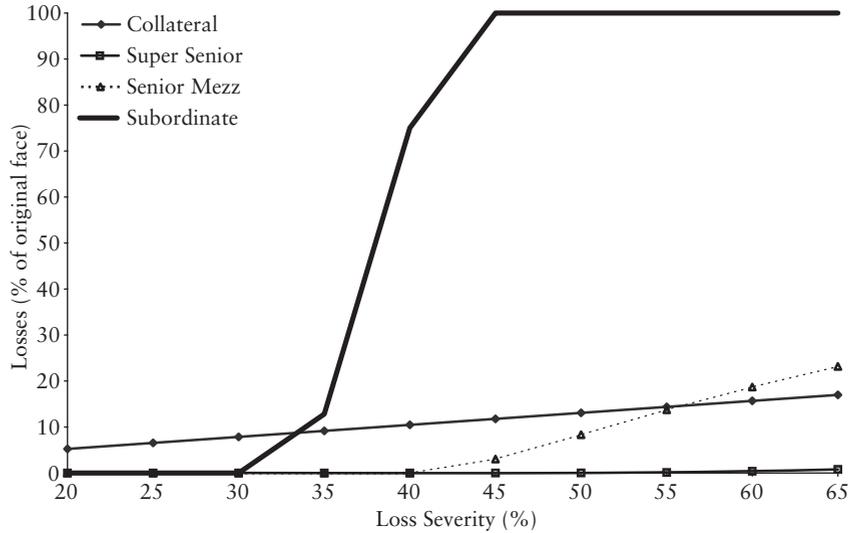

Figure 4 Collateral and Bond Projected Losses at Different Loss Severities (assumption: 4% VPR, 4% CDR, 12-month lag)

For the purposes of the analysis, the bonds were all run at the hypothetical level of a 10% yield to assumptions of 4% VPR, a 6% CDR, a 60% loss severity, and a 12-month lag. (This resulted in prices of 64-12, 48-00, and 6-22 for the three securities.) Using those base-case prices, we ran a few representative scenarios in which different variables were altered, with the goal of ex-

ploring some of the subtleties of the different tranches' returns.

Figure 5 shows yields on the three securities calculated using different CDR projections, assuming a constant 4% VPR along with a 60% loss severity and a 12-month lag. The yield on the SS tranche remains fairly stable (and actually increases slightly until the CDR reaches

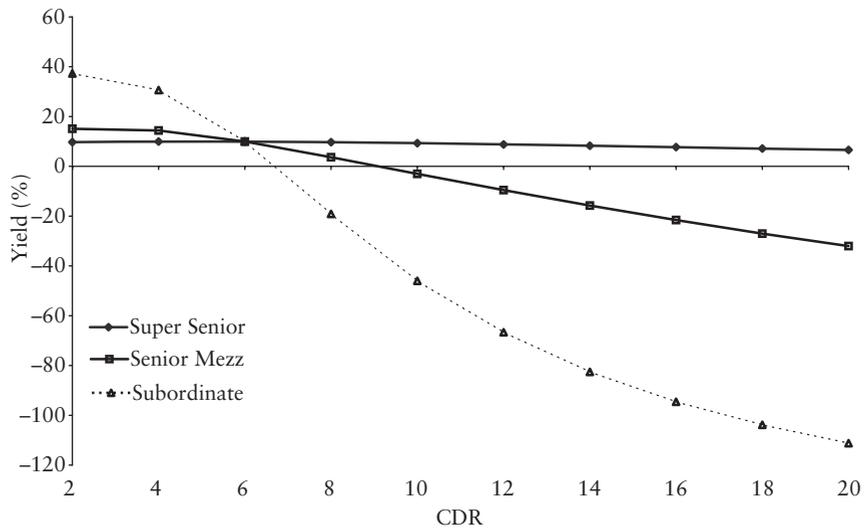

Figure 5 Projected Yields on Different Tranches Using Different CDR (assumption: 4% VPR, 60% severity, 12-month lag)

6%). The reason for this behavior is that faster CDRs effectively increase the overall rate of prepayments to the SS tranche; however, the bond does not absorb losses until the 6% CDR level is breached due to its credit support. Given the tranche's highly discounted dollar price, the faster rate of prepayments increases its yield. By contrast, yields on the more junior tranches decline as CDRs are increased since both bonds realized losses once their limited credit support is exhausted.

The rate of voluntary prepayments also influences returns for some bonds in the transaction. Figure 6 shows projected yields on the three tranches at different assumed VPRs, using a constant 6% CDR (and, as before, 60% severity and a 12-month lag assumption). While their profiles partially reflect the impact of faster prepayments on bonds with deeply discounted prices, voluntary prepayments also have a subtle impact on nonagency MBS. When voluntary prepayments increase, principal is paid back to investors at 100% of face value. This means that there is less principal outstanding that can later go into default, even if the CDR and loss sever-

ity are held constant. As a result, yields for the senior tranches are influenced (and in the SM's case, strongly so) by the expected voluntary prepayment speed.

By contrast, the yield on the sub tranche class is insensitive to changes in the VPR assumption, in part as a result of its place in the deal's structure. (Subordinates generally don't receive voluntary prepayments in an overcollateralization structure unless the deal "steps down," which does not happen under these assumptions.) Its returns, however, are highly sensitive to the combination of assumptions used for CDRs, loss severities, and lags. In particular, the severity assumption plays a key role despite the fact that the bond does not receive principal under most scenarios. As a credit IO, the tranche's outstanding principal value serves as its notional value by dictating how much interest is paid to investors in any single month. Since the severity strongly influences how fast the tranche's face value is written off, it (along with the lag assumption) dictates how long the bond will remain outstanding and thus how much interest investors can expect to receive.

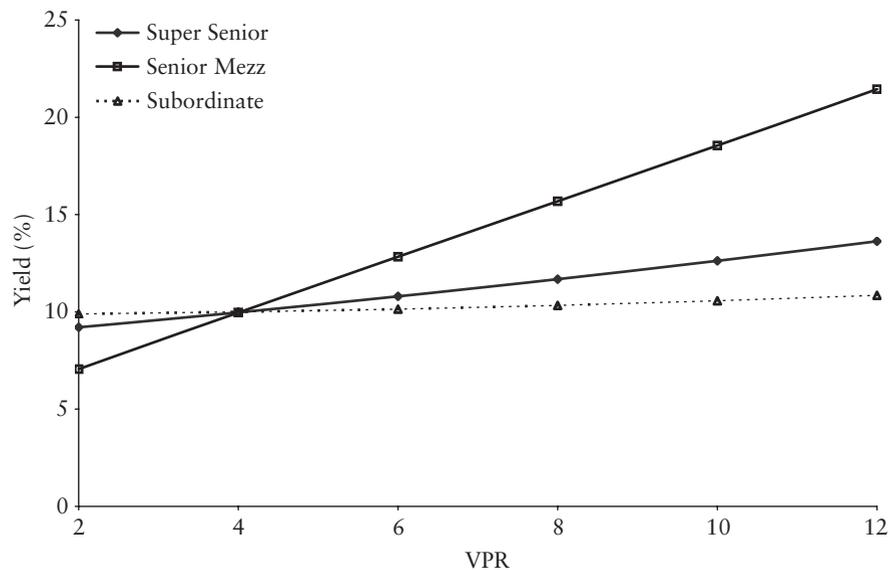

Figure 6 Projected Yields on Different Tranches Using Different VPR (assumption: 6% CDR, 60% severity, 12-month lag)

Evaluating Available Credit Support

Before evaluating projected yields and cash flows for a tranche, a prudent step is to assess the security's remaining credit support relative to the expected level of losses. The objective is to evaluate whether a bond's remaining credit support (i.e., the amount and proportion of bonds junior in priority) is adequate given the losses that the transaction is expected to absorb. The following discussion outlines a simple yet useful methodology for gauging a security's credit support relative to expected losses by using its current performance profile.

The analysis begins by evaluating a transaction's capital structure. Table 3(A) shows the original and current credit structure of a deal.

(While hypothetical, the deal's structure and profile is representative of transactions issued in 2006 and 2007.) The next step, shown in Table 3(B), uses a simple technique to estimate future cumulative losses for the transaction. Utilizing the current performance profile of the transaction, each performance cohort is assigned a probability of ultimate default, along with an assumed loss severity. The example uses a 10% estimate of ultimate default on current loans, a 50% estimate for loans that are D30, while 100% of loans that are seriously delinquent (D90, FC, and REO) are expected to ultimately default. (Note that loans in bankruptcy are not included in this calculation since they are generally captured in other

Table 3 Calculating "Coverage Ratios" for Tranches in a Transaction

A. Original and Current Deal Credit Structure				
Tranche	Orig. Rating	Orig. C/E	Curr. C/E	Curr. Factor
A1 (super senior)	AAA	25.0%	23.2%	0.6950
A2 (senior mezz)	AAA	7.5%	4.5%	0.6950
M1	AA	4.0%	2.4%	1.0000
M2	A	3.5%	1.6%	1.0000
M3	BBB	3.0%	0.8%	1.0000
M4	BB	2.5%	0.0%	1.0000
M5	B	1.5%	0.0%	0.0180
M6	NR	0.0%	n/a	0.0000
B. Current Credit Profile of Transaction				
Performance	UPB	Eventual Default	Assumed Severity	Expected Loss
Current	63.1%	10%	75%	4.73%
D30	4.4%	50%	75%	1.65%
D60	3.1%	90%	75%	2.11%
D90	14.6%	100%	75%	10.96%
FC	12.8%	100%	75%	9.61%
REO	2.0%	100%	75%	1.48%
Total				30.54%
C. Calculating Coverage Ratio				
Tranche		Curr. C/E		Coverage Ratio (curr. CE/expected loss)
A1 (super senior)		23.2%		0.760
A2 (senior mezz)		4.5%		0.147
M1		2.4%		0.079
M2		1.6%		0.052
M3		0.8%		0.026
M4		0.0%		0.000
M5		0.0%		0.000
M6		n/a		n/a

delinquency buckets.) Each delinquency cohort is multiplied by its assigned percentages and the loss severity assumption; the sum of these figures represents the percentage of losses that the deal will ultimately be expected to absorb.

The final step is to divide each tranche's current credit support percentage by the transaction's total expected losses, as shown in Table 3(C). This coverage ratio measures how much credit support is available to each tranche if the expected losses are eventually realized. In the example, the 76% coverage ratio of the A1 tranche suggests that the bond is likely to experience significant future losses, despite its current sizeable cushion. Expected losses will probably also be large enough to eventually cause the other outstanding bonds in the capital structure (i.e., the A2 down to the M5) to be entirely written down.

While this analysis serves as a useful first step in evaluating individual tranches, it is limited by its simplistic approach. The default percentages assigned to each credit bucket are arbitrary, and also cannot account for changes in the credit environment. It also doesn't take into account the issue of time, that is, when losses will accrue and bonds will be written down. This limits its usefulness in evaluating credit IOs and more junior securities. Finally, the analysis doesn't take some forms of credit support, such as excess spread and insurance wraps, into account.

Despite its limitations, however, the methodology serves as a useful first step in evaluating the credit enhancement currently supporting a tranche. In addition, investors evaluating potential purchases of newer securities will find this and related techniques particularly helpful in evaluating both the adequacy of a bond's credit support and whether it is vulnerable to a downgrade by the rating agencies.

Yield and Loss Matrix Analysis

As noted previously, the complexities associated with the product have made loss-adjusted

yield the primary metric for evaluating and comparing credit-related MBS. However, standard yield matrices must be altered in order to account for the numerous additional inputs and outputs necessary to properly evaluate private-label MBS. The additional inputs include separate entries for voluntary and involuntary prepayments, along with the inclusion of expected loss severities, lags, and servicer advances. In some cases, the analysis must also account for the presence of insurance wraps and how long they might remain in place; expectations for how long servicers will continue to advance principal and interest; and whether the deal will pass its triggers (i.e., the tests that dictate cash flow distributions within individual transactions).

In addition, a number of additional outputs are necessary in order to assess a bond's value. In addition to average life, spreads, and durations, investors need to assess expected losses on both the tranche and the deal's collateral at different levels of the inputs. Also useful are the points in time, if applicable, that the bond will experience its first principal loss, along with the amount of liquidations and losses previously realized.

Table 4 contains examples of yield matrices that might be used to evaluate the super-senior and senior mezzanine tranches introduced in an earlier section. Table 4(A) and (B) shows tables for the SS (super senior) tranche and the senior mezzanine (SM) tranche, respectively, priced (as before) at a 10% loss-adjusted yield to a 4% VPR/6% CDR base assumption. The tables in the exhibit show loss-adjusted yields and credit performance data for a range of CDRs, while holding the other variables (i.e., VPR, loss severity, and lag) constant. In addition to yields and average lives, the matrices show the durations, the dates of the first writedown, and the percentages of bond and collateral losses at the different CDR assumptions (which are the same for both tranches in this case).

However, the necessity of holding multiple inputs constant makes this format somewhat

Table 4 Example of Yield Tables for Private-Label MBS Tranches Pricing at 10% Yield at 4% VPR/6% CDR, 60% Severity, and a 12-Month Lag

A. Super-Senior Tranche (Px 64-12)

% Tranche Loss (orig. face)	0.0	18.8	34.0	41.2	45.1	47.6
% Collat. Loss (orig. face)	9.0	15.5	20.4	24.0	26.8	28.9
% Collat. Loss (curr. face)	13.0	22.5	29.6	34.8	38.8	41.9

awkward and time-consuming. For example, the tables would need to be recalculated multiple times in order to account for other assumptions for VPRs, loss severities, and lags. An alternative and somewhat more flexible scheme displays two variables as the axes, with yields and/or bond losses as the output (creating three-dimensional “surfaces” of yields and losses). Table 5 contains a matrix for the SM tranche showing VPRs on the vertical axis and CDRs on the horizontal, while holding the loss severity and lag assumptions constant. As with other forms of matrices, however, this format

is also limited to showing two variables at any one time. Additional matrices would need to be constructed in order to display different factors, depending on how relevant they were to the analysis.

Model-Generated Analysis

The variables used in the above analysis can be generated in a variety of ways, depending on both investors’ practices and the prevailing circumstances. During periods of relatively stable credit and housing performance, for example,

Table 5 Yield and Bond Loss Matrix for Senior Mezzanine Tranche at Base-Case Price

VPR	2	13.420/0.0%	12.166/25.1%	7.081/39.9%	0.309/46.0%	-6.665/49.2%	-13.249/51.1%
	4	15.067/0.0%	14.402/18.8%	9.992/34.1%	3.781/41.2%	-2.786/45.1%	-9.137/47.6%
	6	16.893/0.0%	16.681/13.9%	12.847/29.1%	7.128/36.9%	0.922/41.4%	-5.209/44.4%
	8	18.890/0.0%	19.010/9.9%	15.681/24.8%	10.396/33.1%	4.515/38.1%	-1.409/41.4%
	10	21.050/0.0%	21.394/6.6%	18.515/21.1%	13.621/29.7%	8.033/35.0%	2.306/38.6%
	12	23.368/0.0%	23.843/4.0%	21.368/17.9%	16.830/26.6%	11.509/32.2%	5.968/36.0%
		2	4	6	8	10	12
CDR							

some investors may choose to simply utilize recent history for inputs such as VPRs, CDRs, and loss severities, while making subjective adjustments based on an examination of the transaction's current collateral profile.

Alternatively, some investors may choose to utilize more sophisticated analysis, which can incorporate both the attributes of a deal's collateral along with exogenous economic and market variables. The models can be further incorporated into integrated systems that generate yield and loss figures while simultaneously analyzing and stratifying the collateral. Partial output from such an integrated system is shown in Table 6. The exhibit shows a yield matrix from Vichara Technology's system for the SS tranche.⁶ The matrix shows a variety of outputs at different multiples of the prepayment and default models, assuming unchanged home prices and interest rates. In addition, separate tables generated by the analysis (not shown) display the current credit structure of the deal, the tranche's cash flows, and analyses of the collateral. (The model also allows for the generation of a "credit OAS," although this metric is not widely utilized by investors at this writing due to its sensitivity to modeling error.)

Additional analysis can be generated for different home price appreciation (HPA) and interest rate assumptions. For example, a conservative set of assumptions might call for a 100 basis point parallel increase in rates accompanied by a 10% immediate decline in home prices. In addition, models for HPA that project different appreciation rates based on geographic and economic factors can also be utilized.

In the case of private-label securities, the normal challenge of assessing a model's "reasonableness" is complicated by the interactive nature of the variables. Unlike agency securities, where "model-equivalent CPRs" can be easily estimated (i.e., the bond's average life is iteratively calculated at various CPRs until it equals the model's calculated WAL), the division of prepayments into voluntary and involuntary categories means that a model-

equivalent CDR cannot be calculated unless the VPR is held constant, and vice versa. This necessitates the need for additional output in order to view and judge the model's VPR and CDR projections.

Interpreting the Outputs

The analysis and valuation of most securities (and virtually all fixed income investments) can be broadly summarized as assessing the "correct" level of expected returns given both market conditions and the bond's risks. This means that a number of factors need to be evaluated, including:

- The security's base-case yields and returns.
- Its returns in best- and worst-case scenarios.
- The likelihood of different scenarios being realized.

The relative complexity of analyzing private-label MBS, particularly compared to evaluating agency-backed securities, results from both the multiplicity of factors influencing returns as well as the many exogenous elements that drive these factors.

For example, a cursory evaluation of the yield matrix for the SM tranche (contained in Table 4(B)) indicates that the bond's projected yields decline rapidly as CDRs are increased. However, the matrix in Table 5 also shows that the tranche's yields remain relatively high if VPRs increase commensurately with CDRs (i.e., in the lower-right quadrant of the matrix). Alternatively, its projected yields are negative when higher CDRs are paired with lower VPRs (in the upper-right quadrant), while yields greater than 20% can be achieved with a combination of fast VPRs and slowing CDRs (the lower-left quadrant). If an investor decides that the combination of VPRs and CDRs in the upper-right quadrant represents a likely scenario, the negative yields projected for such scenarios indicates that the base-case yield assumption is too low to compensate investors for the risks being accepted.

Utilizing just these two variables, the analysis requires investors to assess the returns of

potential investments in a range of different prepayment and default scenarios with varying degrees of plausibility. Further inquiries should be made regarding expected principal losses on the investment under the assumed

scenarios, taking the availability and adequacy of credit support into account. The sensitivity of the bond's returns to changes in other relevant factors must then be examined. As an example, expectations for real estate prices will directly

impact expected loss severities, which will in turn affect an investor's willingness to buy securities that are more junior in priority. Another example relates to the state of the foreclosure pipeline and its influence on lags. During much of 2009 and 2010, the backup in the foreclosure pipeline meant that buying credit IOs, which benefited from the extended lag, was a profitable strategy as long as servicers continued to advance P&I.

The most difficult aspect of the analysis is generating expectations for factors that are difficult or impossible to quantify. The previous example of the value of credit IOs serves as an example. In addition to the dearth of significant information from servicers (who treat much of the information as having proprietary value), certain factors simply defy quantification. In addition, investors must continuously check their analysis to be certain that they understand what factors are driving their results. This means that the sort of analyses performed earlier in this entry (particularly in the section describing the interaction of factors) is highly useful in developing intuitions for how bonds can be expected to perform under varying conditions.

Note that this entry's discussions were focused on the evaluation of legacy bonds, that is, private-label MBS issued in the period prior to mid-2007. The techniques described in this entry, however, can also be used to evaluate newly issued securities, although some adjustments to the methodologies might need to be made. Investors analyzing the adequacy of credit support using the "coverage ratio" methodology demonstrated in Table 3, for example, would need to replace the use of a transaction's current credit profile with alternative ways of predicting future losses.

Finally, noticeably absent from these discussions were any mention of the rating agencies. Bond ratings cannot and should never substitute for rigorous analysis, as investors that experienced the post-2007 credit meltdown can attest. Ratings are relevant mainly due to constraints and restrictions on the holdings of regulated investors; when bond holdings are

downgraded to below investment grade, many investors are forced to liquidate them, causing their prices to crater. Techniques similar to the coverage ratios outlined previously can be used to monitor the adequacy of bonds' credit support and identify bonds that are vulnerable to being downgraded.

KEY POINTS

- In the analysis of agency MBS, since the government backing of these securities eliminates investors' exposure to principal writedown, the focus is on estimating the timing of principal cash flows.
- Private-label securities require layers of additional analysis because of the introduction of a series of additional factors that determine the bond's cash flows and thus their projected returns. These factors can be broadly characterized as (1) the amount of principal expected to be returned, (2) the timing of principal returns, and (3) the allocation of principal within the transaction.
- The issue of how much principal is projected to be received as a result of prepayments is a straightforward function of the assumed default rate and loss severity. Loss severity is measured as the percentage of the defaulted principal that will ultimately not be returned to the investment trust and of this measure is the recovery percentage.
- The amount and timing of cash flows to the trust are impacted by a variety of actions and decisions taken by both borrower and servicers, and are also influenced by exogenous factors.
- The analysis and valuation of private-label MBS is complicated by the need to project and account for a number of variables over and above those required to evaluate agency securities, requiring additional metrics necessary to project the principal and interest cash flows paid to the trust, as well as how they will be allocated to the different tranches, under a variety of scenarios.

- The additional complexity associated with private-label MBS means that the dominant metric used to assess expected returns is loss-adjusted yield.
 - Before evaluating projected yields and cash flows for a tranche, a prudent step is to assess the security's remaining credit support relative to the expected level of losses. The objective is to evaluate whether a bond's remaining credit support (i.e., the amount and proportion of bonds junior in priority) is adequate given the losses that the transaction is expected to absorb.
 - The relative complexity of analyzing private-label MBS, particularly compared to evaluating agency-backed securities, results from both the multiplicity of factors influencing returns as well as the many exogenous elements that drive these factors. The most difficult aspect of the analysis is generating expectations for factors that are difficult or impossible to quantify.
2. See Chapter 4 in Fabozzi, Bhattacharya, and Berliner (2011).
 3. The example uses the common notation where loans that are 30 to 59 days delinquent are shown as D30, loans that are 90 or more days delinquent are D90+, and so on. "Pay-off" accounts for loans that are voluntarily prepaid; "Liq" are seriously delinquent loans that are liquidated, with T_1 representing the month when recoveries are received by the trust.
 4. The vectors technically are not the equivalent of VPRs and CPRs since they don't account for the effects of amortization on the cash flows.
 5. The analysis utilized CWALT 07-HY8C A1, A2, and M1.
 6. The system utilizes the deal libraries of Intex Solutions; the analysis shown used models and data provided by CoreLogic.

NOTES

1. For an explanation of nonagency MBS, see Fabozzi (2005) and Fabozzi, Bhattacharya, and Berliner (2011).

Abstract: The valuation of residential mortgage-backed securities begins with a projection of a subject security's cash flow. The monthly cash flow from the underlying pool of mortgage loans includes three components: (1) scheduled principal payments (also referred to as amortization), (2) interest payments, and (3) any prepayments. Prepayments are any payments made by borrowers that are in excess of the scheduled principal payment. Consequently, the cash flow depends on the prepayment behavior of the borrowers in the mortgage pool. In addition to prepayments, the expected credit performance of the underlying loans must be projected to estimate a residential mortgage-backed securities cash flow. The sharp deterioration in mortgage performance that emerged in late 2006 led to the realization that prepayments and defaults often had related effects on the performance of these securities, even though they represent very different phenomena. As a result, new terminology has emerged to clarify the different circumstances that result in the early return of principal to investors. Understanding the terms used in the market to define prepayments and default experience, as well as the methodologies used to generate these metrics, is important for the following reasons: efficient risk-based pricing at the origination level; evaluation of relative value within the residential mortgage-backed securities sector (as well as across the fixed income universe); effective hedging and management of prepayment and credit risk exposure; and ex post performance attribution.

Securities backed by a pool of residential mortgage loans, referred to as *mortgage-backed securities* (MBS) or mortgage-related securities, have complex cash flow characteristics compared to the traditional government, corporate or municipal security. *Residential MBS* are classified as *agency MBS* and *nonagency MBS*. The former include MBS issued by Ginnie Mae (a federally-related government entity) and two government-sponsored enterprises (Fannie Mae and Freddie Mac). Residential MBS not issued by agency MBS are called nonagency or *private label MBS*. In turn nonagency MBS are categorized based on the credit quality of the underlying borrower or lien. There are nonagency MBS backed by prime loans, along with those backed by borrowers with blemished credit histories or an inferior lien on the mortgaged property (e.g., a second mortgage lien). The latter nonagency MBS are generically referred to as subprime MBS.¹

Complicating the cash flows projection of a residential MBS is that borrowers can prepay their loans and will in fact do so for a variety of reasons. Such *prepayments* can occur for a variety of reasons. Virtually all mortgage loans have a “due on sale” clause, which means that the remaining balance of the loan must be paid when the house is sold. Existing mortgages can also be refinanced by the obligor if the prevailing level of mortgage rates declines, or if a more attractive financing vehicle is proposed to them. In addition, homeowners can make partial prepayments on their loan, which serve to reduce the remaining balance and shorten the loan’s remaining term. Prepayments strongly impact the returns and performance of MBS, and investors devote significant resources to studying and modeling them.

For the holder of a mortgage-related security asset, the borrower’s prepayment option creates a unique form of risk. In cases where the obligor refinances the loan in order to capitalize on a drop in market rates, the investor has a high-yielding asset pay off, and it can be replaced only with an asset carrying a lower yield.

Prepayment risk is analogous to “call risk” for corporate and municipal bonds in terms of its impact on returns, and also creates uncertainty with respect to the timing of investors’ cash flows. In addition, changing prepayment “speeds” due to interest rate moves causes variations in the cash flows of mortgages and securities collateralized by mortgage products, strongly influencing their relative performance and making them difficult and expensive to hedge.

Prepayments are phenomena resulting from decisions made by the borrower and/or the lender and occur for the following reasons: (1) sale of the property (due to normal mobility, as well as death and divorce); (2) destruction of the property by fire or other disaster, (3) default on the part of the borrower, and (4) refinancing. Prepayments attributable to the first two reasons are referred to under the broad rubric of “turnover.” Turnover rates tend to be fairly stable over time, but are strongly influenced by the health of the housing market, specifically the levels of real estate appreciation and the volume of existing home sales. Refinancing activity is categorized as either “rate and term” or “cash-out” refinancings. Rate-and-term (or “no cash”) transactions generally depend on a borrower’s ability to obtain a new loan with either a lower rate or a smaller payment. This activity is therefore dependent on the level of interest rates, the shape of the yield curve, and the availability of alternative loan products. These factors also impact cash-out activity, although the primary driver of cash-out refinancings remains home price appreciation; the ability to borrow additional funds against a property is contingent on the property having appreciated in price.

The paradigm in mortgages is thus fairly straightforward. Mortgages with low note rates (that are “out-of-the-money,” to borrow a term from the option market) normally prepay fairly slowly and steadily, while loans carrying higher rates (and are “in-the-money”) are prone to experience spikes in prepayments due to

refinancings when rates decline. In turn, the relationship between a loan's note rate and the prevailing level of mortgage rates dictates whether the borrower has an incentive to refinance.

It is important to understand how changes in prepayment rates impact the performance of mortgages and MBS. Since prepayments increase as bond prices rise and market yields are declining, mortgages shorten in average life and duration when the bond market rallies, constraining their price appreciation. Conversely, rising yields cause prepayments to slow and bond durations to extend, resulting in a greater drop in price than experienced by more traditional (i.e., option-free) fixed income products. As a result, the price performance of mortgages and MBS tends to lag that of comparable fixed maturity instruments (such as Treasury notes) when the prevailing level of yields changes. This phenomenon is generically described as *negative convexity*. The effect of changing prepayment speeds on mortgage durations, based on movements in interest rates, is precisely the opposite of what a bondholder would desire. (Fixed income portfolio managers, for example, extend durations as rates decline, and shorten them when rates rise.) The price performance of mortgages and MBS is, therefore, decidedly nonlinear in nature, and the product will underperform assets that do not exhibit negatively convex behavior as rates fluctuate.

Consequently, it is essential for participants in the residential MBS market to understand the general prepayment and credit performance nomenclature. The market is characterized by the usage of a variety of terms; some terms describe general phenomena, while others are specific to certain types of loan products and assets. In this entry, the basic terms used to characterize residential mortgage-related prepayments and losses are discussed. Our focus is on describing the terminology and outlining the methodologies used in calculating relevant metrics, not on the determinants of prepayment and default behavior.

PREPAYMENT TERMINOLOGY

For fixed-rate fully amortizing assets, such as, home equity loans (HELs), and manufactured housing loans (MHs), the monthly scheduled payment (consisting of scheduled principal and interest) is constant throughout the amortization term. If the borrower pays more than the monthly scheduled payment, the extra payment will be used to pay down the outstanding balance faster than the original amortization schedule, resulting in a prepayment (or, as it is sometimes referenced, an unscheduled principal payment). If the outstanding balance is paid off in full, the prepayment is a complete prepayment; if only a portion of the outstanding balance is prepaid, the prepayment is called either a partial prepayment or curtailment. Prepayments can be the result of natural turnover, refinancings, defaults, partial paydowns, and credit-related events.

The evaluation of prepayments is further complicated by the fact that there is an interplay between *defaults*, which are effectively credit-related prepayments, and prepayments attributable specifically to declining interest rates. In agency MBS (i.e., pools issued by Ginnie Mae, Fannie Mae, and Freddie Mac) there have at times been large numbers of seriously delinquent loans in pools for which Freddie Mac and Fannie Mae continued to pay interest and scheduled principal. In 2010, however, the two government-sponsored enterprises (Fannie Mae and Freddie Mac) changed their policies and began buying loans that were 120 days or more delinquent out of pools. These buyouts initially resulted in a surge in prepayment speeds. Moreover, the new policy meant that pools containing large numbers of lower-quality loans would tend to experience consistently faster prepayment speeds than those pools backed by better-credit loans.

However, for private-label MBS, prepayments resulting from credit events must be treated differently than those attributable to

refinancings. This is because a default means that the investor will probably not receive the entire amount of the defaulted principal, but only the amount recovered after the foreclosure process is completed. Moreover, the timing of payments is also at issue. There is typically a sizeable delay between the time a borrower becomes delinquent on a loan and its ultimate liquidation. This has resulted in the convention where prepayments in private-label securities are separated into *voluntary* and *involuntary prepayments*. Voluntary prepayments occur as a result of a refinancing, the sale of the property, or other events (e.g., the death of the property owner) where the full principal amount is paid immediately to the bondholder. Involuntary prepayments occur as a result of a credit event, for which both the timing and net principal received are uncertain.

Prepayments and defaults can be analyzed on both the loan and pool level. Loan-level prepayment analysis, which requires detailed loan-level information, is more accurate than pool-level prepayment analysis, but is also more computationally intensive. Additionally, this type of analysis allows the inclusion of specific obligor and property characteristics as determinants of prepayments and defaults. Loan-level analysis involves tracking defaults and prepayments on an individual loan basis, projecting each loan's cash flows, and combining these amounts to calculate aggregated metrics. Due to the diversity of the characteristics of the underlying loans in most deals, loan level analysis is generally more accurate and has greater predictive capabilities.

CALCULATING PREPAYMENT SPEEDS

The first critical step in calculating prepayment speed is to define a prepayment. For the purposes of this discussion, a prepayment is defined as the early return of principal to the

investor. By definition, this means that amortization (or scheduled principal payments) must be excluded from the calculation, leaving only unscheduled principal payments to be analyzed.

Conditional Prepayment Rate

The approach most commonly used to generate prepayment speeds is to calculate monthly prepaid principal as a percentage of the security's outstanding balance and then annualize that percentage. Most current approaches to prepayment calculations either quote this annualized periodic speed, known as the *conditional prepayment rate* (CPR) directly or use it as an input to generate other quotation benchmarks.² This methodology is useful in that it allows analysts to both calculate the historical prepayment experience of a security, as well as project prepayment speeds (and thus a security's cash flows) into the future. When used as part of a model to generate projected cash flows, the CPR calculation assumes that some fraction of the unpaid principal balance (or UPB) of the pool is prepaid each month for the remaining term of the mortgage. The advantages of this approach are its simplicity and its flexibility. For example, changes in economic conditions that impact prepayment rates or changes in the historical prepayment pattern of a pool can be analyzed quickly. In addition, the CPR can be used as an input to other models and quotation mechanisms, as noted already.

The CPR is an annual rate. However, because mortgage cash flows are a monthly phenomenon, calculating the CPR requires the generation of a monthly prepayment rate, called the *single monthly mortality rate* (SMM). The SMM is the most fundamental measure of prepayment speeds. SMM measures the monthly prepayment amount as a percentage of the previous month's outstanding balance minus the scheduled principal payment. Mathematically, the SMM is calculated as follows:

$$SMM = \frac{\text{Total payment, including prepayments} - \text{Scheduled interest payment} - \text{Scheduled principal payment}}{[\text{Unpaid principal balance} - \text{Scheduled principal payment}]}$$

For example, if the pool balance at month zero is \$10,000,000, assuming an interest rate of 12%, the scheduled principal and interest payments are \$2,861.26 and \$100,000 in month one, respectively. If the actual payment received by investors in month one is \$202,891.25, the SMM rate is 1%, calculated as

$$SMM = \frac{(\$202,891.25 - \$100,000 - \$2,861.26)}{(\$10,000,000 - \$2,861.26)} = 1\%$$

Therefore, if a mortgage loan prepaid at 1% SMM in a particular month, this means that 1% of that month’s scheduled balance (last month’s outstanding balance minus the scheduled principal payment) has been prepaid.

Given the SMM, a CPR can be computed using the following formula:

$$CPR = 1 - (1 - SMM)^{12}$$

For example, if the SMM is 1%, then the CPR is

$$CPR = 1 - (0.99)^{12} = 11.36\%$$

Conversely, CPRs can be converted into SMMs (and thus be used to generate monthly cash flows) through the following formula:

$$SMM = 1 - (1 - CPR)^{1/12}$$

For example, suppose that the CPR used to estimate prepayments is 6%. The corresponding SMM is

$$SMM = 1 - (1 - 0.06)^{1/12} = 1 - 0.94^{0.08333} = 0.5143\%$$

PSA Prepayment Benchmark

The *Public Securities Association (PSA) prepayment benchmark* is expressed as a monthly series of annual prepayment rates.³ The basic PSA model assumes that prepayment rates are low for newly originated mortgages and then increase linearly as the mortgages age or season.

The PSA standard benchmark assumes the following prepayment rates for 30-year mortgages:

1. A CPR of 0.2% for the first month, increased by 0.2% per year per month for the next 29 months when it reaches 6% per year.
2. A 6% CPR for the remaining years.

This benchmark, referred to as “100% PSA” or simply “100 PSA,” is graphically depicted in the middle graph in Figure 1. Mathematically, 100 PSA can be expressed as follows:

$$\begin{aligned} \text{If } t \leq 30 \text{ then } CPR &= 6\% \times (t/30) \\ \text{If } t > 30 \text{ then } CPR &= 6\% \end{aligned}$$

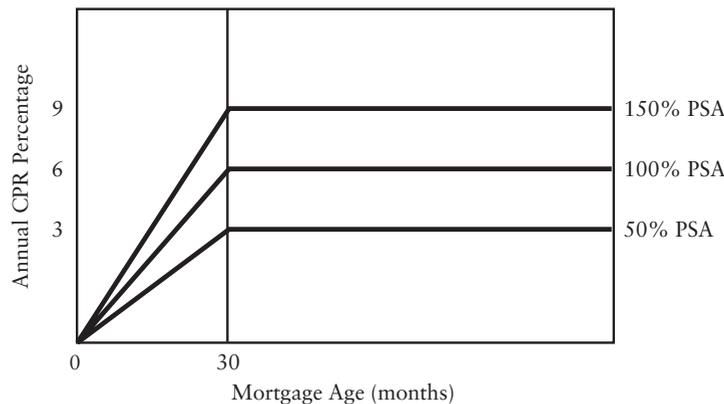

Figure 1 Graphical Depiction of 50 PSA, 100 PSA, and 300 PSA

where t is the number of months since the mortgage was originated. Since the CPR prior to month 30 rises at a constant rate, this period is sometimes referred to as the “ramp,” and loans are considered to be “on the ramp” when they are less than 30 months old.

Slower or faster speeds are then referred to as some percentage of PSA. For example, 50 PSA means one-half the CPR of the PSA benchmark prepayment rate; 150 PSA means 1.5 times the CPR of the PSA benchmark prepayment rate; 300 PSA means three times the CPR of the benchmark prepayment rate. This is illustrated graphically in Figure 1 for 50 PSA, 100 PSA, and 150 PSA. A prepayment rate of 0 PSA means that no prepayments are assumed.

It is important to note that mortgage pools will typically be comprised of loans having different origination months and, therefore, different ages. In practice, the weighted average loan age (WALA) of a pool or security is used as a proxy for its age. However, a large dispersion of loan ages within a pool will distort the PSA calculation.

It is helpful to outline the CPRs and SMMs assumed at different PSA assumptions for different loan ages. The SMMs for month 5, month 20, and months 31 through 360 assuming 100 PSA are calculated as follows:

For month 5:

$$\begin{aligned} \text{CPR} &= 6\% (5/30) = 1\% = 0.01 \\ \text{SMM} &= 1 - (1 - 0.01)^{1/12} = 1 - (0.99)^{0.083333} \\ &= 0.000837 \end{aligned}$$

For month 20:

$$\begin{aligned} \text{CPR} &= 6\% (20/30) = 4\% = 0.04 \\ \text{SMM} &= 1 - (1 - 0.04)^{1/12} = 1 - (0.96)^{0.083333} \\ &= 0.003396 \end{aligned}$$

For months 31–360:

$$\begin{aligned} \text{CPR} &= 6\% \\ \text{SMM} &= 1 - (1 - 0.06)^{1/12} = 1 - (0.94)^{0.083333} \\ &= 0.005143 \end{aligned}$$

The SMMs for month 5, month 20, and months 31 through 360 assuming 165 PSA are computed as follows:

For month 5:

$$\begin{aligned} \text{CPR} &= 6\% (5/30) = 1\% = 0.01 \\ 165 \text{ PSA} &= 1.65 (0.01) = 0.0165 \\ \text{SMM} &= 1 - (1 - 0.0165)^{1/12} \\ &= 1 - (0.9835)^{0.083333} = 0.001386 \end{aligned}$$

For month 20:

$$\begin{aligned} \text{CPR} &= 6\% (20/30) = 4\% = 0.04 \\ 165 \text{ PSA} &= 1.65 (0.04) = 0.066 \\ \text{SMM} &= 1 - (1 - 0.066)^{1/12} = 1 - (0.934)^{0.083333} \\ &= 0.005674 \end{aligned}$$

For months 31 through 360:

$$\begin{aligned} \text{CPR} &= 6\% \\ 165 \text{ PSA} &= 1.65 (0.06) = 0.099 \\ \text{SMM} &= 1 - (1 - 0.099)^{1/12} = 1 - (0.901)^{0.083333} \\ &= 0.007828 \end{aligned}$$

Notice that the SMM assuming 165 PSA is not 1.65 times the SMM at 100 PSA. Rather, the CPR for the pool’s age at 100 PSA is multiplied by 1.65 to generate the CPR representing 165 PSA at that age.

Illustration of Monthly Cash Flow Construction

We now show how to construct a monthly cash flow for a hypothetical agency pass-through given a PSA assumption. For the purpose of this illustration, the underlying mortgages for this hypothetical pass-through are assumed to be fixed rate fully amortizing mortgages with a weighted average coupon (WAC) rate of 6.0%. It will be assumed that the mortgage pass-through rate is 5.5% with a weighted average maturity (WAM) of 358 months.

Table 1 shows the cash flow for selected months assuming 100 PSA. The cash flow is broken down into three components: (1) interest (based on the pass-through rate), (2) the

Table 1 Monthly Cash Flow for a \$400 Million Mortgage Pass-Through with a 5.5% Pass-Through Rate, a WAC of 6.0%, and a WAM of 358 Months, Assuming 100% PSA

^a Since the WAM is 358 months, the underlying mortgage pool is seasoned an average of two months. Therefore, the CPR for month 28 is 6%.

regularly scheduled principal payment, and (3) prepayments based on 100 PSA. Let's walk through Table 1 column by column:

Column 1. This is the month.

Column 2. This column gives the outstanding mortgage balance at the beginning of the month. It is equal to the outstanding balance at the beginning of the previous month reduced by the total principal payment in the previous month.

Column 3. This column shows the SMM for 100 PSA. Two things should be noted in this column. First, for month 1, the SMM is for a pass-through that has been seasoned three months because the WAM is 357 months. This results in a CPR of 0.8%. Second, from month 27 on, the SMM is 0.00514, which corresponds to a CPR of 6%.

Column 4. The aggregate monthly mortgage payments using a 6% note rate are shown in this column. Notice that the total monthly mortgage payment declines over time, as prepayments reduce the mortgage balance outstanding. (In the absence of prepayments, this figure would remain constant.) In essence, the payment is calculated each month as a function of the WAC, the remaining balance at the end of the prior month, and the remaining term (i.e., the original WAM minus the number of months since issuance). For example, the payment in month 10 of \$2,376,474 can be generated on a calculator by inputting \$391,508,422 as the balance or present value, 0.5% (6.0% divided by 12) as the rate, and 348 months as the remaining term.⁴

Column 5. The monthly interest paid to the pass-through investor is found in this column. This value is determined by multiplying the outstanding mortgage balance at the beginning of the month by the pass-through rate of 5.5% and dividing by 12.

Column 6. This column shows the scheduled principal repayment, or amortization. This is the difference between the total monthly

mortgage payment [the amount shown in column (4)] and the gross coupon interest for the month. The gross coupon interest is 6.0% multiplied by the outstanding mortgage balance at the beginning of the month, then divided by 12.

Column 7. The dollar value of prepayments for the month is reported in this column. This amount is calculated by using the following equation:

$$\begin{aligned} \text{Prepayments}_t &= \text{SMM}(\text{Beginning principal balance}_t \\ &\quad - \text{Scheduled principal balance}_t) \end{aligned}$$

So, for example, in month 100, the beginning mortgage balance is \$223,414,587, the scheduled principal payment is \$423,356, and the SMM at 100 PSA is 0.00514301 (only 0.00514 is shown in the table to save space), so the prepayment is

$$\begin{aligned} &0.00514301 \times (\$223,414,587 - \$423,356) \\ &= \$1,146,847 \end{aligned}$$

Column 8. The total principal payment, which is the sum of columns (6) and (7), is shown in this column.

Column 9. The projected monthly cash flow for this pass-through is shown in this last column. The monthly cash flow is the sum of the interest paid to the pass-through investor [column (5)] and the total principal payments for the month [column (8)].

Prospectus Prepayment Curve

A more recent addition to MBS prepayment terminology is the prospectus prepayment curve (PPC). While the logic underlying the PSA convention (i.e., that loans prepay faster as they age, all other factors constant) remains in force, a PPC curve allowed its creator (typically the underwriter of a private-label deal) to specify the prepayment ramp that was used to structure the deal. Evidence suggested that loans have seasoned faster than the 30 month period

implied by the PSA curve, especially for some products (such as alt-A loans) that were believed to season faster than normal. Rather than use a percentage of a publicly utilized ramp, PPC curves (which are quoted in a transaction's prospectus supplement) were used for many nonagency transactions between 2004 and 2007.

Typically, 100% PPC is the base-case prepayment assumption used to create a particular deal. PPC curves (or ramps) are generally specified as a beginning and terminal CPR, along with the associated time period. A typical ramp might be specified as "8–20% CPR over 12 months." This translates to an assumption of 8% CPR in the first month, increasing 1.09% per month for the next 11 months, and terminating at 20% CPR in month 12. However, there is no industry standardization for the usage of this terminology, as the specification is issue-dependent. As a result, investors must confirm how "100% PPC" is defined for each particular issue before performing further analysis.

The language utilized in a deal's prospectus supplement is illuminating. For example, the document for the CWALT 2005-J9 deal has language as follows:

Prepayments of mortgage loans commonly are measured relative to a prepayment standard or model. The model used in this prospectus supplement assumes a constant prepayment rate (i.e., CPR) or an assumed rate of prepayment each month of the then-outstanding principal balance of a pool of new mortgage loans. A 100% prepayment assumption for loan group 1 (the "prepayment assumption") assumes a CPR of 8.0% per annum of the then outstanding principal balance of the applicable mortgage loans in the first month of the life of the mortgage loans and an additional approximately 1.0909090909% (precisely 12%/11) per annum in the second through 11th months. Beginning in the 12th month and in each month thereafter during the life of the mortgage loans, a 100% prepayment assumption assumes a CPR of 20.0% per annum each month.

Note that the prospectus supplement does not directly refer to a "PPC," but rather defines

the prepayment ramp as "a 100% prepayment assumption."

Prepayment Conventions for Securities Backed by Home Equity and Manufactured Housing Loans

While the expression of prepayments in the MBS market is fairly standardized and comprises a combination of PSA curves and CPR calculations as previously described, a variety of descriptions are used to express the pay-down behavior of securities backed by home equity and manufactured housing loans. While issuance of securities backed by these loans fell out of favor in the mid-2000s, a brief discussion of these conventions will nonetheless be helpful in understanding how prepayment conventions have been adjusted in order to represent an asset's unique behavior. Despite the diversity in terminology, most of the concepts used to indicate prepayments for these two sectors of the mortgage market use the CPR concept as the numeraire while incorporating the PSA ramping methodology.

Home Equity Prepayment Speeds

In the early stages of the development of the securitized market for home equity loans, the majority of the loans were fixed rate, closed-end loans. Over the years, the balance has slowly shifted in favor of adjustable rate loans, particularly subprime ARMs. The earliest definition of prepayment speeds in the home equity market was the *home equity prepayment (HEP) curve*.⁵ The primary motivation for using a different prepayment methodology for home equity loans was to capture the faster seasoning ramp observed for the asset class. Typically, home equity loans season faster than traditional single-family loans, making the PSA ramp an inappropriate description of the behavior of prepayments.

The HEP curve reflects the observed behavior in historic HEL data—it has a ramp of

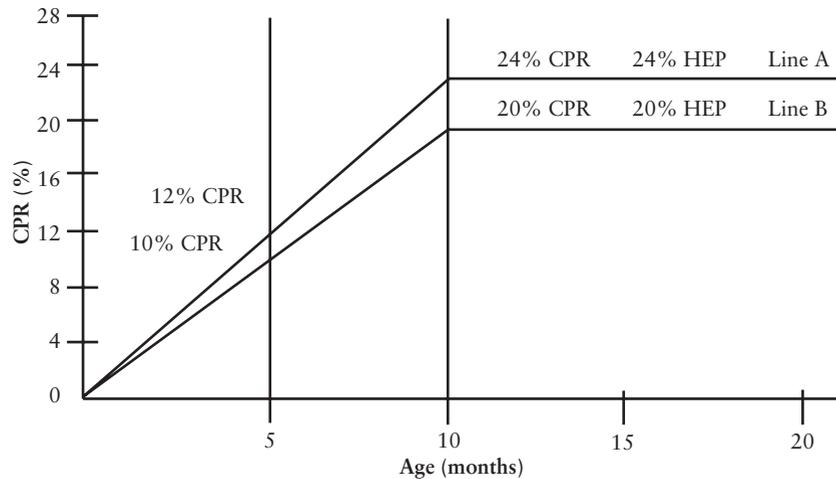

Figure 2 HEP Curves

10 months and a variable long-term CPR to reflect individual issuer speeds. A faster long-term speed means faster CPRs on the ramp because the ramp is fixed at 10 months regardless of the long-term speed. For example, a 20% HEP projection would mean a 10-month ramp increasing to 20% in the 10th month from 2% in the first month and a constant 20% thereafter. Figure 2 shows several HEP curves at 20% HEP and 24% HEP, where month 1 speeds of 2.4% CPR increase over 10 months to 24% CPR.

In addition to utilizing the HEP curve, a PPC ramp is also commonly used to define the base-case prepayment assumption for the product. As with other mortgage products, the specification of the ramp will be dependent on the attributes of the underlying loan collateral, with respect to both the beginning and terminal speeds as well as the duration of the ramp. Occasionally, deals are also priced to a constant CPR assumption, ignoring the impact of seasoning in generating the deal's cash flows.

Manufactured Housing Prepayment Curve

The *manufactured housing prepayment* (MHP) curve is a measure of prepayment behavior for manufactured housing, based on the Green Tree

Financial manufactured housing prepayment experience. MHP is similar to the PSA curve, except that the seasoning ramp is slightly different to account for the specific behavior of manufactured loans: 100% MHP is equivalent to 3.6% CPR at month zero and increases 0.1% CPR every month until month 24, when it plateaus at 6% CPR. Figure 3 shows the prepayment speeds at 50% MHP, 100% MHP, and 200% MHP.

DELINQUENCY, DEFAULT, AND LOSS TERMINOLOGY

The measurement of potential and actual cash flow impairment resulting from borrower credit problems is critically important to the analysis of private label or nonagency MBS. Historically, the importance of these measures stemmed from their role in allowing investors in subordinate MBS tranches to assess relative value and risk. However, the mortgage crisis that began in 2007 demonstrated to investors that all nonagency securities have exposure to defaults and losses; put differently, it is impossible to invest in nonagency MBS without taking on a material degree of credit risk. This means that any divergence in realized default and loss experience from investors' initial expectations can result in writedowns and losses on the investment.

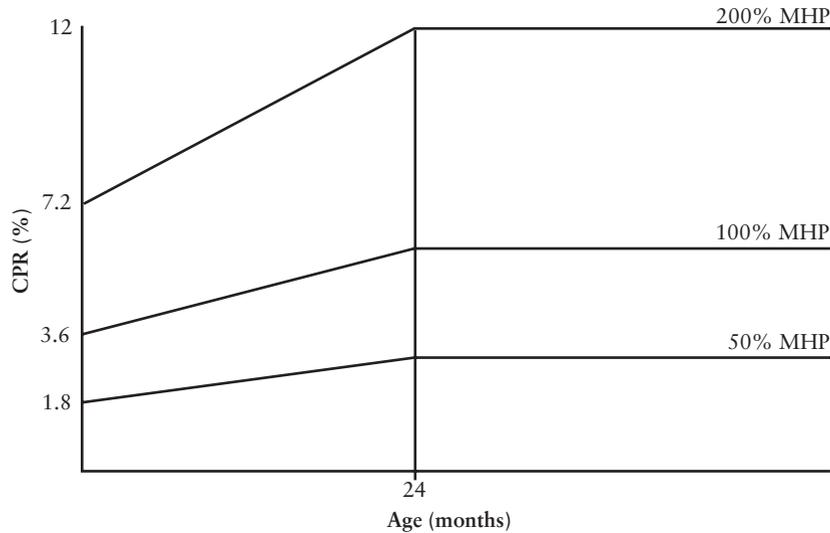

Figure 3 MHP Curves

Despite the importance of delinquencies, losses, and defaults in the mortgage-related markets, the terminology is not standardized. For instance, static pool losses may be reported on a monthly or annualized basis as a percentage of either current or original balance, with the metric based upon current balance being the preferred method to ensure consistency with prepayment reporting.

Before we discuss the measurement of defaults and losses, it is instructive to briefly review the various outcomes of a loan when the obligor ceases making scheduled payments. A loan becomes delinquent when the obligor fails to make the contractual payment on the stated date. If the underlying property has appreciated from the initial purchase price, the homeowner can often sell the home and use the proceeds to settle the mortgage debt. (This generally is categorized as a voluntary prepayment and is considered part of housing turnover.) If the homeowner cannot sell the property at a high enough price and remains delinquent, the loan is declared to be in default once all collection (and modification) efforts have failed. At that point, the issuer (or the servicer) has several options. There may either be a short sale, where the borrower sells the property in a negotiated

transaction subject to approval by the servicer; alternatively, the property may go into the foreclosure or repossession process and be eventually sold by the servicer. Therefore, the process chain is delinquency to default to foreclosure (or repossession) to liquidation, at which time the severity of loss can be assessed.

Delinquency Measures

As mentioned, when a borrower fails to make one or more timely payments, the loan is said to be delinquent. Delinquency measures are designed to gauge whether borrowers are current on their loan payment as well as to stratify unpaid loans according to the seriousness of the delinquency. The calculation method used is determined by the servicer. When the underlying pool of assets is comprised of mortgage loans, the two commonly used methods for classifying delinquencies are those recommended by the now-defunct Office of Thrift Supervision (OTS) and the Mortgage Bankers Association (MBA).

The OTS method uses the following loan delinquency classifications:

- Payment due date to 30 days late: Current
- 30–60 days late: 30 days delinquent

- 60–90 days late: 60 days delinquent
- More than 90 days late: 90+ days delinquent

The MBA method is a somewhat more stringent classification method, classifying a loan as 30 days delinquent once payments are not received after the due date. Thus, a loan classified as “current” under the OTS method would be listed as “30 days delinquent” under the MBA method. The two methods can report significantly different delinquencies.⁶

Default Measures

The conditions that result in classification of some loans as delinquent (such as the loss of a job or illness) may change, resulting in the resumption of timely principal and interest payments. However, some portion of the loans classified as delinquent typically end up in default. By definition, default is the point where the borrower loses title to the property in question.

Two broadly used measures for quantifying default are the cumulative default rate and the conditional default rate. The cumulative default rate (denoted as the CDX) is the proportion of the total face value of loans in a pool that have gone into default as a percentage of the total face value of the security.

The *conditional default rate* (CDR) is the annualized value of the unpaid principal balance of newly defaulted loans over the course of a month as a percentage of the unpaid balance of the pool (before scheduled principal payment) at the beginning of the month. It is computed by first calculating the *monthly default rate* (MDR) as shown below:

$$\text{MDR for month } t = \frac{\text{Default loan balance in month } t}{\text{Beginning balance for month } t - \text{Scheduled principal payment in month } t}$$

This is then annualized as follows to get the CDR:

$$\text{CDR}_t = 1 - (1 - \text{Default rate for month } t)^{12}$$

Note that the conversion of MDR to CDR is identical to the formula for converting SMMs

to CPRs. As described earlier, the default rate represents involuntary prepayments, and the CDR represents the involuntary prepayment speed calculated for nonagency MBS. Voluntary prepayment speeds (i.e., those resulting from refinancing activity and housing turnover) must be calculated separately.

Let’s use the following as an example. Assume that a nonagency pool⁷ with an 8% note rate and 300 months left to maturity has a balance at time t of \$10,000,000. The pool’s scheduled monthly payment is \$77,181.62, comprised of \$66,666.67 in interest and \$10,514.96 in scheduled principal. Assume that the pool receives \$20,000 of voluntary prepayments and \$15,000 in involuntary prepayments.⁸

The monthly voluntary prepayment speed is calculated as follows:

$$\text{Voluntary SMM} = \frac{\$20,000}{\$10,000,000 - \$10,514.96} = 0.002$$

This can then be converted to 2.37% CPR.

The MDR is calculated similarly:

$$\text{MDR} = \frac{\$15,000}{\$10,000,000 - \$10,514.96} = 0.0015$$

which can be converted to 1.78% CDR.

In some cases, the involuntary and voluntary prepayment speeds are combined to calculate a single prepayment speed. In this case, the calculation of a “total CPR” is as follows:

$$\text{Total SMM} = \frac{\$35,000}{\$10,000,000 - \$10,514.96} = 0.0035$$

which can be converted to a total CPR of 4.12%.

There are a number of issues implied by these calculations. First, note that the voluntary SMM and MDR equals the pool’s total SMM. (It is not true, however, that CPRs and CDRs sum to equal the total pool CPR; it is only the monthly rates that are additive.) In using the output of a model, it is also important to ascertain what the vendor means when they quote a “CPR.” Since many systems will show CPRs as the annualized rate of all prepayments (i.e., total CPRs)

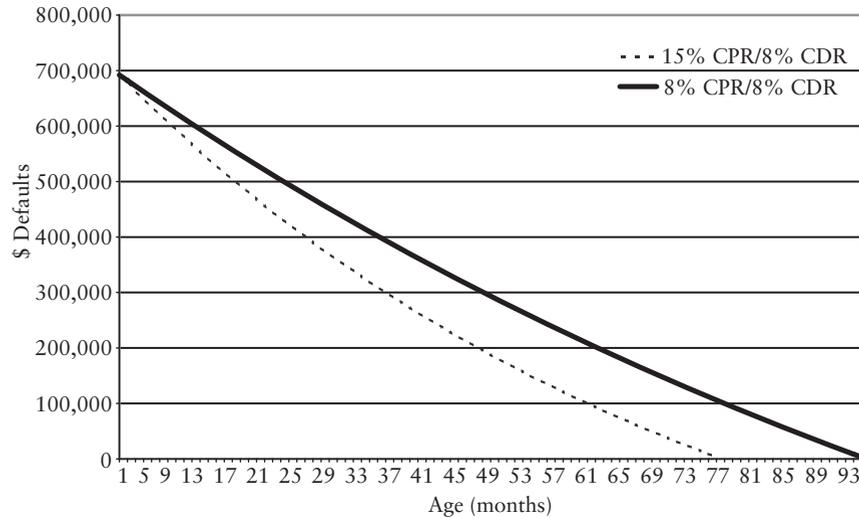

Figure 4 Monthly Dollar Amounts of Defaults on a \$100 Million Pool Using 8% CDR at Different Voluntary Prepayment Speeds

and show CDRs separately, the voluntary prepayment speed must be calculated independently. This can be accomplished by deannualizing the CPRs and CDRs (i.e., converting them to SMMs and MDRs), subtracting the MDR from the SMM, and annualizing the difference. In the above example, the voluntary SMM is 0.0035 less 0.0015 or 0.002, which annualizes to a 2.37% voluntary CPR.

Also note that the CDR metric measures only the amount of defaults and not the amount of losses because actual losses depends upon the amounts that can be recovered on loans in default, adjusted for the costs of collection and servicer advances, if applicable. In the extreme case, if there is full recovery of the unpaid principal balance of the defaulted loans, the losses will be zero except for the costs of recovery. However, depending upon the timing of the recovery of the defaulted loan balances, the cash flows to certain bondholders may be interrupted.

There is also an interesting and important relationship between the voluntary prepayment speed and the dollar amount of defaults in a pool. Every dollar of principal that is prepaid voluntarily is returned at 100 cents on the dollar

and cannot subsequently go into default. Therefore, the dollar amount of a pool's principal that goes into default declines as voluntary prepayment speeds increase, even if the assumed CDR remains constant. This is illustrated in Figure 4. The figure shows the projected dollar amounts of defaults on a \$100 million pool with an 8.5% note rate at 8% CDR for two different voluntary CPRs. At a combination of 15% CPR and 8% CDR, the pool is expected to lose a total of \$21.9 million in face value; the projected amount of defaulted principal using 8% CPR and 8% CDR increases to \$29.0 million.

As with prepayment analysis, there are disadvantages to using constant CDRs that tend to distort credit analysis. A constant CDR assumption is not necessarily consistent with the actual behavior of defaults, and also does not allow the analysis to take variations in the timing of defaults into account. As with prepayments, credit problems have historically tended to be very low immediately after the loans are closed, but generally increase with time as the pool in question ages.

One time-honored methodology is to utilize the Standard Default Assumption (SDA) convention, which assumes that defaults (as

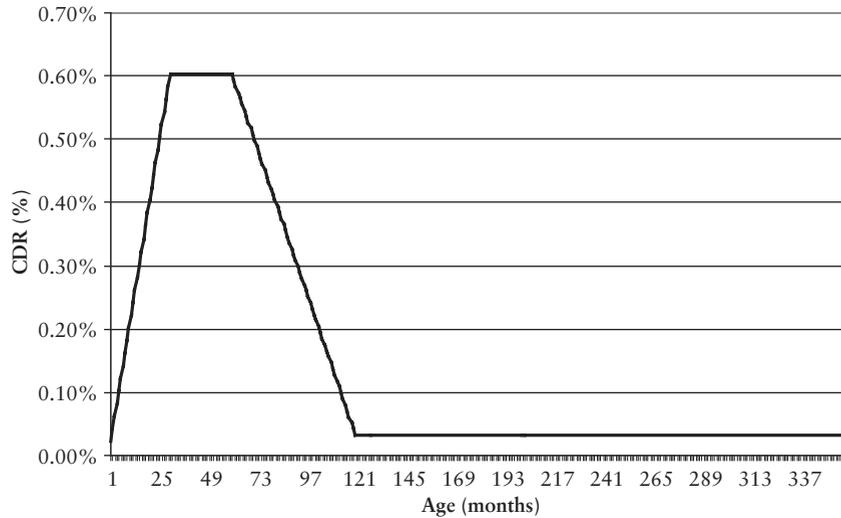

Figure 5 100% SDA Without Effects of Prepayments

measured in annual terms using CDRs) have a fairly consistent pattern over the life of the pool. The SDA model is similar in concept to the PSA convention used in prepayment analysis, and is specified as follows:

- 0.02% initial CDR, rising 0.02% CDR until reaching 0.6% CDR in month 30.
- A constant 0.6% CDR from months 30 to 60.
- A linear decline of 0.0095% between months 61 and 120, reaching 0.03% in month 120.
- A constant 0.03% CDR for the remaining term.

The base SDA curve is shown in Figure 5.

In addition to the prescribed CDR curve described above, the base SDA model explicitly accounts for the effects of voluntary prepayments by assuming a prepayment speed of 150% PSA. One hundred percent SDA at 150% PSA results in cumulative defaults of around 2.73%. The dollar amount of monthly defaults is calculated as the product of monthly default rates or MDRs (i.e., the deannualized CDR) and the monthly balance factor at the projected prepayment speed. Cumulative defaults are the sum of this vector. Table 2 shows how 100% SDA would be calculated, assuming a 6.0% coupon pass-through (as in the prior examples).

A depiction of monthly defaults using the base assumptions of the SDA model at 150% PSA is shown in Figure 6.

Loss Severity Measures

Where the lender has a lien on the property, a portion of the value of the loan can be recovered through the legal recovery process (i.e., through foreclosure and repossession) and subsequent sale of the asset. The difference between the proceeds received from the recovery process (after all transaction costs) and principal balance of the loan is the loss in dollars. The historical loss severity rate in any month is defined as follows:

$$\text{Loss severity rate} = 1 - \frac{\text{Liquidation Proceeds}}{\text{Liquidation Balance}_t}$$

The loss severity rate ranges from 0 to 1 (or 0% to 100%). If the loss severity rate is zero, then liquidation proceeds are equal to the liquidated loan balance. A loss severity rate of 1 (or 100%) means that there are no liquidation proceeds. The loss rate is equal to the annual default rate multiplied by the loss assumption severity. In projecting future cash flows and losses, investors will often use a constant loss

Table 2 Calculation of Monthly Defaults Using 100% SDA at 150% PSA for a Pass-Through with a 5.5% Pass-Through Rate, a WAC of 6.0%, and a WAM of 357 Months

(1)	(2)	(3)	(4)	(5)

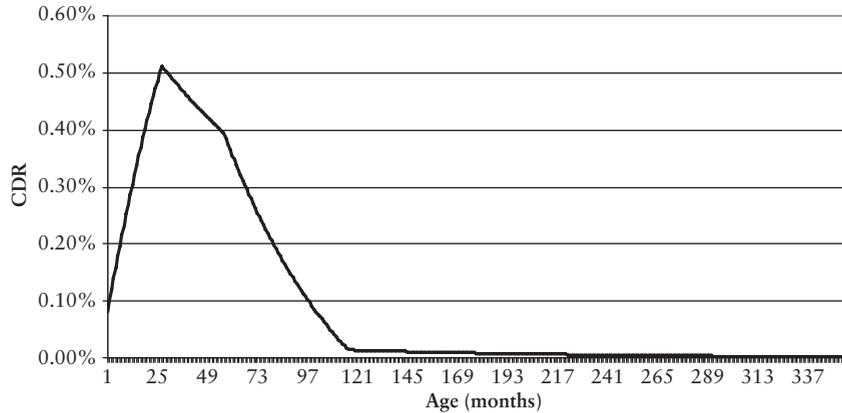

Figure 6 Monthly CDRs for 100% SDA Using 150% PSA

severity assumption based on a combination of loan attributes, projected changes in home prices, and the length of time until liquidation. The percentage of loss severity is then applied to the monthly default amount (generated by using the applicable MDR) in order to calculate monthly losses.

Default and loss severity assumptions (which translate into expected losses) are critical metrics for holders of mortgages and MBS that have exposure to mortgage credit performance. From the viewpoint of issuers, the assumptions used to value and capitalize investments in retained tranches are critical for assessing a firm's value, as any deterioration in the performance of retained tranches can negatively impact overall corporate valuations. Investors in whole-loan mortgages and subordinate MBS routinely use the credit metrics discussed above to analyze the relative value of different alternatives by generating default- and loss-adjusted returns and valuations.

KEY POINTS

- The monthly cash flow from the underlying pool of mortgage loans for a residential mortgage-backed security includes scheduled principal payments, interest payments, and any principal payments made by borrowers that is in excess of the scheduled principal payment. The last component is referred to as prepayments.
- The valuation of residential mortgage-backed securities requires the generation of a residential MBS's cash flow. Prepayment speeds and default rates must be projected in order to do so.
- The performance of a residential MBS depends on the prepayments and performance of the loan pool.
- The measurement of potential and actual cash flow impairment resulting from borrower credit problems is critically important to the analysis of nonagency or private label MBS.
- Complicating the evaluation of prepayments is the interplay between defaults, which are effectively credit-related prepayments, and prepayments attributable specifically to declining interest rates.
- The approach most commonly used to measure prepayment speeds is the conditional prepayment rate, which calculates monthly prepaid principal (i.e., that excludes scheduled principal amortizations) as a percentage of the security's outstanding balance and then annualizes that percentage. The CPR is an annual rate; the corresponding monthly rate is the single monthly mortality rate.
- The Public Securities Association (PSA) prepayment benchmark is expressed as a monthly series of annual prepayment rates

that assumes prepayment rates are low for newly originated mortgages and then will speed up as the mortgages age.

- A loan is classified as delinquent when a borrower fails to make one or more timely payments. Measures of delinquency are designed to gauge whether borrowers are current on their loan payment as well as stratifying unpaid loans according to the seriousness of the delinquency. The calculation method used is determined by the servicer. The two commonly used methods for classifying delinquencies are those recommended by the now-defunct Office of Thrift Supervision (OTS) and the Mortgage Bankers Association (MBA).
- Cumulative default rate and conditional default rate are the two broadly used metrics for quantifying defaults for a mortgage pool. The cumulative default rate is the proportion of the total face value of loans in a pool that have gone into default as a percentage of the total face value of the collateral pool. The conditional default rate is the annualized value of the unpaid principal balance of newly defaulted loans over the course of a month as a percentage of the unpaid balance of the pool (before scheduled principal payment) at the beginning of the month. To compute this measure, the monthly default rate must first be calculated.

NOTES

1. For a detailed discussion of the types of mortgage loans and residential MBS, see Fabozzi, Bhattacharya, and Berliner (2011).
2. Also called the *constant prepayment rate*.
3. This benchmark is commonly referred to as a “prepayment model,” suggesting that it can be used to estimate prepayments. Characterization of this benchmark as a prepayment model is inaccurate. It is simply a market convention. While the PSA has changed its name to the Securities Industry and Financial Markets Association, or SIFMA, the benchmark is still referred to as the “PSA prepayment benchmark.”
4. The calculation can also be presented as a series of formulas, which are available in Chapter 21 Fabozzi (2006).
5. The HEP curve was developed by Prudential Securities based on the prepayment experience of \$10 billion of home equity loan deals.
6. For example, a June 9, 2000, report by Moody’s titled, “Contradictions in Terms: Variations in Terminology in the Mortgage Market,” shows that the reported delinquencies can differ dramatically when the different conventions are used.
7. For clarity’s sake, we assume a simple pool with no credit enhancement.
8. These payments are reported in the monthly remittance reports compiled by a transaction’s trustee.

Abstract: Prepayments and their impact on principal cash flows are critical components of the valuation, trading, and risk management of residential mortgage-backed securities. Because of this, substantial resources are expended by investors and dealers in understanding and modeling prepayment “speeds.” However, prepayment behavior is not static and has evolved repeatedly since the first prepayment waves in the early 1990s. Moreover, the very definition of “prepayments” has evolved from one focused primarily on borrowers’ refinancing options to one encompassing a plethora of actions and decisions.

In general, a mortgage is a loan that is secured by underlying assets that can be repossessed in the event of default. In the residential housing market, a mortgage is defined as a loan made to the owner of a one- to four-family residential dwelling and secured by the underlying property (i.e., the land, the structure and any improvements). The fundamental unit in the *residential mortgage-backed securities* (MBS) market is the pool. At its lowest common denominator, mortgage-backed pools are aggregations of large numbers of mortgage loans with similar

(but not identical) characteristics. Loans with a commonality of attributes such as note rate (i.e., the interest rate paid by the borrower on the loan), term to maturity, credit quality, loan balance, and product type are combined using a variety of legal mechanisms to create relatively fungible investment vehicles.

To value a residential MBS, a financial modeler must project the cash flow. For an individual mortgage, the monthly cash flow includes the scheduled principal payments (also referred to as amortization), interest

payments, and any prepayments. *Prepayments* are any payments made by borrowers that are in excess of the scheduled principal payment. Consequently, the cash flow depends on the prepayment behavior of the borrowers in the mortgage pool. This risk faced by investors is referred to as prepayment risk and is similar to the risk faced by investors in callable corporate bonds.

Both the valuation and the subsequent performance of a residential MBS depend on prepayments—projected in the former case and realized in the latter case. In this entry, we discuss the underlying factors impacting principal repayment rates. We also draw distinctions between the traditional view of prepayments and a broader one that puts credit-related factors into context.

PREPAYMENT FUNDAMENTALS

Traditional prepayment analysis has focused on borrowers' option to retire their loans prior to maturity. Virtually all mortgage loans allow for the early repayment of principal. Prepayment behavior can be divided into several categories. The first of these is referred to as *turnover*, which occurs when the underlying property is sold and the associated loan is retired. Turnover can occur for a number of reasons:

- The homeowner moves or trades up to a larger house.
- The obligor relocates as part of changes in their job or employment.
- The property is sold subsequent to the death of the homeowner or as part of a divorce settlement.
- The property is destroyed by a fire or other natural disaster.

In all these cases, the resulting proceeds (from either the property's sale or an insurance settlement) are passed on as prepaid principal to the holder of the mortgage. In the event of the sale

of the property, the loan is paid off from the proceeds of the sale; in fact, most loans contain a "due-on-sale" clause ensuring that the loan is retired once the property is sold. Properties are also sold in the event that the obligors encounter financial difficulties. While we discuss credit-related factors at several points in this entry, it is important to note that prepayments resulting from credit events are sometimes taken into account under the broad umbrella of "turnover."

A second form of prepayment can be broadly ascribed to refinancing. This behavior can take a number of forms. A *rate-and-term refinancing* is undertaken solely to reduce the borrower's monthly payment, most commonly due to a decline in the level of consumer mortgage rates. Such a change puts the market rate for new mortgages below the rate of existing loans, creating incentives to refinance. A related activity takes place when borrowers refinance in order to liquefy their home's equity by increasing the balance on their new loan. Such transactions, referred to as *cash-out refinancings*, often are taken as an alternative to second lien loans. Cash-out activity is strongly correlated with rates of home price appreciation which, logically enough, creates the borrower equity extracted through the transaction. Such activity can also be relatively insensitive to traditional refinancing incentives, and has at times boosted prepayment speeds for lower-coupon MBS.

At various points in time, borrowers have also been inclined to refinance from one product into a different one that offers a payment savings. A simple form of *product transition* is to refinance from a fixed-rate loan into an adjustable-rate mortgage (ARM) that offers a lower rate. Borrowers have also transitioned into products with alternative amortization schemes, such as interest-only and negative amortization loans, in order to reduce their monthly payment burdens. Such transitions are contingent on the availability and popularity of alternative products, as well as borrowers' ability (either through lower rates or other nontraditional means) to achieve payment reductions.

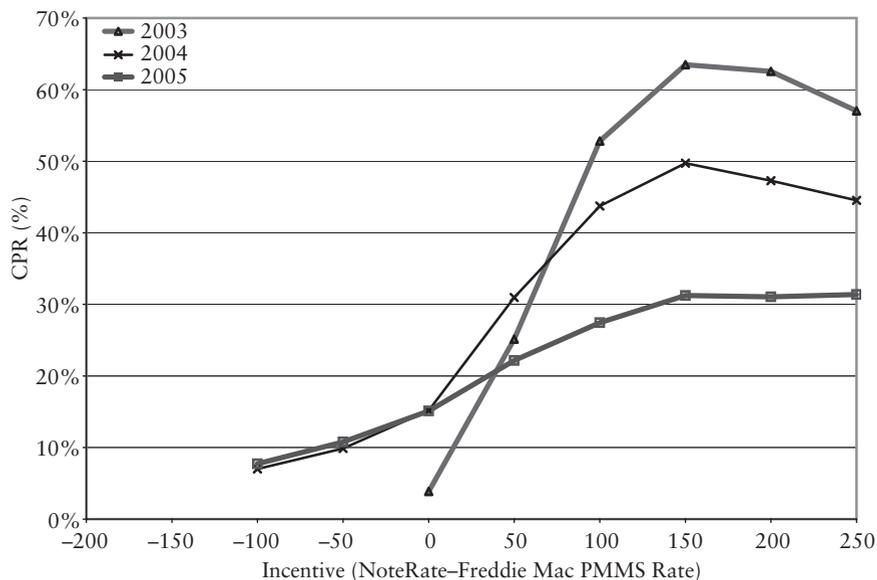

Figure 1 Prepayment S-Curves for Different Years for 30-year Fixed Rate Conventional Loans
Data Source: eMBS.

Another critical factor in prepayments is based on the borrower's financial situation. However, the impact of borrower credit on prepayments is quite complex. Prepayments often result directly from changes to homeowners' financial situation. At its simplest, principal is returned to investors when borrowers default on their loans, although the amount and timing of principal cash flows is subject to many variables. However, credit-related factors also exert more subtle effects on prepayment behavior. For example, borrowers with weak credit, or who don't have significant equity in their home, may not be able to take advantage of declining interest rates by obtaining new loans.

Taken together, these factors and activities result in prepayment speeds that vary across the MBS market. The most common way to assess prepayment speeds within a product group is by a simple view of prepayment speeds as measured by conditional prepayment rates (CPRs) at various levels of refinancing incentive. Prepayment *S-curves* show prepayment speeds for different levels of mortgage rates and/or refinancing incentives. S-curves can be created us-

ing a number of different methodologies and data sources. Either projected or historical prepayment speeds can be shown; additionally, the level of prepayments can be compared by showing either the absolute level of rates or the relative degree of refinancing incentive.

An example of S-curves for different periods of time is shown in Figure 1. The figure shows historical prepayment speeds for 30-year conventional fixed-rate pools exhibited by refinancing incentive (defined as the cohort's WAC less the Freddie Mac 30-year fixed survey rate for that period). The different shapes of the S-curves are indicative of different consumer behaviors. For example, the curve for 2003 was quite steep, indicating that borrowers were extremely sensitive to refinancing opportunities; borrowers that had an incentive to refinance (or, to borrow a term from the option market, were "in-the-money") did so in large numbers. At the same time, prepayments on "out-of-the-money" pools (i.e., those with lower weighted-average coupons (WACs) and no apparent refinancing incentive) were relatively slow, reflecting slow housing turnover

and limited cash-out activity. By contrast, the S-curves for 2004 and 2005 were increasingly flat. This reflected faster housing turnover, brisk levels of cash-out activity, and growing product transition activity for loans with minimal or negative incentives, while in-the-money borrowers were less responsive to apparent refinancing opportunities.

The following subsections discuss the primary drivers of prepayment speeds in more detail.

Turnover

As previously described, *turnover* refers to activity in which the underlying property is sold or liquidated, with the proceeds of the sale subsequently passed through to the holder of the mortgage as a prepayment. There are a number of ways to observe the level of turnover. A simple way to assess turnover is to look at the prepayment speeds of out-of-the-money MBS pools, such as, for example, prepayment speeds on Fannie 4.0s when mortgage rates are 5% or higher.

However, prepayment speeds for lower-coupon MBS can also be influenced by factors other than turnover. For example, high levels of cash-out refinancings (when borrowers refinance primarily to monetize the equity in their homes) will also increase prepayment speeds on out-of-the-money coupons. Product transition activity, which was widespread from 2004 through early 2007, can also distort the normal calculation of “in-the-moneyness.” As discussed later in this entry, transitions typically are associated with the widespread availability and popularity of products that allow borrowers to reduce their monthly payment obligations through either lower loan rates or alternative amortization schemes.

A truer estimate of housing turnover can be obtained by calculating existing home sales for single-family homes as a percentage of the number of such homes owned. Existing home sales data are published monthly by the National Association of Realtors, while the number of

single-family homes outstanding is reported by the Census Bureau on a quarterly basis, subject to periodic adjustments. Research indicates that turnover has varied over time, primarily reflecting changes in the level of home sales.

It is tempting to associate elevated housing turnover with robust growth in home prices. Purely speaking, however, housing turnover is not directly associated with real estate price appreciation, but rather with the level of home sales activity and the number of completed transactions. While home prices and sales are highly correlated, it is conceivable that home prices could stagnate while sales activity remains firm, and vice versa.

Refinancing

Refinancing (“refi”) activity can be broadly defined as transactions where borrowers replace their existing mortgage with a new loan, using the proceeds from the new loans to pay off their preexisting mortgage obligations. While it encompasses a number of different activities, it most commonly occurs when the prevailing level of interest rates declines to the point where borrowers can take out new loans and reduce their monthly payments (after accounting for transaction costs and potential penalties).¹

As noted already, refinancing activity can be broadly categorized as rate-and-term refinancings, where borrowers act solely to reduce their mortgage payments, and cash-out refinancings for which the new loan is larger than the one being retired. Rate-and-term refis are easily conceptualized as a form of option exercise. In a fashion similar to a corporation calling a debt issue, homeowners can reduce their required debt service obligations by calling their current loans carrying above-market rates and issuing new debt.

However, the nature of mortgage lending complicates borrowers’ refinancing decisions. Homeowners refinancing their loans are subject to a variety of costs and fees, many of which are fixed. The expected monthly savings, by

contrast, is a function of the size of the loan in question. This implies that refinancing incentives are strongly impacted by loan size, as smaller loans typically require a greater refinancing incentive in order to trigger refinancing activity. Take, for example, two loans with 5% note rates and balances of \$200,000 and \$400,000, respectively. A 50 basis point rate savings reduces the payment on the \$200,000 loan by \$60 per month, while the same rate savings reduces the larger loan's monthly payment by roughly \$120. If both loans are subject to \$1,000 in refinancing costs, the borrower with the \$400,000 loan will recoup the initial outlay in month 8; the borrower with the smaller loan needs more than double the time to break even. This makes loan size a critical variable in modeling and projecting future prepayment speeds.

Cash-out refinancings are commonly viewed as a subset of overall refinancing activity. For example, Freddie Mac defines cash-out refis as transactions where the new loan is at least 5% larger than the original one, and reports cash-outs as a percentage of overall prepayment activity. The level of cash-out activity has varied significantly over time. For example, the relative level of cash-out activity was extremely high in the late 1980s and 1990s, as well as in the period between 2003 and 2007.

The primary driver of cash-out activity at any point in time is the amount of equity borrowers have in their homes. In turn, equity is a function of both the original equity in the home (i.e., the inverse of a loan's loan-to-value (LTV) ratio) and the rate of home price appreciation since the home was purchased.

Aggregate refinancing incentives can be observed by examining the distribution of note rates within the MBS universe at various points in time. Keep in mind that the outstanding mortgage population is always changing, as new loans are issued and older loans are retired. The distribution of note rates for the population of outstanding loans is strongly impacted by refinancing activity, which can be thought

of as recycling older high-rate loans into new mortgages with lower rates.

A useful technique is to compare the outstanding balances and the cumulative percentages of note rates for MBS products at different points in time. The cumulative balance percentages are calculated as follows:

- Divide the outstanding market balances into discrete segments or "buckets" by WAC. (The following analysis uses 12.5 basis point WAC buckets.)
- For each WAC bucket, calculate the percentage of the remaining balances with note rates equal to and below that bucket.

For example, if the lowest WAC bucket is 5.0% to 5.124% and it represents 2% of the remaining balance, its cumulative percentage is 2%. If the next WAC bucket (5.125% to 5.249%) comprises 6% of the unpaid balance of the market, its cumulative balance is therefore 8%. This process is completed for all WAC buckets. This technique is particularly useful in assessing the "refinanceability" of the market at particular points in time.

FACTORS INFLUENCING PREPAYMENT SPEEDS

In understanding and evaluating prepayment behavior, the level of consumer mortgage rates is the single factor upon which most attention is paid. However, there is no single "market" rate that analysts can observe. There are always differences in the rate offerings of different lenders; since loans are the "product" they offer, it's not surprising that there are pricing discrepancies. Individual lenders also have a variety of offerings, with different combinations of interest rates and up-front fees (or "points," which vary inversely with the rate offered). While these options give borrowers choices between up-front costs and monthly payments, the relationship between rates and points is highly lender-specific and a function of their pricing algorithms. Finally, lenders seek

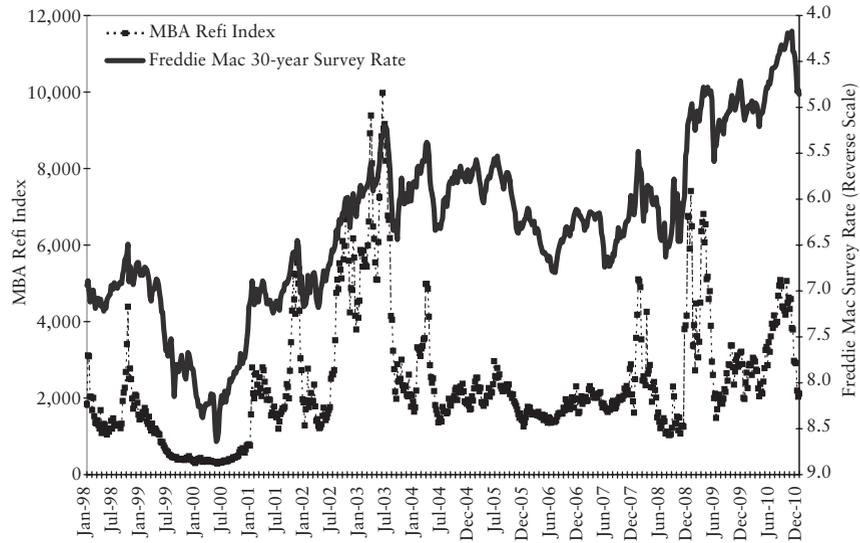

Figure 2 MBA Refi Index versus Freddie Mac 30-year Survey Rate
Data Sources: Mortgage Bankers Association and Freddie Mac.

to price in the risk of loans to various borrowers in a series of activities broadly classified under “risk-based pricing.”²

However, a variety of outside factors that influence prepayment speeds and refinancing behavior can be outlined. These include exogenous factors, mortgage industry economics, and consumer behaviors and preferences.

Borrower Inefficiencies

Rational borrowers will always seek to lower their borrowing costs by refinancing their debts. Refinancing opportunities present themselves to both institutional and individual borrowers. Unlike corporations and municipalities, however, residential borrowers are relatively inefficient in capitalizing on refinancing opportunities. (If mortgagors were efficient, for example, few if any premium pools would be outstanding; however, there were approximately \$110 billion of 30-year Fannie Maes with coupons of 6.5% and higher at the end of 2010.)

Borrower inefficiencies exist for a number of reasons. Homeowners have varying degrees of awareness of financial market rates and condi-

tions, and as a result are not always cognizant of refinancing opportunities. Borrowers often hear about declines in rates from their friends and co-workers; they also may read about it in the financial press or see it discussed on news programs. These are collectively referred to as *media effects*. While the growth of the financial press (with information available from print, television, and the Internet) has improved refinancing efficiency over time, it often takes a significant and noteworthy drop in rates to generate conversation and media “buzz.” This explains the tendency for refinancings to occur in waves, as illustrated in Figure 2. The figure shows mortgage rates (using Freddie Mac’s 30-year survey rate as a proxy, shown on a reverse scale) versus refinancing activity, using the Mortgage Bankers Association’s refinancing applications index. The figure indicates that refinancing activity often remains tepid for long periods of time, but spikes when mortgage rates decline beyond some indeterminate threshold.

In addition, the costs associated with refinancing alter the refinancing economics for borrowers. The need to overcome cost hurdles serves to inhibit refinancing activity and complicates

refinancing decisions. As noted previously, this is particularly relevant for borrowers with smaller loan balances, who typically require a greater refinancing incentive before engaging in rate-and-term refinancings.

Refinancing efficiency has also been impacted by the structure of the mortgage industry. Beginning in the mid-1990s, lenders became increasingly adept at marketing their products and generating refinancing activity. Some of these activities involve directly contacting existing customers, while others involve mass marketing through television commercials, print advertisements, and direct mail and phone solicitations. Also contributing to the marketing effort was a cadre of mortgage brokers and other “third-party originators” who acted as agents linking lenders and borrowers. These developments contributed to improved refinancing efficiency.

The events that culminated in the financial crisis in 2008, however, led to sharp contraction in “wholesale” lending activities. Brokers were blamed for poor loan quality and sloppy paperwork; since they did not make loans directly, they arguably had no incentive to insure the quality of their loans. As a result, many smaller originators that were dependent on the wholesale channel failed, while a number of large originators curtailed or severely limited their interaction with third-party lenders. This development in turn served to impair borrowers’ ability and/or willingness to capitalize on refinancing opportunities.

Finally, additional factors impact refinancing activities. After 2007, for example, a combination of significantly tighter lending standards, fewer product offerings, and declining borrower equity due to falling home prices acted to further depress refinancing activity. Referring to Figure 2, the inability of the MBA’s refi index to reach and maintain high levels reflected the fact that the pool of borrowers with the ability to refinance was quickly exhausted when mortgage rates plummeted beginning in early 2009.

Product Choices and Transitions

Both rate-and-term and cash-out refinancing activity is at times influenced by *product transitions*. This means that borrowers can lower their monthly payment by refinancing from one product into another. This type of activity has varied over time, depending on the availability, popularity, and pricing of alternative products. When the yield curve has been relatively steep, for example, large numbers of borrowers have sometimes refinanced out of fixed rate loans into adjustable rate products.

Transition activity has varied substantially over time, however, driven by both lender offerings and consumer preferences. Prior to mid-2003, for example, ARMs were a niche product targeted primarily to first-time home buyers. In the summer of 2003, however, ARM volumes rose fairly dramatically, as consumers refinanced out of fixed rate products into newly popular hybrid ARMs. This reflected both consumers’ increased comfort with adjustable rate loans as well as marketing efforts by mortgage lenders designed to maintain issuance volumes. By mid-2007, borrowers once again eschewed ARMs, in part due to bad publicity emphasizing their riskiness.

These abrupt changes in behavior are illustrated in Figure 3. The figure contains a scatterchart showing the Freddie Mac 30-year fixed survey rate on the horizontal axis, and the percentage of loans taken as ARMs on the vertical axis. The figure demonstrates the existence of three distinct regimes. ARMs were relatively unpopular in the years prior to mid-2003, and only reflected a large share of activity when mortgage rates were relatively high. From mid-2003 through early 2008, by contrast, the percentage of ARMs was relatively high irrespective of the level of mortgage rates and, by implication, refi activity. After the beginning of 2008, ARMs again fell out of favor; by 2010 they comprised less than 10% of new loan applications.

The varying popularity of fixed-to-ARM refinancings has several implications. Because

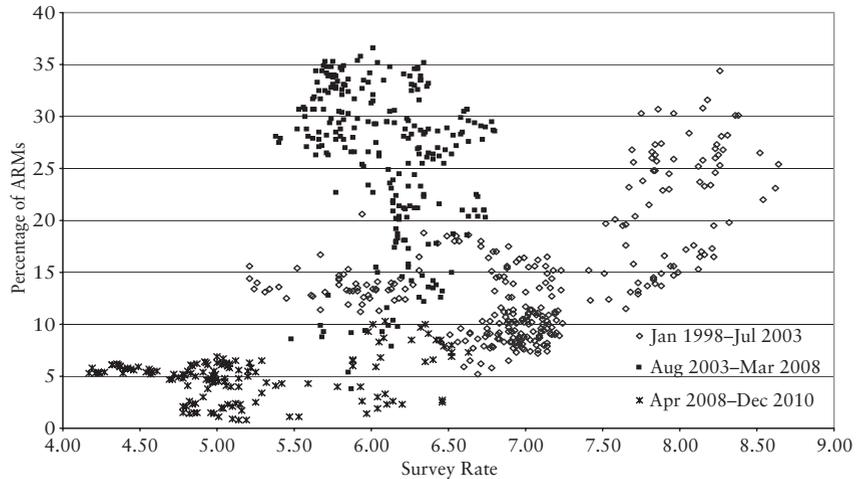

Figure 3 Freddie Mac 30-Year Survey Rate versus MBA's ARM Percentage
Data Sources: Mortgage Bankers Association and Freddie Mac.

of the generally upward slope of the yield curves, ARM rates are typically lower than fixed rates. This means that borrowers willing to utilize adjustable rate products will be presented with an apparent refinancing incentive more often than those borrowers that eschew ARMs and will only consider fixed rate products. (Of course, this savings is only guaranteed for an ARM's fixed rate or "teaser" period.) Taking available ARM rates into account means that more borrowers can reduce their mortgage rates by refinancing.³ As a result, regimes where ARMs are a popular product choice (due to consumer preferences and/or a steep yield curve) are characterized by steady levels of refinancing activity and relatively flat S-curves.

Alternatively, when short rates rise and push ARM rates higher, fixed-to-ARM refinancing incentives are reduced. In fact, regimes associated with flat yield curves are often characterized by ARM-to-fixed transitions, as borrowers seek to lock in lower long-term rates. Taken together, these phenomena indicate that refinancing behavior is not simply dictated by the level of intermediate and long interest rates. The levels of *all* interest rates, as well as the shape of the

yield curve, are important drivers of refinancing incentives and prepayment activity.

Large-scale transitions also have been observed as borrowers utilized loan products with alternative amortization schedules and payment schemes. As a simple example, a borrower with a \$200,000 loan balance and a 30-year loan with a fixed 5% note rate would have monthly P&I payments of \$1,074. If they refinanced into an interest-only loan with the same term and note rate, their new monthly payment would be \$833, an initial savings of \$240. However, the savings would only be available for the period that the borrower was allowed to make interest-only payments; after that point, the loan is "recast" (i.e., the payments are recalculated) over the remaining term. If the borrower chooses a new loan with an interest-only period of 10 years, the post-recast monthly payment would be \$1,320, significantly higher than the payment on the original loan.

The borrower's decision thus trades off early savings for a sharply increase monthly payment (or *payment shock*) at the recast. While such decisions were popular during the period of widespread product transitions, the mortgage crisis of 2007 led to the realization that these

types of transitions exposed both borrowers and lenders to serious embedded risks. As a result, transitions into alternative payment products became fairly rare by 2008.

Changes in Homeowner Equity and Credit

As noted earlier, the experience of the post-2007 period has highlighted the interrelationship between prepayments and home prices and, by extension, borrower credit. We already highlighted the importance of cash-out refinancings and the critical role that home price appreciation plays in this activity. In addition, deteriorating borrower credit (of which homeowner equity is a crucial element) often directly results in prepayments, as we discuss next.

However, changing home prices and borrower credit have other subtle affects on prepayments. For example, borrowers often are presented with an enhanced refinancing incentive when their credit improves. If they took loans with relatively high rates because of risk-based pricing, they can capitalize on their improved situation by refinancing. Such “credit curing” can be related to economic factors such as improving labor markets and consumer credit conditions, particularly when observing local or regional activity. A similar phenomenon is associated with rapid increases of home prices. Borrowers with high LTVs who were saddled with higher risk-based mortgage rates and/or mortgage insurance premiums can lower their payments once their homes appreciate in value, even if the overall level of mortgage rates remains unchanged.

Alternatively, borrower credit can also act to slow prepayment speeds. Borrowers with deteriorating credit may not be able to capitalize on declining interest rates if they cannot obtain new loans because of tighter credit standards. Declining real estate values can also prevent homeowners from refinancing existing loans by reducing or eliminating their equity. If homeowners’ equity disappears or becomes nega-

tive (a situation often referenced as “being underwater”), they may lose the ability to obtain new loans. Moreover, significant declines in home values ultimately serve to constrain homeowners from selling their properties, as they would be forced to realize large losses on their homes. These developments are collectively called *prepayment lock-in*, and serve to slow both refinancing- and turnover-related prepayments.

Time

Prepayment rates vary with the passage of time. In addition to purely random variations, fairly predictable changes occur to prepayment speeds due to factors that are independent of interest rates. The behavior of borrowers undergoes a variety of secular and cyclical changes as time elapses; in addition, the composition of closed loan populations (i.e., loans collateralizing a pool) changes as the pool ages and loans drop out for any number of reasons.

Time-related factors mean that evaluating any MBS at a single constant speed is unrealistic. This realization was first incorporated into the PSA prepayment benchmark, which recognized the fact that loans are more likely to prepay as they age (or season). Borrowers are disinclined to prepay their loans immediately after issuance, but become increasingly open to the possibility as time elapses. This is due to a variety of factors:

- Borrowers typically are reluctant to undertake the effort and expense of refinancing until their loans are at least a few months old.
- Borrowers are unlikely to sell their properties and move immediately after purchasing a home. This is true even for homeowners that relocate frequently; evidence suggests that they tend to stay in their homes for at least a year.
- It takes some time for borrowers to build equity in their property (assuming, of course, a regime of rising home prices).

The key insight introduced by the PSA model is the concept that prepayment speeds are not constant over time, especially early in loans' lives. It is, however, simplistic in its assumption of a constant prepayment speed after 30 months, and does not account for other time-related behaviors. One such factor is seasonality, which suggests that prepayments typically increase during spring and summer months. Another behavior, burnout, accounts for the observation that loans remaining in a population are less likely to refinance after a certain point in time. The underlying logic is that borrowers that have not availed themselves of refinancing opportunities lack the ability and/or the inclination to do so.

The combination of these behaviors means that a time series of CPRs generated by a prepayment model (as well as the realized prepayment speeds for any security)—the *CPR vector*—will look very different from the equivalent speeds quoted as percentages of the PSA model.

Time-related changes to prepayment speeds are even more profound for mortgage products that do not require fixed monthly payments over their life. For example, ARMs typically experience a spike in prepayment speeds as the loans approach their first reset date. (For example, the monthly payments on 5/1 hybrid ARMs change when the loans reset at month 60.) Interest-only loans exhibit comparable behavior, as their required monthly payments increase once the IO period expires. All such products exhibit prepayment patterns reflecting variations in the loans' monthly payments and, by implication, refinancing incentives.

The spike in ARM speeds at their reset results from a variety of factors. Unlike homeowners in Europe, U.S. borrowers have traditionally been somewhat averse to adjustable-rate loans. This means that borrowers often prepay hybrid ARMs simply to avoid being exposed to changing interest rates and variable payments. It also is a function of the level of the benchmark rate at the reset; in regimes where the yield curve is flat or inverted, the new loan rates are often

higher than the teaser rate. The resulting payment shock creates a refinancing incentive for borrowers during periods when the new rate is higher than that for either a new ARM or a fixed rate loan.

Empirical evidence shows a sharp increase in CPRs at the reset; in addition, models also project a cyclical increase in speed every 12 months thereafter, corresponding with the annual rate resets for the loans as well as normal seasonal patterns.⁴

DEFAULTS AND "INVOLUNTARY" PREPAYMENTS

The mortgage crisis that erupted in early 2007 underscored the critical role of credit performance in all sectors of the mortgage and MBS markets. In the past, investors assumed that senior nonagency MBS were "money-good" by virtue of their triple-A ratings. The collapse of mortgage performance both reinforced the importance of sound credit analysis of private-label securities, while also giving investors a painful and expensive lesson on the factors influencing residential mortgage credit performance.

Factors Influencing Default Frequency and Credit Performance

The general thinking has long been that borrower equity simply provides a cushion for the lender in cases when the home must be repossessed. However, a critical lesson learned from the post-2006 experience is that borrower credit performance and home prices are strongly interrelated at a number of levels, and that high-LTV loans have, all else being equal, an increased likelihood of default.

At its most basic, appreciating home prices give borrowers the ability to monetize their home's equity in order to meet their financial obligations and mitigate cash flow problems. In addition, steady or rising home prices also impact the resolution of troubled loans.

Delinquent borrowers that have equity in their homes can sell their properties and, using the net proceeds, pay off their loans instead of going into foreclosure. In theory, borrowers should never default if their homes' values are great enough to extinguish the loan and pay the associated costs. Borrowers whose homes have declined to the point where their LTVs are greater than 100% (i.e., where their loans are greater than the value of their homes) do not have this option. This accounts for why some loan vintages (such as the year 2000) have experienced relatively high levels of delinquency but limited defaults and losses; borrowers in financial difficulty were able to sell their homes and emerge "whole."⁵

The decline in home prices that began in 2007 resulted in unexpectedly large increases in defaults. The loss of home equity induced numerous borrowers to exercise the option embedded in any collateralized loan that allows the collateral to revert back to the lender. It is axiomatic in corporate credit theory that borrowers are expected to default on loans once the value of the loans' collateral declines below the value of the loans themselves. However, the mortgage sector has long operated under the assumption that obligors rarely walk away from the properties because of the importance of dwellings to families' well-being. This behavior was untested until 2007, in large part because home prices have never before experienced significant and widespread declines. However, the new phenomenon of the "strategic default" emerged during the mortgage crisis, where large numbers of homeowners with income and assets sufficient to service their loans nevertheless ceased making monthly mortgage payments.

The emergence of this activity has a number of implications. The most important realization is that home prices and mortgage credit performance are closely linked. In this light, the strong credit performance exhibited by the mortgage market since the 1950s was arguably skewed higher by decades of steady home price appreciation. This assertion implicitly argues that res-

idential mortgage loans are riskier assets than previously assumed. In addition, mortgage underwriters have placed undue faith in metrics such as credit scores which, while valuable, cannot serve as reliable proxies for borrowers' willingness to service their loans during times of financial distress.

Voluntary and Involuntary Prepayments

Once borrowers cease making regular payments, the loans eventually go into default, meaning that the borrowers lose title to the underlying properties. The properties are subsequently liquidated, typically by being placed in foreclosure; this means that the servicer eventually takes possession of the property and sells it. The proceeds of the sale, less associated costs, are categorized as recovered principal or *recoveries*. Since recoveries are typically less than the amount of the loan, some entity must absorb a principal loss.

Losses for agency MBS are absorbed by the entity or agency that guaranteed them. At some point, seriously delinquent loans in agency pools are classified as "nonperforming" and subsequently bought out of the pools, either by the GSEs or (in the case of FHA and VA loans) the servicer. Because of the principal guaranty, the full face value of principal is quickly returned to investors. This means that all unscheduled principal payments can be captured in a single "prepayment speed" reported for the security in question. This measure is calculated based on the total principal repaid on the pool and the breakdown (either reported or estimated) between amortizations and prepayments (i.e., between scheduled and unscheduled principal payments). As a result, many agency securities exhibited increased prepayment speeds during periods of poor credit performance and widespread delinquencies, particularly when the agencies change their buyout policies.⁶ (This also blurs the line between credit-related prepayments and normal housing "turnover.")

By contrast, traditional and credit-related prepayments must be calculated and reported separately for nonagency securities. This is because of the fact that credit support for these securities is internal; deals are structured such that senior bonds in a transaction have priority over other bonds in receiving principal and interest. Since the transaction itself will absorb incurred losses, traditional prepayments (which return all of principal to the security holder) and credit-related prepayments (which result in shortfalls that must be allocated within structures) must be segregated. As a result, private-label securities report both *voluntary prepayments*, which encompass traditional prepayment activity, and credit-related *involuntary prepayments*. The latter result from defaults or other events specifically related to credit events (such as short sales of homes), while also accounting for the likelihood that less than the full amount of principal will be returned to the transaction (or, more accurately, the trust holding the deal's collateral).

These factors complicate the projection and calculation of prepayment speeds for private-label securities. Voluntary prepayments are typically quoted as *VPRs*, which stands for voluntary prepayment rate. They are calculated similarly to a CPR, in which a monthly percentage of prepaid principal (sometimes called a VMM) is annualized. Involuntary prepayment speeds are quoted as conditional default rates (CDRs) which are calculated by annualizing the monthly default rates or MDRs. Note that the sum of the monthly VMMs and MDRs equals the total deal SMM for any particular month.

Involuntary prepayments require additional metrics to be reported. In addition to the rate of default, an estimate must be made of the loss severity (which indicates how much of the defaulted principal amount is returned to investors) as well as the lag between the time when loans go into default (i.e., when the borrowers lose title to the properties) and when the trusts receive the recovered principal.

Interactions Between Prepayments and Defaults

There are some interesting interactions between voluntary and involuntary prepayment speeds that impact the analysis of private-label securities. All things equal, fast prepayments enhance the performance of these securities; faster return of principal means that there is less principal outstanding to go into default. At the same assumed CDR, faster voluntary prepayment speeds (i.e., a higher VPR assumption) will typically result in higher projected yields and returns.

This assertion is somewhat simplistic, however, since it doesn't take the changing composition of the pool into account. For example, it is unlikely that the CDR would remain constant under the different VPR assumptions, as the profile of any closed population of mortgages changes over time. In addition to home prices and economic conditions, the composition of the collateral pool backing a transaction evolves as the result of attrition. Loans pay off over time as a result of both voluntary and involuntary factors. Voluntary prepayments negatively impact the composition of a pool because "better" borrowers (i.e., those with stronger credit and/or more equity in their homes) are able to take advantage of refinancing opportunities; since weaker borrowers are locked into their existing loans, the credit profile of the remaining population deteriorates. This is known as *adverse selection*, and suggests that the credit quality of a pool typically declines over time, all things equal.

The high level of defaults experienced during the mortgage crisis also created a new and unanticipated phenomenon. High levels of defaults means that weaker borrowers are dropping out of the collateral pools. In turn, the remaining borrowers generally have stronger credit, meaning that the population's credit profile improves over time. This is especially noteworthy during periods of declining home prices. Borrowers with poor credit (i.e., both those unable or unwilling to service their loans)

go into default in large numbers, while stronger borrowers who are nonetheless “locked in” by a lack of equity continue to service their loans and remain in the pool. This process is sometimes called *favorable selection*, and was most prominently observed in subprime and alt-A pools, which experienced very high levels of defaults.

Neither the processes of adverse nor favorable selection take place in a vacuum. For example, the performance of a cohort assumed to be adversely selected (i.e., having experienced relatively high levels of voluntary prepayments) will improve in the face of home price appreciation. Alternatively, a population of subprime loans may experience a renewed surge in defaults if money-market rates increase sharply. Since many subprime loans have adjustable-note rates with very high loan margins, rising rates create widespread payment shock that challenges the ability of borrowers to service their loans.

KEY POINTS

- Traditional prepayment analysis has focused on borrowers’ option to retire their loans prior to maturity.
- The two primary drivers of prepayment behavior are turnover and refinancing.
- Turnover occurs when the underlying properties are sold and the associated loan is retired.
- Refinancing behavior includes rate-and-term refinancing (undertaken to reduce the borrower’s monthly payment, most commonly due to a decline in the level of consumer mortgage rates) and cash-out refinancing (often are taken as an alternative to second lien loans and strongly correlated with rates of home price appreciation).
- The most common way to assess prepayment speeds within a product group at various levels of refinancing incentive is with the prepayment S-curves. These curves show pre-

payment speeds for different levels of mortgage rates and/or refinancing incentives.

- In understanding and evaluating prepayment behavior, the level of consumer mortgage rates is the single factor to which most attention is paid.
- Outside factors that influence prepayment speeds and refinancing behavior include exogenous factors, mortgage industry economics, and consumer behaviors and preferences.

NOTES

1. For a more detailed discussion, see Chapter 3 in Fabozzi, Bhattacharya, and Berliner (2011).
2. See Bhattacharya, Berliner, and Fabozzi (2008).
3. If ARM rates are low enough, virtually the entire fixed rate coupon stack can be considered in-the-money.
4. See Bhattacharya, Berliner, and Fabozzi (2008).
5. In these cases, the transaction is recorded as a home sale and captured under “turnover.”
6. In early 2010, Fannie Mae and Freddie Mac instituted policies in which loans that were 120 days or more delinquent were automatically bought out of pools. Prior to that, buy-outs had been left to their discretion. The process of buying out large numbers of seriously delinquent loans led to sharp short-term spikes in prepayment speeds, as well as huge writedowns for Fannie Mae and Freddie Mac.

Abstract: At one time the belief was that financial institutions are exposed to two main risks. Operational risk was regarded as a mere part of “other” risks. That view has changed. This risk is now viewed as a major risk faced by financial institutions as the world financial system has been shaken by a number of banking failures since the mid 1980s, and the risks—that internationally active banks, in particular, have had to deal with—have become more complex and challenging. More than 100 operational losses exceeding \$100 million in value each and a number of losses exceeding \$1 billion have impacted financial firms globally since the end of the 1980s. There is no question that the cause is unrelated to market or credit risks. Such large-scale losses have resulted in bankruptcies, mergers, or substantial equity price declines of a large number of highly recognized financial institutions.

A long-held belief is that credit risk and market risk have been considered the two largest contributors to the risks faced by financial entities such as banks, insurance companies, and asset management firms. Credit risk is the risk of counterparty failure; market risk is the loss due to changes in market indicators, such as equity prices, interest rates, and exchange rates. It is now recognized that operational risk is a major risk faced by financial entities. In general terms, *operational risk* is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. This risk encompasses legal risks, which includes, but is

not limited to, exposure to fines, penalties, or punitive damages resulting from supervisory actions, as well as private settlements.

Operational losses have been reflected in banks’ balance sheets for many decades. Operational risk affects the soundness and operating efficiency of all banking activities and all business units. Most of the losses are relatively small in magnitude—the fact that these losses are frequent makes them predictable and often preventable. Examples of such operational losses include losses resulting from accidental accounting errors, minor credit card fraud, or equipment failures. Operational risk-related

events that are often more severe in the magnitude of incurred loss include tax noncompliance, unauthorized trading activities, major internal fraudulent activities, business disruptions due to natural disasters, and vandalism.

Until around the 1990s, the latter events have been infrequent, and even if they did occur, banks were capable of sustaining the losses without major consequences. This is quite understandable because the operations within the banking industry until about the middle of the 1980s have been subject to numerous restrictions, keeping trading volumes relatively modest and diversity of operations limited. Therefore, the significance of operational risk (whose impact is positively correlated with income size and dispersion of business units) has been perceived as minor, with limited effect on management's decision making and capital allocation when compared to credit risk and market risk. However, serious changes in the global financial markets have caused noticeable shifts in banks' risk profiles.

In this entry, we discuss some key aspects that distinguish operational risk from credit risk and market risk. They are related to the arrival process of loss events, the loss severity, and the dependence structure of operational losses across a bank's business units.

OPERATIONAL RISK DEFINED

Let's begin by distinguishing operational risk from other categories of financial risk. Operational risk is, in large part, a firm-specific and nonsystematic risk.¹ Early publications of the Bank for International Settlements (BIS) defined operational risk as:²

- Other risks.
- "Any risk not categorized as market and credit risk."
- "The risk of loss arising from various types of human or technical errors."

Other definitions proposed in the literature include:

- Risk "arising from human and technical errors and accidents."³
- "A measure of the link between a firm's business activities and the variation in its business results."⁴
- "The risk associated with operating a business."⁵

The formal definition that is currently widely accepted was initially proposed by the British Bankers Association (2001) and adopted by the BIS in January 2001. Operational risk was defined as "the risk of direct or indirect loss resulting from inadequate or failed internal processes, people or systems or from external events."

The industry responded to this definition with criticism regarding the lack of a clear definition of "direct" and "indirect" losses. A refined definition of operational risk dropped the two terms, hence finalizing the definition of operational risk as:

Operational risk is the risk of loss resulting from inadequate or failed internal processes, people or systems, or from external events. (BIS, 2001b, p. 2)

This definition includes legal risk, but excludes strategic and reputational risk (these will be defined soon). The definition is "causal-based," providing a breakdown of operational risk into four categories based on its sources: (1) people, (2) processes, (3) systems, and (4) external factors. According to Barclays Bank, the major sources of operational risk include operational process reliability, IT security, outsourcing of operations, dependence on key suppliers, implementation of strategic change, integration of acquisitions, fraud, error, customer service quality, regulatory compliance, recruitment, training and retention of staff, and social and environmental impacts.⁶

Large banks and financial institutions sometimes prefer to use their own definition of operational risk. For example, Deutsche Bank defines operational risk as

*potential for incurring losses in relation to employees, contractual specifications and documentation, technology, infrastructure failure and disasters, external influences and customer relationships.*⁷

The Bank of Tokyo-Mitsubishi defines operational risk as “the risk of incurring losses that might be caused by negligence of proper operational processing, or by incidents or misconduct by either officers or staffs.”⁸

In October 2003, the U.S. Securities and Exchange Commission (SEC) defined operational risk as:

*the risk of loss due to the breakdown of controls within the firm including, but not limited to, unidentified limit excesses, unauthorized trading, fraud in trading or in back office functions, inexperienced personnel, and unstable and easily accessed computer systems.*⁹

OPERATIONAL RISK EXPOSURE INDICATORS

The probability of an operational risk event occurring increases with a larger number of personnel (due to increased possibility of committing an error) and with a greater transaction volume. Examples of operational risk exposure indicators include:¹⁰

- Gross income.
- Volume of trades or new deals.
- Value of assets under management.
- Value of transactions.
- Number of transactions.
- Number of employees.
- Employees’ years of experience.
- Capital structure (debt to equity ratio).
- Historical operational losses.
- Historical insurance claims for operational losses.

For example, larger banks are more likely to have larger operational losses. Shih, Samad-Khan, and Medapa (2000) measured the dependence between a bank size and operational loss amounts. They found that, on average, for every unit increase in a bank size, operational losses are predicted to increase by roughly a

fourth root of that. This means that when they regressed log-losses on a bank’s log-size, the estimated coefficient was approximately 0.25. In a different study, Chapelle, Crama, Hübner, and Peters (2005) estimated the coefficient to be 0.15.

CLASSIFICATION OF OPERATIONAL RISK

Operational risk can be classified according to

- The nature of the loss: internally inflicted or externally inflicted.
- The impact of the loss: direct losses or indirect losses.
- The degree of expectancy: expected or unexpected.
- Risk type, event type, and loss type.
- The magnitude (or severity) of loss and frequency of loss.

We discuss each one below.

Internal versus External Operational Losses

Operational losses can be either internally inflicted or result from external sources. *Internally* inflicted sources include most of the losses caused by human, process, and technology failures, such as those due to human errors, internal fraud, unauthorized trading, injuries, business delays due to computer failures, or telecommunication problems. *External* sources include man-made incidents such as external fraud, theft, computer hacking, terrorist activities, and natural disasters such as damage to physical assets due to hurricanes, floods, and fires.

Many of the internal operational failures can be prevented with appropriate internal management practices; for example, tightened controls and management of the personnel can help prevent some employee errors and internal fraud, and improved telecommunication networks can help prevent some technological failures.

External losses are very difficult to prevent. However, it is possible to design insurance or other hedging strategies to reduce or possibly eliminate externally inflicted losses.

Direct versus Indirect Operational Losses

Direct losses are the losses that directly arise from the associated events. For example, an incompetent currency trading can result in a loss for the bank due to adverse exchange rate movements. As another example, mistakenly charging a client \$50,000 instead of \$150,000 results in the loss for the bank in the amount of \$100,000. The Basel II Capital Accord sets guidelines regarding the estimation of the regulatory capital charge by banks based only on direct losses. Table 1 identifies the Basel II Capital Accord's categories and definitions of direct operational losses.

Indirect losses are generally opportunity costs and the losses associated with the costs of fixing an operational risk problem, such as near-miss losses, latent losses, or contingent losses.

Near-Miss Operational Losses

Near-miss losses (or near-misses) are the estimated losses from those events that could potentially occur but were successfully prevented. The rationale behind including near-misses into internal databases is as follows: The definition

of "risk" should not be solely based on the past history of actual events but instead should be a forward-looking concept and include both actual and potential events that could result in material losses. The mere fact that a loss was prevented in the past (be it by luck or by conscious managerial action) does not guarantee that it will be prevented in the future. Therefore, near-misses signal flaws in a bank's internal system and should be accounted for in internal models. It is also possible to view near-misses from quite the opposite perspective: The ability to prevent these losses before they happen demonstrates the bank's effective operational risk management practices. Therefore, the losses that would result had these events taken place should not be included in the internal databases.

Muermann and Oktem (2002, p. 30) define near-miss as:

an event, a sequence of events, or an observation of unusual occurrences that possesses the potential of improving a system's operability by reducing the risk of upsets some of which could eventually cause serious damage.

They assert that internal operational risk measurement models must include adequate management of near-misses.

Muermann and Oktem propose developing a pyramid-type three-level structure for the near-miss management system: corporate level, branch level, and individual level. At the corporate level within every bank, they propose

Table 1 Direct Loss Types and Their Definitions According to the Basel II Capital Accord

Loss Type	Contents
Write-downs	Direct reduction in value of assets due to theft, fraud, unauthorized activity, or market and credit losses arising as a result of operational events
Loss of recourse Restitution	Payments or disbursements made to incorrect parties and not recovered Payments to clients of principal and/or interest by way of restitution, or the cost of any other form of compensation paid to clients
Legal liability	Judgements, settlements, and other legal costs
Regulatory and compliance	Taxation penalties, fines, or the direct cost of any other penalties, such as license revocations
Loss of or damage to assets	Direct reduction in value of physical assets, including certificates, due to an accident, such as neglect, fire, and earthquake

Source: BIS (2001a), p. 23, with modifications.

establishing a Near-Miss Management Strategic Committee whose primary functions would include:

- Establishing guidelines for corporate and site near-miss structures.
- Developing criteria for classification of near-misses.
- Establishing prioritizing procedures for each near-miss class.
- Auditing the near-miss system.
- Integrating quality and other management tools into near-miss management practice.
- Identifying gaps in the near-miss management structure based on analysis of incidents with higher damage (beyond near-misses) and taking corrective actions.
- Developing guidelines for training site management and employees on near-miss system.

At the branch level, they propose establishing a Near-Miss Management Council for every business unit. The key responsibilities of the council would include:

- Adapting criteria set by Near-Miss Management Strategic Committee to the branch practices.
- Monitoring site near-miss practices.
- Promoting the program.
- Ensuring availability of necessary resources for analysis and corrective action, especially for high priority near-misses.
- Periodically analyzing reported near-misses for further improvement of the system.
- Training employees on NM implementation.

Finally, a successful near-miss management system relies on the individual actions by managers, supervisors, and employees. Appropriate training is necessary to recognize operational issues before they become a major problem and develop into operational losses for the bank.

Expected versus Unexpected Operational Losses

Some operational losses are expected, some are not. The *expected* losses are generally those that occur on a regular (such as every day) basis, such as minor employee errors and minor credit card fraud. *Unexpected* losses are those losses that generally cannot be easily foreseen, such as terrorist attacks, natural disasters, and large-scale internal fraud.

Operational Risk Type, Event Type, and Loss Type

Confusion arises in the operational risk literature because of the distinction between risk type (or hazard type), event type, and loss type. When banks record their operational loss data, it is crucial to record it separately according to event type and loss type, and correctly identify the risk type.¹¹ The distinction between the three is comparable to cause and effect:¹²

- *Hazard* constitutes one or more factors that increase the probability of occurrence of an event.
- *Event* is a single incident that leads directly to one or more effects (e.g., losses).
- *Loss* constitutes the amount of financial damage resulting from an event.

Thus, hazard potentially leads to event, and event is the cause of loss. Therefore, an event is the effect of a hazard while loss is the effect of an event.

Figure 1 illustrates the mechanism of operational loss occurrence. The following example, adopted from Mori and Harada (2001), further illustrates how the correct identification of the “event type” is critical in determining whether a loss of a particular “loss type” is attributed to market, credit, or operational risk.

Consider the following example:

- A reduction in the value of a bond due to a change in the market price.

Operational Risk

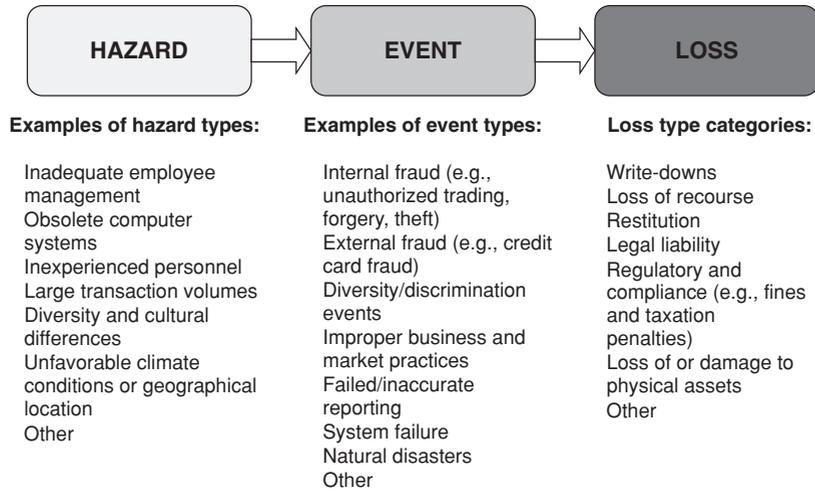

Figure 1 The Process of Operational Loss Occurrence
 Source: Mori and Harada (2001), p. 3, with modifications.

- A reduction in the value of a bond due to the bankruptcy of the issuer.
- A reduction in the value of a bond due to a delivery failure.

risk, credit risk, and operational risk, respectively. Accurate documentation of operational risk by the type of hazard, event, and loss is also essential for an understanding of operational risk.

In this example, the write-down of the bond (the loss type) belongs to the scope of market

The Basel II Capital Accord classifies operational risk into seven event-type groups (see

Table 2 Operational Risk Event Types and Their Descriptions According to the Basel II Capital Accord

Event Types and Descriptions According to Basel II	
Event Type	Definition and Categories
1. Internal Fraud	Acts intended to defraud, misappropriate property, or circumvent regulations, the law, or company policy, which involves at least one internal party. <i>Categories:</i> unauthorized activity and theft and fraud.
2. External Fraud	Acts of a type intended to defraud, misappropriate property, or circumvent the law, by a third party. <i>Categories:</i> (1) theft and fraud and (2) systems security.
3. Employment Practices and Workplace Safety	Acts inconsistent with employment, health, or safety laws or agreements, from payment of personal injury claims, or from diversity/discrimination events. <i>Categories:</i> (1) employee relations, (2) safe environment, and (3) diversity and discrimination.
4. Clients, Products, and Business Practices	Unintentional or negligent failure to meet a professional obligation to specific clients (including fiduciary and suitability requirements), or from the nature or design of a product. <i>Categories:</i> (1) suitability, disclosure, and fiduciary, (2) improper business or market practices, (3) product flaws, (4) selection, sponsorship, and exposure, and (5) advisory activities.
5. Damage to Physical Assets	Loss or damage to physical assets from natural disaster or other events. <i>Categories:</i> disasters and other events.
6. Business Disruption and System Failures	Disruption of business or system failures. <i>Categories:</i> systems.
7. Execution, Delivery, and Process Management	Failed transaction processing or process management, from relations with trade counterparties and vendors. <i>Categories:</i> (1) transaction capture, execution, and maintenance, (2) monitoring and reporting, (3) customer intake and documentation, (4) customer/client account management, (5) trade counterparties, and (6) vendors and suppliers.

Table 2) and six operational loss types (see Table 1).

Operational Loss Severity and Frequency

We have already stated that expected losses generally refer to the losses of low severity (or magnitude) and high frequency. Generalizing this idea, operational losses can be broadly classified into four main groups:

1. Low frequency/low severity.
2. High frequency/low severity.
3. High frequency/high severity.
4. Low frequency/high severity.

The idea is illustrated in the top half of Figure 2.

According to Samad-Khan (2005), the third group is implausible. More precisely, he suggests classifying each of the frequency and

severity of operational losses into three groups: low, medium, and high. This creates a 3 × 3 matrix of all possible “frequency/severity” combinations. He states that “medium frequency/high severity,” “high frequency/medium severity,” and “high frequency/high severity” losses are unrealistic.

Recently, the financial industry also agreed that the first group is not feasible. Therefore, the two remaining categories of operational losses that the financial industry needs to focus on are “high frequency/low severity” and “low severity/high frequency” losses. The idea is illustrated in the bottom half of Figure 2.

The losses of “high frequency/low severity” are relatively unimportant for an institution and can often be prevented. What poses the greatest damage is the “low frequency/high severity” losses. Banks must be particularly attentive to these losses as these cause the greatest financial consequences to the institution, including

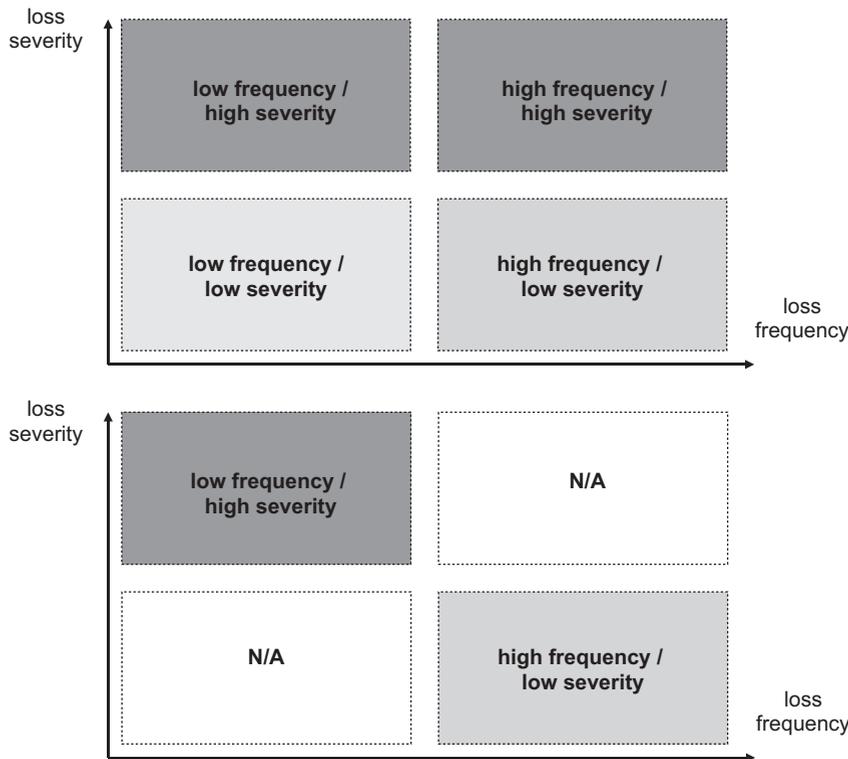

Figure 2 Classification of Operational Risk by Frequency and Severity: Unrealistic View (top) and Realistic View (bottom)

potential bankruptcy.¹³ Just a few of such events may result in bankruptcy or a significant decline in the market value of the bank. Therefore, it is critical for banks to be able to capture such losses in their internal risk models.

KEY POINTS

- Financial institutions bear various operational losses on a daily basis. Examples are losses resulting from employee errors, internal and external fraud, equipment failures, business disruptions due to natural disasters, and vandalism.
- Credit risk and market risk had been perceived as the two biggest sources of risk for financial institutions. Operational risk has been regarded as a mere part of “other” risks. Failures of major financial entities have made market participants aware of the importance of this risk.
- Operation risk is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. This definition identifies operational risk as coming from four major causes: processes, human, systems, and external factors.
- Operational risk can be classified according to several principles: nature of the loss (internally inflicted or externally inflicted), direct losses or indirect losses, degree of expectancy (expected or unexpected), risk type, event type or loss type, and by the magnitude (or severity) of loss and the frequency of loss.
- Operational risk can be the cause of reputational risk, a risk that can occur when the market reaction to an operational loss event results in reduction in the market value of a bank that is greater than the amount of the initial loss.

NOTES

1. However, operational risk is not entirely idiosyncratic. Two recent studies—Allen and Bali (2007) and Chernobai, Jorion, and Yu (2011)—found evidence of the effect of

macroeconomic factors on operational risk in banks.

Abstract: In general terms, operational risk is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. The models that have been proposed for assessing operational risk can be broadly classified into top-down models and bottom-up models. Top-down approaches quantify operational risk without attempting to identify the events or causes of losses. Bottom-up models quantify operational risk on a micro level being based on identified internal events. The obstacle hindering the implementation of these models is the scarcity of available historical operational loss data.

Identifying the core principles that underlie the *operational risk* process is the fundamental building block in deciding on the optimal model to be used. In this entry we provide an overview of models that have been put forward for the assessment of operational risk. These models are broadly classified into *top-down models* and *bottom-up models*.

Operational risk is distinct from credit risk and market risk, posing difficulties of implementation of the Basel II guidelines and strategic planning. We discuss some key aspects that distinguish operational risk from credit risk and market risk. They are related to the *arrival process* of loss events, the *loss severity*, and the dependence structure of operational losses across

a bank's business units. Finally in this entry we reconsider the normality assumption—an assumption often made in modeling financial data—and question its applicability for the purpose of operational risk modeling.

OPERATIONAL RISK MODELS

Broadly speaking, operational risk models stem from two fundamentally different approaches: (1) the top-down approach, and (2) the bottom-up approach. Figure 1 illustrates a possible categorization of quantitative models.

Top-down approaches quantify operational risk without attempting to identify the events

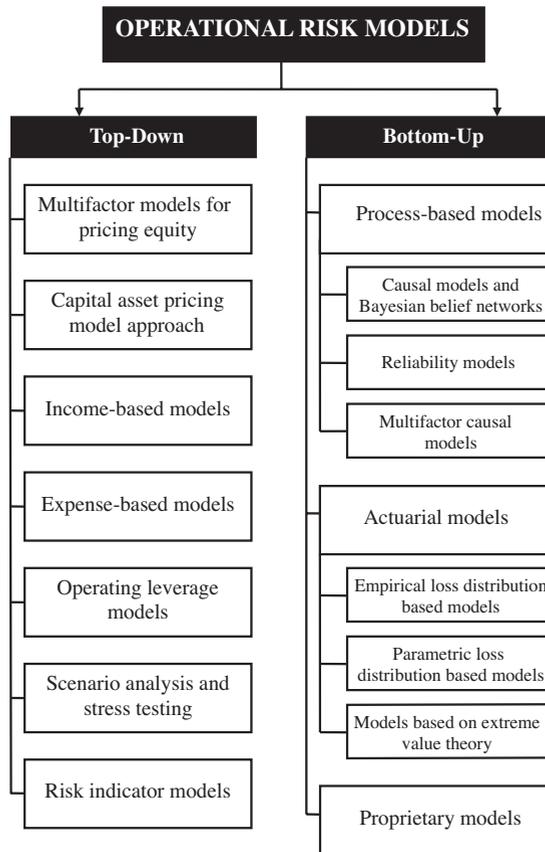

Figure 1 Topology of Operational Risk Models

or causes of losses.¹ That is, the losses are simply measured on a macro basis. The principal advantage of this approach is that little effort is required with collecting data and evaluating operational risk. Bottom-up approaches quantify operational risk on a micro level being based on identified internal events, and this information is then incorporated into the overall capital charge calculation. The advantage of bottom-up approaches over top-down approaches lies in their ability to explain the mechanism of how and why operational risk is formed within an institution. Banks can either start with top-down models and use them as a temporary tool to estimate the capital charge and then slowly shift to the more advanced bottom-up models, or they can adopt bottom-up models from the start, provided that they have robust databases.

Models Based on Top-Down Approaches

In this section we will provide a brief look at the seven top-down approaches shown in Figure 1.²

Multifactor Equity Pricing Models

Multifactor equity pricing models, also referred to as multifactor models, can be utilized to perform a global analysis of banking risks and may be used for the purpose of integrated risk management, in particular for publicly traded firms. The stock return process R_t can be estimated by regressing stock return on a large number of external risk factor indexes I_t related to market risk, credit risks, and other nonoperational risks (such as interest rate fluctuations, stock price movements, and macroeconomic effects). Operational risk is then measured as the volatility of the residual term. Such models rely on the assumption that operational risk is the residual banking risk, after credit and market risks are accounted for.³

$$R_t = a_t + b_1 I_{1t} + \dots + b_n I_{nt} + \varepsilon_t$$

in which ε_t is the residual term, a proxy for operational risk.

This approach relies on the widely known efficient market hypothesis that was introduced by Fama (1970), that states that in efficient capital markets all relevant past, publicly, and privately available information is reflected in current asset prices.

Capital Asset Pricing Model

Under the capital asset pricing model (CAPM) approach all risks are assumed to be measurable by the CAPM and represented by beta (β). CAPM, developed by Sharpe (1964), is an equilibrium model that describes the pricing of assets. It concludes that the expected security risk premium (i.e., expected return on security minus the risk-free rate of return) equals beta times the expected market risk premium

(i.e., expected return on the market minus the risk-free rate of return).

Under the CAPM approach, operational risk is obtained by measuring market, credit, and other risks' betas and deducting them from the total beta. With respect to applications to operational risk, the CAPM approach was discussed by Hiwatashi and Ashida (2002) and van den Brink (2002). According to van den Brink (2002), the CAPM approach has some limitations and so has not received a wide recognition for operational risk, but was in the past considered by Chase Manhattan Bank.

Income-Based Models

Income-based models resemble the multifactor equity price models: Operational risk is estimated as the residual variance by extracting market, credit, and other risks from the historical income (or earnings) volatility. Income-based models are described by Allen, Boudoukh, and Saunders (2004), who refer to these models as earnings at risk models and by Hiwatashi and Ashida (2002), who refer to them as the volatility approach. According to Cruz (2002), the profit and loss (P&L) volatility in a financial institution is attributed 50%, 15%, and 35% to credit risk, market risk, and operational and other risks, respectively.

Expense-Based Models

Expense-based models measure operational risk as fluctuations in historical expenses rather than income. The unexpected operational losses are captured by the volatility of direct expenses (as opposed to indirect expenses, such as opportunity costs, reputational risk, and strategic risk, that are outside the agreed scope of operational risk), adjusted for any structural changes within the bank.

Operating Leverage Models

Operating leverage models measure the relationship between operating expenses and total assets. Operating leverage is measured as a weighted combination of a fraction of fixed as-

sets and a portion of operating expenses. Examples of calculating operating leverage amount per business line include taking 10% of fixed assets plus 25% times three months' operating expenses for a particular business, or taking 2.5 times the monthly fixed expenses.⁴

Scenario Analysis and Stress Testing Models

Scenario analysis and stress testing models can be used for testing the robustness properties of loss models, in monetary terms, in the presence of potential events that are not part of banks' actual internal databases. These models, also called expert judgment models by van den Brink (2002), are estimated based on the "what if" scenarios generated with reference to expert opinion, external data, catastrophic events that occurred in other banks, or imaginary high-magnitude events. Experts estimate the expected risk amounts and their associated probabilities of occurrence. For any particular bank, examples of scenarios include:⁵

- Bank's inability to reconcile a new settlement system with the original system.
- A class action suit alleging incomplete disclosure.
- Massive technology failure.
- High-scale unauthorized trading (for example, adding the total loss borne by the Barings bank preceding its collapse into the database, and reevaluating the model).
- Doubling the bank's maximum historical loss amount.

Additionally, stress tests can be used to see the likely increase in risk exposure due to removing a control or reduction in risk exposure due to tightening of controls.

Risk Indicator Models

Risk indicator models rely on a number (one or more) of operational risk exposure indicators to track operational risk. In the operational risk literature, risk indicator models are also called indicator approach models,⁶ risk profiling

models,⁷ and peer-group comparison.⁸ A necessary aspect of such models is testing for possible correlations between risk factors. These models assume that there is a direct and significant relationship between the indicators and target variables. For example, Taylor and Hoffman (1999) illustrate how training expenditure has a reverse effect on the number of employee errors and customer complaints and Shih, Samad-Khan, and Medapa (2000) illustrate how a bank's size relates to the operational loss amount.

Risk indicator models may rely on a single indicator or multiple indicators. The former model is called the single-indicator approach;⁹ an example of such a model is the Basic Indicator Approach for quantification of the operational risk regulatory capital, proposed by the Basel II. The latter model is called the multi-indicator approach; an example of such a model is the Standardized Approach.

Models Based on Bottom-Up Approaches

An ideal internal operational risk assessment procedure would be to use a balanced approach, and include both top-down and bottom-up elements in the analysis.¹⁰ For example, scenario analysis can prove effective for backtesting purposes, and multifactor causal models are useful in performing operational Value-at-Risk (VaR) sensitivity analysis. Bottom-up approach models can be categorized into three groups:¹¹ process-based models, actuarial-type models (or statistical models), and proprietary models.

Process-Based Models

There are three types of process-based models: (1) causal models and Bayesian belief networks, (2) reliability models, and (3) multifactor causal models. We describe each below.

The first group of process-based models is the causal models and Bayesian belief networks. Also called causal network models, causal

models are subjective self-assessment models. Causal models form the basis of the scorecard models.¹² These models split banking activities into simple steps; for each step, bank management evaluates the number of days needed to complete the step, the number of failures and errors, and so on, and then records the results in a "process map" (or scorecards) in order to identify potential weak points in the operational cycle. Constructing associated event trees that detect a sequence of actions or events that may lead to an operational loss is part of the analysis.¹³ For each step, bank management estimates a probability of its occurrence, called the subjective (or prior) probability. The ultimate event's probability is measured by the posterior probability. Prior and posterior probabilities can be estimated using the Bayesian belief networks.¹⁴ A variation of the causal models, connectivity models, focuses on the ex ante cause of operational loss event, rather than the ex post effect.

The second group of process-based models encompasses reliability models. These models are based on the frequency distribution of the operational loss events and their interarrival times. Reliability models focus on measuring the likelihood that a particular event will occur at some point or interval of time. We discuss this model below.

If $f(t)$ is the density of a loss amount occurring at time t , then the reliability of the system is the probability of survival up to time t , denoted by $R(t)$ and calculated as

$$R(t) = 1 - \int_0^t f(s)ds$$

The *hazard rate* (or the *failure rate*), $h(t)$, is the rate at which losses occur per unit of time t , defined as

$$h(t) = \frac{f(t)}{R(t)}$$

In practical applications, it is often convenient to use the Poisson-type arrival model to describe the occurrence of operational loss events. Under the simple Poisson model with the

intensity rate λ (which represents the average number of events in any point of time), the inter-arrival times between the events (i.e., the time intervals between any two consecutive points of time in which an event takes place) follow an exponential distribution having density of form $f(t) = \lambda e^{-\lambda t}$ with mean interarrival time equal to $1/\lambda$. The parameter λ is then the hazard rate for the simple Poisson process.

Finally, the third group of process-based models is multifactor causal models. These models can be used for performing the factor analysis of operational risk. These are regression-type models that examine the sensitivity of aggregate operational losses (or, alternatively, VaR) to various internal risk factors (or risk drivers). Multifactor causal models have been discussed in the VaR and operational risk literature.¹⁵ Examples of control factors include system downtime in minutes per day, number of employees in the back office, data quality (such as the ratio of the number of transactions with no input errors to the total number of transactions), total number of transactions, skill levels, product complexity, level of automation, customer satisfaction, and so on. Cruz (2002) suggests using manageable explanatory factors. In multifactor causal models, operational losses OR_t , or VaR, in a particular business unit at a point t , are regressed on a number of control factors:

$$OR_t = a_t + b_1 X_{1t} + \dots + b_n X_{nt} + \varepsilon_t$$

where X_k , $k = 1, 2, \dots, n$, are the explanatory variables, and b 's are the estimated coefficients. The model is forward-looking (or ex ante) as operational risk drivers are predictive of future losses. Extensions to the simple regression model may include autoregressive models, regime-switching models, ARMA/GARCH models, and others.

Actuarial Models

Actuarial models (or statistical models) are generally parametric statistical models. They have two key components: (1) the loss frequency and

(2) the loss severity distributions of the historic operational loss data. Operational risk capital is measured by the VaR of the aggregated one-year losses.¹⁶

For the frequency of the loss data it is common to assume a Poisson process, with possible generalizations, such as a Cox process.

Actuarial models can differ by the type of the loss distribution. Empirical loss distribution models do not specify a particular class of loss distributions, but directly utilize the empirical distribution derived from the historic data. Parametric loss distribution models make use of a particular parametric distribution for the losses (or part of them), such as lognormal, Weibull, Pareto, and so on. Models based on extreme value theory (EVT) restrict attention to the tail events (i.e., the losses in the upper quantiles of the severity distribution), and VaR or other analyses are carried out upon fitting the generalized Pareto distribution to the data beyond a fixed high threshold. Van den Brink suggests using all three models simultaneously; Figure 2, inspired by his discussions, illustrates possible approaches. Yet another possibility is to fit an ARMA/GARCH model to the losses below a high threshold and the generalized Pareto distribution to the data exceeding it.

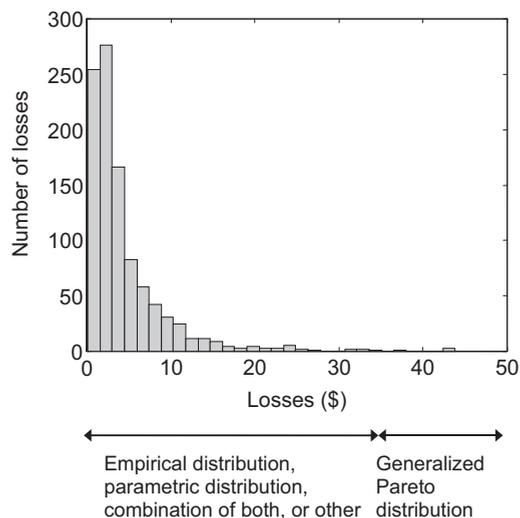

Figure 2 An Example of a Histogram of the Operational Loss Severity Distribution

Proprietary Models

Proprietary models for operational risk have been developed by major financial service companies and use a variety of bottom-up and top-down quantitative methodologies, as well as qualitative analysis, to evaluate operational risk. Banks can input their loss data into ready and systematized spreadsheets, which would be further categorized. The system then performs a qualitative and quantitative analysis of the data, and can carry out multiple tasks such as calculating regulatory capital, pooling internal data with external, performing Bayesian network analysis, and so on.

SPECIFICS OF OPERATIONAL LOSS DATA

The nature of operational risk is very different from that of market risk and credit risk. In fact, operational losses share many similarities with insurance claims, suggesting that most actuarial models can be a natural choice of the model for operational risk, and models well developed by the insurance industry can be almost exactly applied to operational risk. In this section we discuss some key issues characterizing operational risk that must be taken into consideration before quantitative analysis is undertaken.

Scarcity of Available Historical Data

The major obstacle banks face in developing comprehensive models for operational risk is the scarcity of available historical operational loss data. As of 2011, generally, even the largest banks have no more than 11–12 years of loss data. Shortage of relevant data means that the models and conclusions drawn from the available limited samples would lack sufficient explanatory power. This in turn means that the estimates of the expected loss and VaR may be highly volatile and unreliable. In addition, complex statistical or econometric models cannot be tested on small samples.

The problem becomes amplified when dealing with modeling extremely high operational losses: One cannot model tail events when only a few such data are present in the internal loss database. Three solutions have been proposed: (1) pooling internal and external data, (2) supplementing actual losses with near-miss losses, and (3) scenario analysis and stress tests (discussed earlier in this entry).

The idea behind pooling internal and external data is to populate a bank's existing internal database with data from outside the bank. The rationale is twofold: (1) to expand the database and hence increase the accuracy of statistical estimations and (2) to account for losses that have not occurred within the bank but that are not completely improbable based on the histories of other banks. According to BIS,

... a bank's internal measurement system must reasonably estimate unexpected losses based on the combined use of internal and relevant external loss data... (BIS, 2006, p. 150)

Baud, Frachot, and Roncalli (2002) propose a statistical methodology to pool internal and external data. Their methodology accounts for the fact that external data are truncated from below (banks commonly report their loss data to external parties in excess of \$1 million) and that bank size may be correlated with the magnitudes of losses. They showed that pooling internal and external data may help avoid underestimation of the capital charge.

Data Arrival Process

One of the difficulties that arise with modeling operational losses has to do with the irregular nature of the event arrival process. In market risk models, market positions are recorded on a frequent basis, many times daily depending on the entity, by marking to market. Price quotes are available daily or for those securities that are infrequently traded, model-based prices are available for marking a position to market. As for credit risk, credit ratings by rating agencies are available. In addition, rating agencies

provide credit watches to identify credits that are candidates for downgrades. In contrast, operational losses occur at irregular time intervals suggesting a process of a discrete nature. This makes it similar to the reduced-form models for credit risk, in which the frequency of default (i.e., failure to meet a credit agreement) is of nontrivial concern. Hence, while in market risk we need to model only the return distribution in order to obtain VaR, in operational risk both loss severity and frequency distributions are important.

Another problem is related to timing and data recording issues. In market and credit risk models, the impact of a relevant event is almost immediately reflected in the market and credit returns. In an ideal scenario, banks would know how much of the operational loss would be borne by the bank from an event at the very moment the event takes place and would record the loss at this moment. However, from the practical point of view, this appears nearly impossible to implement, because it takes time for the losses to accumulate after an event takes place. Therefore, it may take days, months, or even years for the full impact of a particular loss event to be evaluated. Hence, there is the problem of discrepancy (i.e., a time lag) between the occurrence of an event and the time at which the incurred loss is being recorded.

This problem directly affects the method in which banks choose to record their operational loss data. When banks record their operational loss data, they record (1) the amount of loss, and (2) the corresponding date. We can identify three potential scenarios for the types of date banks might use:¹⁷

1. *Date of occurrence*: the date on which the event that has led to operational losses actually took place.
2. *Date on which the existence of event has been identified*: the date when bank authorities realize that an event that has led to operational losses has taken or is continuing to take place. Recording a loss at this date may be relevant

in cases when the true date of occurrence is impossible or hard to track.

3. *Accounting date*: the date on which the total amount of operational losses due to a past event are realized and fully measured, and the state of affairs of the event is closed or assumed closed.

Depending on which of the three date types is used, the models for operational risk and conclusions drawn from them may be considerably different. For example, in the third case of accounting dates, we are likely to observe cyclical/seasonal effects in the time series of the loss data (for example, many loss events would be recorded around the end of December), while in the first and second cases such effects are much less likely to be present in the data. Fortunately, however, selection of the frequency distribution does not have a serious impact on the resulting capital charge.¹⁸

Loss Severity Process

There are three main problems that operational risk analysts must be aware of with respect to the severity of operational loss data: (1) the non-negative sign of the data, (2) the high degree of dispersion of the data, and (3) the shape of the data.

The first problem related to the loss severity data deals with the sign of the data. Depending on the movements in the interest or exchange rates, the oscillations in the market returns and indicators can take either a positive or negative sign. This is different in the credit and operational risk models—usually, only losses (i.e., negative cash flows) are assumed to take place.¹⁹ Hence, in modeling operational loss magnitudes, one should either consider fitting the loss distributions that are defined only on positive values, or should use distributions that are defined on negative and positive values, truncated at zero.

The second problem deals with the high degree of dispersion of loss data. Historical

observations suggest that the movements in the market indicators are generally of relatively low magnitude. Bigger losses are usually attributed to credit risk. Finally, although most of the operational losses occur on a daily basis and hence are small in magnitude, the excessive losses of financial institutions are in general due to the operational losses, rather than credit or market risk-related losses. Empirical evidence indicates that there is an extremely high degree of dispersion of the operational loss magnitudes, ranging from near-zero to billions of dollars. In general, this dispersion is measured by variance or standard deviation.²⁰

The third problem concerns the shape of the loss distribution. The shape of the data for operational risk is very different from that of market or credit risk. In market risk models, for example, the distribution of the market returns is often assumed to be nearly symmetric around zero. Asymmetric cases refer to the data whose distribution is either left-skewed (i.e., the left tail of the distribution is very long) or right-skewed (i.e., the right tail of the distribution is very long) and/or whose distribution has two or more peaks of different height. Operational losses are highly asymmetric, and empirical evidence on operational risk indicates that the losses are highly skewed to the right. This is in part explained by the presence of “low frequency/high severity” events. See Figure 2 for an exemplary histogram of operational losses.

As previously discussed, empirical evidence on operational losses indicates a majority of observations being located close to zero, and a small number of observations being of a very high magnitude. The first phenomenon refers to a high kurtosis (i.e., peak) of the data, and the second one indicates heavy tails (or fat tails). Distributions of such data are often described as leptokurtic.

The Gaussian (or normal) distribution is often used to model market risk and credit risk. It is characterized by two parameters, μ and σ , that are its mean and standard deviation. Figure 3 provides an example of a normal density.

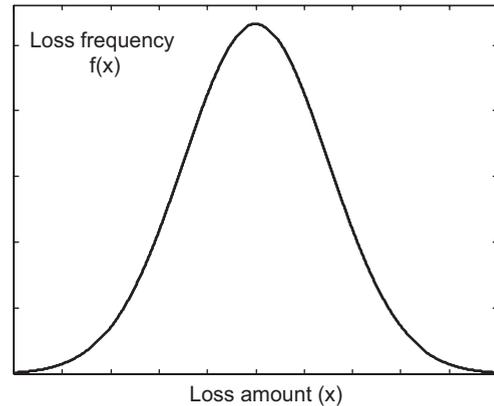

Figure 3 An Example of a Gaussian Density

Despite being easy to work with and having attractive features (such as symmetry and stability under linear transformations), the Gaussian distribution makes several critical assumptions about the loss data. They include the following:

- The Gaussian assumption is useful for modeling the distribution of events that are symmetric around their mean. It has been empirically demonstrated that operational losses are not symmetric and severely right-skewed, meaning that the right tail of the loss distribution is very long.
- In most cases (except for the cases when the mean is very high), the use of Gaussian distribution allows for the occurrence of negative values. This is not a desirable property for modeling loss severity because negative losses are usually not possible.²¹
- More importantly, the Gaussian distribution has an exponential decay in its tails (this property puts the Gaussian distribution into the class of light-tailed distributions), which means that the tail events (i.e., the events of an unusually high or low magnitude) have a near-zero probability of occurrence. However, very high-magnitude operational losses can seriously jeopardize a financial institution. Thus, it would be inappropriate to model operational losses with a distribution that essentially excludes the possibility of high-impact individual losses. Empirical evidence

strongly supports the conjecture that the distribution of operational losses is in fact very leptokurtic—that is, has a high peak and very heavy tails (i.e., very rare events are assigned a positive probability).

For the reasons presented above, it is unlikely that the Gaussian distribution would find much application for the assessment of operational risk.²² Heavier tailed distributions such as log-normal, Weibull, and even Pareto and alpha-stable, ought to be considered.

Dependence Between Business Units

In order to increase the accuracy of operational risk assessment, banks are advised to classify their operational loss data into groups of different degrees and nature of exposure to operational risk. Following this principle, the advanced measurement approaches (AMA) for the quantification of the operational risk capital charge, proposed by Basel II, suggest estimating operational risk capital separately for each “business line/event type” combination. Such a procedure is not common in market risk and credit risk models.

The most intuitive approach to combine risk measures collected from each of these “business line/event type” combinations is to add them up.²³ However, such an approach may result in overestimation of the total capital charge because it implies a perfect positive correlation between groups. To prevent this from happening, it is essential to account for dependence between these combinations. Covariance and correlation are the simplest measures of dependency, but they assume a linear type of dependence, and therefore can produce misleading results if the linearity assumption is not true. An alternative approach would involve using copulas that are more flexible with respect to the form of the dependence structure that may exist between different groups. Another attractive property of copulas is their ability to cap-

ture the tail dependence between the distributions of random variables. Both properties are preserved under linear transformations of the variables.

KEY POINTS

- Operational risk measurement models are divided into top-down and bottom-up models.
- Top-down models use a macro-level regulatory approach to assess operational risk and determine the capital charge. They include multifactor equity price models, income and expense-based models, operating leverage models, scenario analysis and stress testing models, and risk indicator models.
- Bottom-up models originate from a micro-level analysis of a bank’s loss data and consideration for the process and causes of loss events in determination of the capital charge. They include process-based models (such as causal network and Bayesian belief models, connectivity models, multifactor causal models, and reliability models), actuarial models, and proprietary models.
- Scarcity and reliability of available internal operational loss data remains a barrier preventing banks from developing comprehensive statistical models. Sufficiently large datasets are especially important for modeling low frequency high severity events. Three solutions have been put forward to help expand internal databases: pooling together internal and external data, accounting for near-misses, and stress tests.
- The nature of operational risk is fundamentally different from that of credit and market risks. Specifics of operational loss process include discrete data arrival process, delays between time of event and loss detection/accumulation, loss data taking only positive sign, high dispersion in magnitudes of loss data, distribution of loss data being severely right-skewed and heavy-tailed, and dependence between business units and event types.

- While many market and credit risk models make the convenient Gaussian assumption on the market returns or stock returns, this distribution is unlikely to be useful for the operational risk modeling because it is unable to capture the nonsymmetric and heavy-tailed nature of the loss data.

NOTES

1. An exception is the scenario analysis models in which specific events are identified and included in internal databases for stress testing. These events are, however, imaginable and do not appear in the banks' original databases.
2. Some of these models are described in Allen, Boudoukh, and Saunders (2004).
3. See Chapter 2 in Chernobai, Rachev, and Fabozzi (2007) for an example of an empirical study that utilized such models in order to evaluate the sensitivity of operational risk to macroeconomic factors.
4. See Marshall (2001).
5. The first four examples are due to Marshall (2001).
6. See Hiwatashi and Ashida (2002).
7. See Allen, Boudoukh, and Saunders (2004).
8. See van den Brink (2002).
9. See van den Brink (2002).
10. The Internal Measurement Approach (see description in BIS, 2001) combines some elements of the top-down approach and bottom-up approach: The gamma parameter in the formula for the capital charge is set externally by regulators, while the expected loss is determined based on internal data.
11. See Allen, Boudoukh, and Saunders (2004).
12. In February 2001 the Basel Committee suggested the Scorecard Approach as one possible advanced measurement approach to measure the operational risk capital charge.
13. See, for example, Marshall (2001) on the "fishbone analysis."
14. Relevant Bayesian belief models with applications to operational risk are discussed in Alexander and Pezier (2001), Neil and Tranham (2002), and Giudici (2004), among others.
15. See also Haubenstock (2003) and Cruz (2002). The empirical study by Allen and Bali (2007) investigates the sensitivity of operational VaR to macroeconomic, rather than a bank's internal, risk factors.
16. Actuarial models form the basis of the loss distribution approach, an advanced measurement approach for operational risk. See BIS (2001).
17. Identification of the three types of dates are based on discussions with Marco Moscadelli (Banking Supervision Department, Bank of Italy).
18. See Carillo Menéndez (2005).
19. Certainly, it is possible that an event due to operational risk can incur unexpected profits for a bank, but usually this possibility is not considered.
20. Some very heavy-tailed distributions, such as the heavy-tailed Weibull, Pareto, or alpha-stable, can have an infinite variance. In these situations, robust measures of spread must be used.
21. Certainly, it is possible to use a truncated (at zero) version of the Gaussian distribution to fit operational losses.
22. Of course, a special case is fitting the Gaussian distribution to the natural logarithm of the loss data. This is equivalent (in terms of obtaining the maximum likelihood parameter estimates) to fitting the lognormal distribution to the original loss data.
23. This is the approach that was proposed in BIS (2001).

Abstract: A major risk faced by financial entities is operational risk. In general terms, operational risk is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. The two principal approaches in modeling operational loss distributions are the nonparametric approach and the parametric approach. It is important to employ a model that captures tail events and for this reason in operational risk modeling, distributions that are characterized as light-tailed distributions should be used with caution.

For financial entities, representing a stream of uncertain *operational losses* with a specified model is a difficult task: Data can be wrongly recorded, fuzzy, incomplete (e.g., truncated or censored), or simply limited. Two main approaches may be undertaken: nonparametric and parametric. In this entry, we focus on the nonparametric approach, common loss distributions, and mixture distributions. We begin by reviewing the nonparametric approach to modeling operational losses and then proceed to the parametric approach and review some common continuous distributions that can be relevant for modeling operational losses. For each of the distributions, we focus on its major characteristics that are important when using

them to model the operational loss data: density, distribution, tail behavior, mean, variance, mode, skewness, and kurtosis.

APPROACHES TO OPERATIONAL RISK MODELING

The two main approaches to *operational risk* modeling are:

1. *Nonparametric approach.* One approach would be to directly use the empirical density of the data or its smoothed curve version.¹ This nonparametric approach can be relevant in

two circumstances: first, when the available data are not believed to follow any conventional distribution,² and second, when the data set available at hand is believed to be sufficiently comprehensive.³

2. *Parametric approach.* The task is considerably simplified if we are able to fit a curve of a simple analytical form that satisfies certain properties. The general goal of this parametric approach is to find a loss distribution that would most closely resemble the distribution of the loss magnitudes of the available data sample.

Figure 1 shows a common histogram for the operational loss data with a fitted continuous curve. Visual examination suggests that magnitudes of the majority of the losses are very close to zero as is seen from the high peak around zero of the histogram; an insignificant fraction of data account for the long right tail of the histogram. Clearly, if we choose the parametric approach and if the fitted curve represents a density of some chosen parametric distribution, the loss distributions that would be adequate for modeling operational losses are those that are right-skewed, possibly leptokurtic, and have support on the positive values.

Figure 2 summarizes possible approaches to modeling operational loss severity.

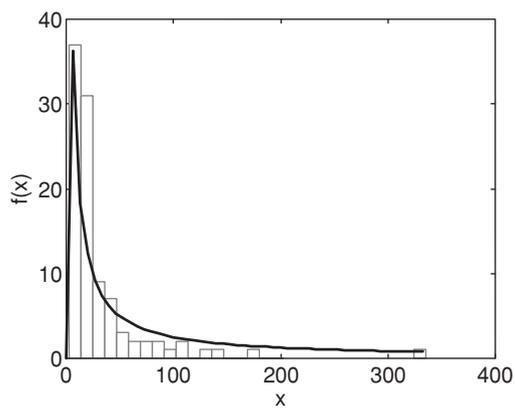

Figure 1 Illustration of a Histogram of Loss Data and Fitted Continuous Density

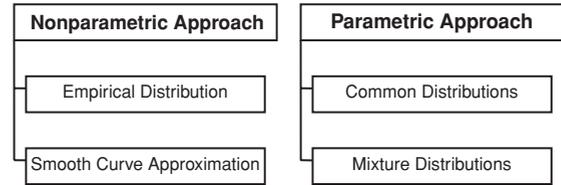

Figure 2 Approaches to Modeling Loss Severity

NONPARAMETRIC APPROACH: EMPIRICAL DISTRIBUTION FUNCTION

Modeling operational losses with their empirical distribution function is a nonparametric approach as it does not involve estimation of the parameters of a loss distribution. In this sense, it is the simplest approach. On the other hand, it makes the following two critical assumptions regarding future loss data:

- Historic loss data are sufficiently comprehensive.
- All past losses are equally likely to reappear in the future, and losses of other magnitudes (such as potential extreme events that are not a part of existent database) cannot occur.

Suppose we want to find the empirical distribution function of a random variable X . It is found by:

$$P(X \leq x) = \frac{\text{number of losses} \leq x}{\text{total number of losses}}$$

The empirical distribution function looks like a step function, with a step up occurring at each observed value of X . Figure 3 provides an illustration. The density function⁴ is simply a relative frequency histogram with a bar at each observed data value, and the height of each bar shows the proportion of losses of this magnitude out of total.

Note that the empirical distribution is often used in goodness-of-fit tests. One can compare it with a fitted loss distribution, and if the fitted loss distribution follows closely the empirical distribution, then this indicates a good fit; if it does not follow closely the empirical

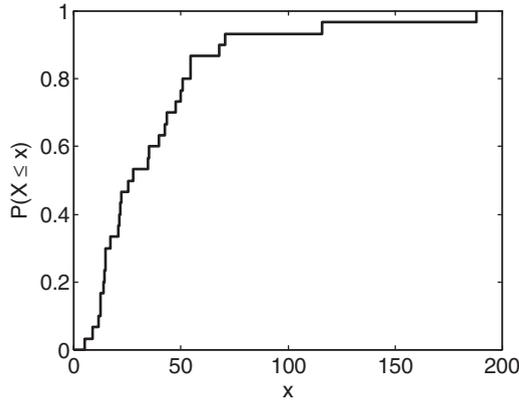

Figure 3 Illustration of Empirical Distribution Function

distribution function, then the loss distribution is not optimal.

PARAMETRIC APPROACH: CONTINUOUS LOSS DISTRIBUTIONS

In this section, we review several popular loss distributions. Certainly, a variety of additional distributions may be created by using some transformation of the original data and then fitting a distribution to the transformed data. A popular transformation involves taking the natural logarithm of the data. It is notable that if the original data are severely right-skewed, then the distribution of the log-data often becomes “bell-shaped” and nearly symmetric. For example, fitting the normal distribution to the log-data is equivalent to fitting the lognormal distribution to the original data.

Exponential Distribution

The exponential distribution for a random variable X of length n is described by its density f and distribution F of the following form:

$$f(x) = \lambda e^{-\lambda x}, \quad F(x) = 1 - e^{-\lambda x}, \quad x > 0$$

The distribution is characterized by only one parameter λ ($\lambda > 0$), which is the scale parameter.

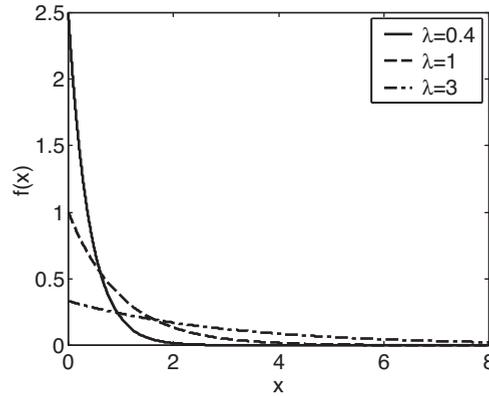

Figure 4 Illustration of Exponential Density

Examples of exponential densities are illustrated in Figure 4. The maximum likelihood estimate (MLE) for λ is

$$\hat{\lambda} = \frac{1}{\bar{x}} \quad \text{where} \quad \bar{x} = \frac{1}{n} \sum_{j=1}^n x_j$$

Raw moments are calculated as:

$$\mathbb{E}(X^k) = \frac{k!}{\lambda^k}$$

and so the population mean and variance are

$$\text{mean}(X) = 1/\lambda, \quad \text{var}(X) = 1/\lambda^2$$

The mode of an exponential distribution is located at zero. The skewness and kurtosis coefficients are $\gamma_1 = 2$ and $\gamma_2 = 6$, respectively.

The inverse of the distribution has a simple form $F^{-1}(p) = -1/\lambda \log(1 - p)$, $p \in (0, 1)$, and so an exponential random variate can be simulated using the inverse transform method by $X = -\frac{1}{\lambda} \log U$, where U is distributed uniformly on the $(0, 1)$ interval. Another popular simulation method uses the Von Neumann algorithm.

The exponential density is monotonically decreasing toward the right and is characterized by an exponentially decaying right tail of the form $\bar{F}(x) = e^{-\lambda x}$, which means that high-magnitude events are given a near-zero probability. For this reason, it is unlikely that it would find much use in modeling operational losses, where arguably the central concern is the

losses of a very high magnitude (unless, perhaps, some generalizations of the exponential distribution or mixture models are considered).

Note that another parameterization of the exponential distribution is possible, with the density specified as $f(x) = \frac{1}{\lambda} e^{-\frac{1}{\lambda}x}$.

Lognormal Distribution

A random variable X has a lognormal distribution if its density and distribution are:

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma x} e^{-\frac{(\log x - \mu)^2}{2\sigma^2}}$$

$$F(x) = \Phi\left(\frac{\log x - \mu}{\sigma}\right), \quad x > 0$$

where $\Phi(x)$ is the distribution of a standard normal, $N(0, 1)$, random variable, and can be obtained by looking up the table of the standard normal quantiles.⁵

Examples of the lognormal density are illustrated in Figure 5. The parameters μ ($-\infty < \mu < \infty$) and σ ($\sigma > 0$) are the location and scale parameters, respectively, and can be estimated with MLE as:

$$\hat{\mu} = \frac{1}{n} \sum_{j=1}^n \log x_j, \quad \hat{\sigma}^2 = \frac{1}{n} \sum_{j=1}^n (\log x_j - \hat{\mu})^2 \quad (1)$$

Raw moments are calculated as:

$$\mathbb{E}(X^k) = e^{\mu k + \frac{\sigma^2 k^2}{2}}$$

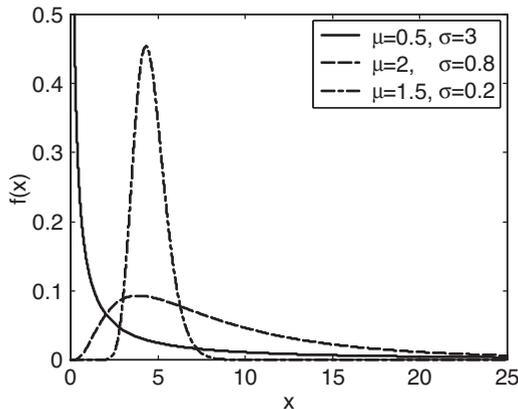

Figure 5 Illustration of Lognormal Density

and so the population mean and variance are calculated to be

$$\text{mean}(X) = e^{\mu + \frac{\sigma^2}{2}}, \quad \text{var}(X) = (e^{\sigma^2} - 1)e^{2\mu + \sigma^2}$$

The mode is located at $e^{\mu - \sigma^2}$. The skewness and kurtosis coefficients are:

$$\gamma_1 = \sqrt{e^{\sigma^2} - 1}(2 + e^{\sigma^2})$$

$$\gamma_2 = e^{4\sigma^2} + 2e^{3\sigma^2} + 3e^{2\sigma^2} - 6$$

The inverse of the distribution is $F^{-1}(p) = e^{\Phi^{-1}(p)\sigma + \mu}$, and so a lognormal random variate can be simulated by $X = e^{\Phi^{-1}(U)\sigma + \mu}$, where Φ is the standard normal distribution. Note that a lognormal random variable can be obtained from a normal random variable Y with parameters μ and σ (this is often written as $N(\mu, \sigma)$) via the transformation $X = e^Y$. Thus, if X has a lognormal distribution, then $\log X$ has a normal distribution with the same parameters.

The lognormal distribution is characterized by moderately heavy tails, with the right tail $\bar{F}(x) \sim x^{-1}e^{-\log^2 x}$. To fit a lognormal distribution to the data, one can take the natural logarithm of the dataset, and then fit to it the normal distribution. Note that the MLE will produce the same estimates, but the method of moments will produce different parameter estimates.

Weibull Distribution

The Weibull distribution is a generalization of the exponential distribution: Two parameters instead of one parameter allow for greater flexibility and heavier tails. The density and distribution are⁶

$$f(x) = \alpha\beta x^{\alpha-1} e^{-\beta x^\alpha}, \quad F(x) = 1 - e^{-\beta x^\alpha}, \quad x > 0$$

with β ($\beta > 0$) being the scale parameter and α ($\alpha > 0$) the shape parameter.

Examples of the density are illustrated in Figure 6. The MLE estimators for the parameters do not exist in closed form, and should be evaluated numerically. Raw moments are calculated as:

$$\mathbb{E}(X^k) = \beta^{-k/\alpha} \Gamma\left(1 + \frac{k}{\alpha}\right)$$

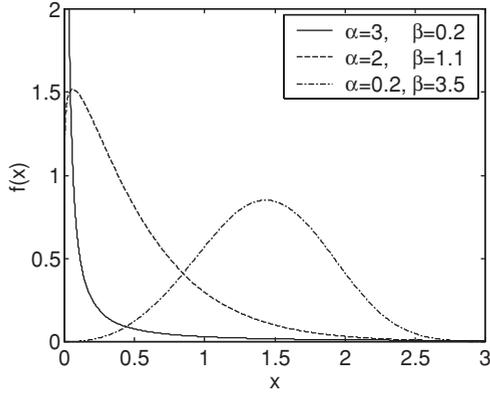

Figure 6 Illustration of Weibull Density

and so the population mean and variance are:

$$\text{mean}(X) = \beta^{-1/\alpha} \Gamma\left(1 + \frac{1}{\alpha}\right)$$

$$\text{var}(X) = \beta^{-2/\alpha} \left(\Gamma\left(1 + \frac{2}{\alpha}\right) - \Gamma^2\left(1 + \frac{1}{\alpha}\right) \right)$$

The mode is located at $\beta^{-1}(1 - \alpha^{-1})^{1/\alpha}$ for $\alpha > 0$ and at zero otherwise. The formulae for the skewness and kurtosis coefficients are:

$$\gamma_1 = \frac{2\Gamma^3(1 + \frac{1}{\alpha}) - 3\Gamma(1 + \frac{1}{\alpha})\Gamma(1 + \frac{2}{\alpha}) + \Gamma(1 + \frac{3}{\alpha})}{[\Gamma(1 + \frac{2}{\alpha}) - \Gamma^2(1 + \frac{1}{\alpha})^{3/2}]}$$

$$\gamma_2 = \frac{-6[\Gamma^4(1 + \frac{1}{\alpha}) - 12\Gamma^2(1 + \frac{1}{\alpha})\Gamma(1 + \frac{2}{\alpha}) - 3\Gamma^2(1 + \frac{2}{\alpha}) - 4\Gamma(1 + \frac{1}{\alpha})\Gamma(1 + \frac{3}{\alpha}) + \Gamma(1 + \frac{4}{\alpha})]}{[\Gamma(1 + \frac{2}{\alpha}) - \Gamma^2(1 + \frac{1}{\alpha})]^2}$$

The inverse of a Weibull random variable does not exist in a simple closed form. To generate a Weibull random variable, one can first generate an exponential random variable Y with parameter β and then follow the transformation $X = Y^{1/\alpha}$.

The right tail behavior of a Weibull random variable follows the form $\bar{F}(x) = e^{-\beta x^\alpha}$, and so the distribution is heavy-tailed for $\alpha < 1$. Weibull distribution has been found to be the optimal distribution in reinsurance models⁷ as well as in asset returns models.⁸

Note the following regarding the Weibull distribution. First, if $\alpha = 1$, then the Weibull distribution reduces to the exponential distribution. Second, other parameterizations of the Weibull distribution are possible. For example, some au-

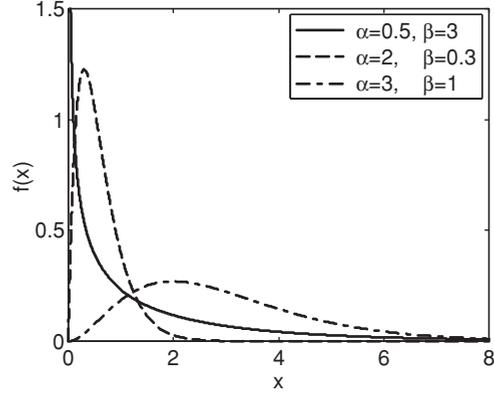

Figure 7 Illustration of Gamma Density

thors use $1/\beta$ instead of β . Sometimes $1/\beta^\alpha$ is used instead of β .

Gamma Distribution

The gamma distribution is another generalization of an exponential distribution and

is specified by its density and distribution given by⁹

$$f(x) = \frac{\beta^\alpha}{\Gamma(\alpha)} x^{\alpha-1} e^{-\beta x}$$

$$F(x) = \Gamma(\alpha; \beta x), \quad x > 0$$

where the two parameters, α ($\alpha > 0$) and β ($\beta > 0$), characterize the shape and scale, respectively.

Examples of the density are illustrated in Figure 7. The MLE estimates for the parameters can be only evaluated numerically. The raw moments are found by:

$$\mathbb{E}(X^k) = \frac{\Gamma(\alpha + k)}{\Gamma(\alpha)\beta^k}$$

yielding the population mean and variance as

$$\text{mean}(X) = \frac{\alpha}{\beta}, \quad \text{var}(X) = \frac{\alpha}{\beta^2}$$

The mode is $\frac{\alpha-1}{\beta}$ for $\alpha > 1$ and zero otherwise. The skewness and kurtosis coefficients are found by

$$\gamma_1 = \frac{2}{\sqrt{\alpha}}, \quad \gamma_2 = \frac{6}{\alpha}$$

If α is an integer,¹⁰ then to generate a gamma random variable with parameters α and β one can generate a sum of α exponential random variables each with parameter β . Hence, if $U_1, U_2, \dots, U_\alpha$ are independent uniform $(0, 1)$ random variables, then $X = -1/\beta \log(\prod_{j=1}^\alpha U_j)$ has the desired distribution. A variety of methods for generation of a gamma random variable is described in Devroye (1986).

Beta Distribution

The beta distribution has density and distribution of the following form:¹¹

$$f(x) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1-x)^{\beta-1}$$

$$F(x) = I(x; \alpha, \beta), \quad 0 \leq x \leq 1$$

Examples of the density are illustrated in Figure 8. Note that X has a bounded support on $[0, 1]$. Certainly, operational loss data may be rescaled to fit this interval. In this case, the following version of the beta density and distri-

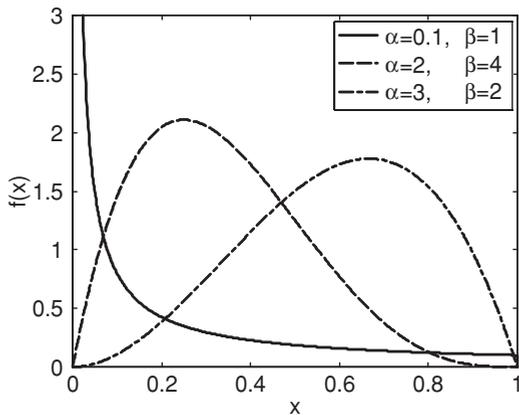

Figure 8 Illustration of Beta Density

bution is possible (the parameter θ is assumed known):

$$f(x) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha + \beta)} \left(\frac{x}{\theta}\right)^{\alpha-1} \left(1 - \frac{x}{\theta}\right)^{\beta-1} \frac{1}{x}$$

$$F(x) = I\left(\frac{x}{\theta}; \alpha, \beta\right), \quad 0 < x < \theta, \quad \theta > 0$$

The parameters α ($\alpha > 0$) and β ($\beta > 0$) determine the shape of the distribution. The MLE estimators can be evaluated numerically. The raw moments for the regular version of the beta density can be found by

$$\mathbb{E}(X^k) = \frac{(\alpha + \beta - 1)!(\alpha + k - 1)!}{(\alpha - 1)!(\alpha + \beta + k - 1)!}$$

yielding the mean and the variance:

$$\text{mean}(X) = \frac{\alpha}{\alpha + \beta}$$

$$\text{var}(X) = \frac{\alpha\beta}{(a + \beta)^2(\alpha + \beta + 1)}$$

The mode is equal to $(\alpha - 1)/(\alpha + \beta - 2)$. The skewness and kurtosis coefficients are estimated by

$$\gamma_1 = \frac{2(\beta - \alpha)\sqrt{1 + \alpha + \beta}}{\sqrt{\alpha + \beta}(2 + \alpha + \beta)}$$

$$\gamma_2 = \frac{6[\alpha^3 + \alpha^2(1 - 2\beta) + \beta^2(1 + \beta) - 2\alpha\beta(2 + \beta)]}{\alpha\beta(\alpha + \beta + 2)(\alpha + \beta + 3)}$$

The beta random variate can be generated using an algorithm described in Ross (2001, 2002) or Devroye (1986).

Note that the beta distribution is related to the gamma distribution. Suppose we have two gamma random variables X and Y with parameters α_1, β_1 and α_2, β_2 , respectively. Then the variable $Z = X/(X+Y)$ has a beta distribution with parameters α_1, α_2 . This property can be used to generate a beta random variate from two gamma random variates.

Pareto Distribution

The Pareto distribution is characterized by its density and distribution of the form:

$$f(x) = \frac{\alpha\beta^\alpha}{x^{\alpha+1}}, \quad F(x) = 1 - \left(\frac{\beta}{x}\right)^\alpha, \quad \beta < x < \infty$$

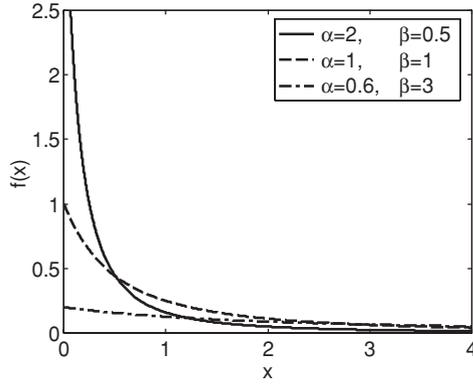

Figure 9 Illustration of Pareto Density

Note that the range of permissible values of X depends on the scale parameter β ($\beta > 0$). The parameter α ($\alpha > 0$) determines the shape.

Figure 9 illustrates some examples of the density. No closed-form expressions for the MLE estimators exist (except for the case when $\beta = 1$, in which case $\hat{\alpha} = n / \sum_{j=1}^n \log x_j$), so they have to be evaluated numerically.

The raw moments are estimated by

$$\mathbb{E}(X^k) = \frac{\alpha\beta^k}{\alpha - k}$$

from which the population mean and variance are found to be

$$\begin{aligned} \text{mean}(X) &= \frac{\alpha\beta}{\alpha - 1} \quad \text{for } \alpha > 1 \\ \text{var}(X) &= \frac{\alpha\beta^2}{(\alpha - 1)^2(\alpha - 2)} \quad \text{for } \alpha > 2 \end{aligned}$$

The mode is equal to zero. The skewness and kurtosis coefficients are:

$$\begin{aligned} \gamma_1 &= \sqrt{\frac{\alpha - 2}{\alpha} \frac{2(\alpha + 1)}{\alpha - 3}} \\ \gamma_2 &= \frac{6(\alpha^3 + \alpha^2 - 6\alpha - 2)}{\alpha(\alpha - 3)(\alpha - 4)} \end{aligned}$$

The inverse of the distribution is $F^{-1}(p) = \beta((1 - p)^{-1/\alpha} - 1)$, which can be used to generate a Pareto random variate.

The Pareto distribution is a very *heavy-tailed distribution*, as is seen from the tail behavior. α determines the heaviness of the right tail, which is monotonically decreasing for the Pareto dis-

tribution: The closer it is to zero, the thicker the tail, $\bar{F}(x) = \left(\frac{\beta}{\beta+x}\right)^\alpha$. Tails proportional to $x^{-\alpha}$ are called the power tails (as opposed to the exponentially decaying tails) because they follow a power function. The case when $\alpha \leq 1$ refers to a very heavy-tailed case, in which the mean and the variance are infinite (see the formulas for mean and variance earlier), means that losses of an infinitely high magnitude are possible.

While on one hand the Pareto distribution appears very attractive for modeling operational risk, as it is expected to capture very high-magnitude losses, on the other hand, from the practical point of view, the possibility of infinite mean and variance could pose a problem.

Note the following:

- Different versions of the Pareto distribution are possible. Occasionally a simplified, 1-parameter version of the Pareto distribution is used, with $\beta = 1$.
- A 1-parameter Pareto random variable may be obtained from an exponential random variable via a simple transformation. If a random variable Y follows an exponential distribution with parameter λ , then $X = e^Y$ has the 1-parameter Pareto distribution with the same shape parameter.
- A 2-parameter Pareto distribution may be reparameterized in such a way that we obtain the generalized Pareto distribution (GPD). The GPD can be used to model extreme events that exceed a high threshold.

Burr Distribution

The Burr distribution is a generalized three-parameter version of the Pareto distribution and allows for greater flexibility in the shape due to additional shape parameter γ ($\gamma > 0$). The density and distribution functions can be written as

$$\begin{aligned} f(x) &= \gamma\alpha\beta^\alpha \frac{x^{\gamma-1}}{(\beta + x^\gamma)^{\alpha+1}} \\ F(x) &= 1 - \left(\frac{\beta}{\beta + x^\gamma}\right)^\alpha, \quad x > 0 \end{aligned}$$

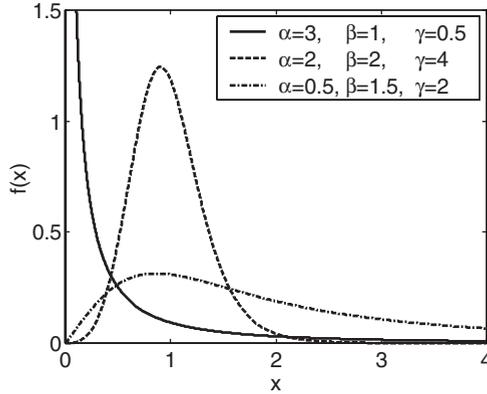

Figure 10 Illustration of Burr Density

Examples of the density are depicted in Figure 10. The MLE estimators for the parameters can generally be evaluated only numerically. The raw moments are estimated as:

$$\mathbb{E}(X^k) = \frac{\beta^{k/\gamma} \Gamma\left(1 + \frac{k}{\gamma}\right) \Gamma\left(\alpha - \frac{k}{\gamma}\right)}{\Gamma(\alpha)},$$

$$-\gamma < k < \gamma\alpha$$

from which the population mean and variance are calculated as:

$$\text{mean}(X) = \frac{\beta^{1/\gamma} \Gamma\left(1 + \frac{1}{\gamma}\right) \Gamma\left(\alpha - \frac{1}{\gamma}\right)}{\Gamma(\alpha)}$$

$$\gamma\alpha > 1$$

$$\text{var}(X) = \frac{\beta^{2/\gamma} \Gamma\left(1 + \frac{2}{\gamma}\right) \Gamma\left(\alpha - \frac{2}{\gamma}\right)}{\Gamma(\alpha)}$$

$$- \frac{\beta^{2/\gamma}}{\Gamma^2(\alpha)} \Gamma^2\left(1 + \frac{1}{\gamma}\right) \Gamma^2\left(\alpha - \frac{1}{\gamma}\right),$$

$$\gamma\alpha > 2$$

The mode is equal to $\frac{1}{\beta^{1/\gamma}} \left(\frac{\gamma-1}{\alpha\gamma+1}\right)^{1/\gamma}$ for $\gamma > 1$ and zero otherwise.

The Burr random variable can be generated by the inverse transform method, using $F^{-1}(p) = (\beta((1-p)^{-1/\alpha} - 1))^{1/\gamma}$.

The right tail has the power law property and obeys $\bar{F}(x) = \left(\frac{\beta}{\beta+x^\gamma}\right)^\alpha$. The distribution is heavy-tailed for the case $\alpha < 2$ and is very heavy-tailed when $\alpha < 1$. The Burr distribution has been used in the insurance industry, and has been found to be an optimal distribution for natural catastrophe insurance claims.¹²

Note the following two points. First, if $\gamma = 1$, then the Burr distribution reduces to the Pareto distribution. Second, other parameterizations of the Burr distribution are possible. For example, the Burr distribution with $\beta = 1$ is known as the loglogistic distribution.

EXTENSION: MIXTURE LOSS DISTRIBUTIONS

Histograms of the operational loss data often reveal a very high peak close to zero and a smaller but distinct peak toward the right tail. This may suggest that the operational loss data often do not follow a pattern of a single distribution, even for data belonging to the same loss type (such as operational losses due to business disruptions) and the same business line (such as commercial banking). One approach in modeling such losses would be to consider the GPD to model the tail events and an empirical or other distribution for the remaining lower-magnitude losses. Alternatively, one may consider a single distribution composed by a mixture of two or more loss distributions.

The density and distribution of a m -point mixture distribution can be expressed as

$$f(x) = \sum_{j=1}^m w_j f_j(x), \quad F(x) = \sum_{j=1}^m w_j F_j(x)$$

where $w_j, j = 1, 2, \dots, m$, are the positive weights attached to each member distribution, adding up to 1. It is possible to have a mixture of different types of distributions, such as exponential and Weibull, or of the same type of distribution but with different parameters.

An example of a mixture of two lognormal distributions ($\mu_1 = 0.9, \sigma_1 = 1, \mu_2 = 3, \sigma_2 = 0.5$) is depicted in Figure 11.

The MLE estimates of the parameters (including the weights) of mixture distributions can generally be evaluated only numerically. A commonly used procedure to estimate the parameters of mixture distributions is the expectation-maximization algorithm. The raw

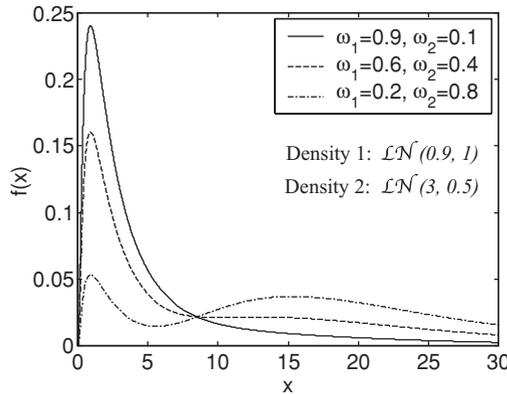

Figure 11 Illustration of 2-Point Lognormal Mixture Density

moments are found as the weighted sum of the k th moments evaluated individually for each of the m member distributions. The population mean and variance are found by

$$\text{mean}(X) = \sum_{j=1}^m w_j \mathbb{E}_j(X), \quad \text{var}(X) = \sum_{j=1}^m w_j^2 \sigma_j^2(X)$$

where the subscripts j refer to each member density. The right tail follows $\bar{F}(x) = \sum_{j=1}^m w_j \bar{F}_j(x)$.

The advantage of using mixture distributions is that they can be fitted to practically all shapes of loss distributions. On the other hand, the models may lack reliability due to a large number of parameters that need to be estimated (in particular, when the available loss data set is not large enough). For example, a 2-point mixture of exponential distributions requires only three parameters, but a 4-point mixture of exponential distributions requires seven parameters. In some cases, this problem may be overcome when certain simplifications are applied to the model. For example, it is possible to achieve a 2-point mixture of Pareto distributions with four, instead of five, unknown parameters; the following distribution has been successfully applied to liability insurance:

$$F(x) = 1 - a \left(\frac{\beta_1}{\beta_1 + x} \right)^\alpha + (1 - a) \left(\frac{\beta_2}{\beta_2 + x} \right)^{\alpha+2}$$

with the first distribution covering smaller magnitude events and having a higher weight a attached, and the second distribution covering infrequent large-magnitude events.¹³

An extension to mixture distributions may be to allow m to be a parameter, and “let the data decide” on how many distributions should enter the mixture. This, however, makes the model data-dependent and more complex.¹⁴

Note that the term mixture distribution is sometimes also used for distributions in which an unknown parameter is believed to be random and follows some distribution rather than being fixed. For example, a mixture of Poisson and gamma distributions (i.e., the parameter of the Poisson distribution follows a gamma distribution) will result in a hypergeometric distribution.

A NOTE ON THE TAIL BEHAVIOR

Operational risk managers are concerned with finding a model that would capture the “tail events.” In the context of operational losses, it is understood that *tail events* refer to the events in the upper tail of the loss distribution. A crucial task in operational risk modeling is to produce a model that would give a realistic account to the possibility of losses exceeding a very high amount (this becomes critical in the estimation of the Value-at-Risk).

In operational risk modeling, thin-tailed distributions should be used with caution. The following example illustrates the danger of fitting a *light-tailed distribution* to the data whose true distribution is heavy-tailed.¹⁵ We generated 5,000 points from the Pareto distribution (heavy-tailed) with parameters $\alpha = 1.67$ and $\beta = 0.6$. We then fitted an exponential distribution (light-tailed) to the data. The MLE procedure resulted in the exponential parameter of $\lambda = 1.61$. Figure 12 demonstrates the difference in the behavior of the tails of both distributions. In the far right, the probability of exceeding any high point is significantly lower (roughly, by

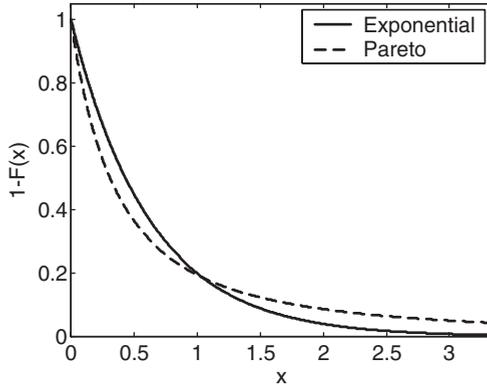

Figure 12 Tails of Pareto and Exponential Distributions Fitted to Simulated Pareto Random Variable

5%) under the exponential fit. This indicates that the probability of high-value events (and exceeding them) will be underestimated if one commits the mistake of fitting a thin-tailed loss distribution to the loss data. Such mistakes may be costly and lead to serious consequences in the operational risk management, if the potential for high-magnitude losses is being inadequately assessed.

In Table 1 common distributions are classified into two categories depending on the heaviness of the right tail. Note that the Weibull distribution can be thin-tailed or heavy-tailed depending on the value of the shape parameter. Regarding the lognormal distribution, some

literature refers to it as a thin-tailed distribution, but we follow Embrechts, Klüppelberg, and Mikosch (1997), who put it in the class of medium-tailed distributions. The beta distribution has a bounded support, which makes it a thin-tailed distribution.

EMPIRICAL EVIDENCE WITH OPERATIONAL LOSS DATA

In this section we provide results from empirical studies based on operational loss data that apply the distributions described in this entry. There are two types of studies: Those based on real operational loss data and those based on simulated data.

The empirical studies indicate that practitioners try a variety of possible loss distributions for the loss data and then determine an optimal one on the basis of goodness-of-fit tests. It is common to use the Kolmogorov-Smirnov (KS) and Anderson-Darling (AD) tests to examine the goodness of fit of the model to the data. The two tests use different measures of the discrepancy between the fitted continuous distribution and the empirical distribution functions. The KS test better captures the discrepancy around the median of the data, while the AD test is more optimal for the tails. A smaller value of the test statistic indicates a

Table 1 Tail Behavior of Common Loss Distributions

Name	Tail $\bar{F}(x)$	Parameters
Thin-Tailed Distributions		
Normal	$\bar{F}(x) = 1 - \Phi\left(\frac{x-\mu}{\sigma}\right)$	$-\infty < \mu < \infty, \sigma > 0$
Exponential	$\bar{F}(x) = e^{-\lambda x}$	$\lambda > 0$
Gamma	$\bar{F}(x) = 1 - \Gamma(\alpha; \beta x)$	$\alpha, \beta > 0$
Weibull	$\bar{F}(x) = e^{-\beta x^\alpha}$	$\alpha \geq 1, \beta > 0$
Beta	$\bar{F}(x) = 1 - I(x; \alpha, \beta)$	$\alpha, \beta > 0$
Medium-Tailed and Heavy-Tailed Distributions		
Lognormal	$\bar{F}(x) = 1 - \Phi\left(\frac{\log x - \mu}{\sigma}\right)$	$-\infty < \mu < \infty, \sigma > 0$
Weibull	$\bar{F}(x) = e^{-\beta x^\alpha}$	$0 < \alpha < 1, \beta > 0$
Pareto	$\bar{F}(x) = \left(\frac{\beta}{\beta+x}\right)^\alpha$	$\alpha, \beta > 0$
Burr	$\bar{F}(x) = \left(\frac{\beta}{\beta+x^\gamma}\right)^\alpha$	$\alpha, \beta, \gamma > 0$

better fit. Other goodness-of-fit tests include Kuiper, Cramér-von Mises, and Pearson's χ^2 test, among others.

Studies with Real Data

We review some empirical studies based on real operational loss data from financial institutions.

Müller Study of 1950–2002 Operational Loss Data

Müller (2002) carried out empirical analysis with external operational loss data obtained from worldwide institutions in the 1950–2002 period, made available then by the IC² Operational Loss F1RST Database. Only data in U.S. dollars for the events whose state of affairs was “closed” or “assumed closed” on an indicated date were considered for the analysis. The data were available for five loss types:

- “Relationship” (such as events related to legal issues, negligence, and sales-related fraud).
- “Human” (such as events related to employee errors, physical injury, and internal fraud).
- “Processes” (such as events related to business errors, supervision, security, and transactions).
- “Technology” (such as events related to technology and computer failures and telecommunications).
- “External” (such as events related to natural and man-made disasters and external fraud).

Figure 13 shows the histograms of the five data sets. There is a clear peak in the beginning, which is captured by the excessive kurtosis; a heavy right tail is also evident and is captured by the high degree of positive skewness (see Table 2).

From the common distributions discussed in this entry, exponential, lognormal, Weibull, gamma, and Pareto distributions were used. Table 2 demonstrates the five samples' MLE parameter estimates and KS and AD statistic values for the five distributions. The center of the data is best explained by the lognormal distribution, as is concluded from the lowest KS

statistic values, for all except “Technology” type losses for which Weibull is the best. The same conclusions are drawn regarding the tails of the datasets.

Cruz Study of Legal Loss Data

Cruz (2002) applies exponential, Weibull, and Pareto distributions to a sample (in U.S. dollars) from a legal database (from an undisclosed source), consisting of 75 points.¹⁶ The sample's descriptive statistics, as well as the MLE parameters for the three distributions¹⁷ and goodness-of-fit statistics are depicted in Table 3. The data are highly leptokurtic and significantly right-skewed. Based on visual and formal tests for the goodness of fit,¹⁸ Cruz concluded that the Pareto distribution fits the data best. Nevertheless, none of the considered loss distributions is able to capture well the heaviness of the upper tail.

Moscadelli Study of 2002 LDCE Operational Loss Data

Moscadelli (2004) explores the data (in euros) collected by the Risk Management Group (RMG) of the Basel Committee in June 2002's Operational Risk Loss Data Collection Exercise (LDCE). There were 89 participating banks from 19 countries worldwide that provided their internal loss data for the year 2001. The data were classified into eight business lines and pooled together across all banks. The eight business lines are:

- BL1: Corporate Finance.
- BL2: Trading and Sales.
- BL3: Retail Banking.
- BL4: Commercial Banking.
- BL5: Payment and Settlement.
- BL6: Agency Services.
- BL7: Asset Management.
- BL8: Retail Brokerage.

The lognormal, gamma, Gumbel, Pareto, and exponential distributions were fitted to the

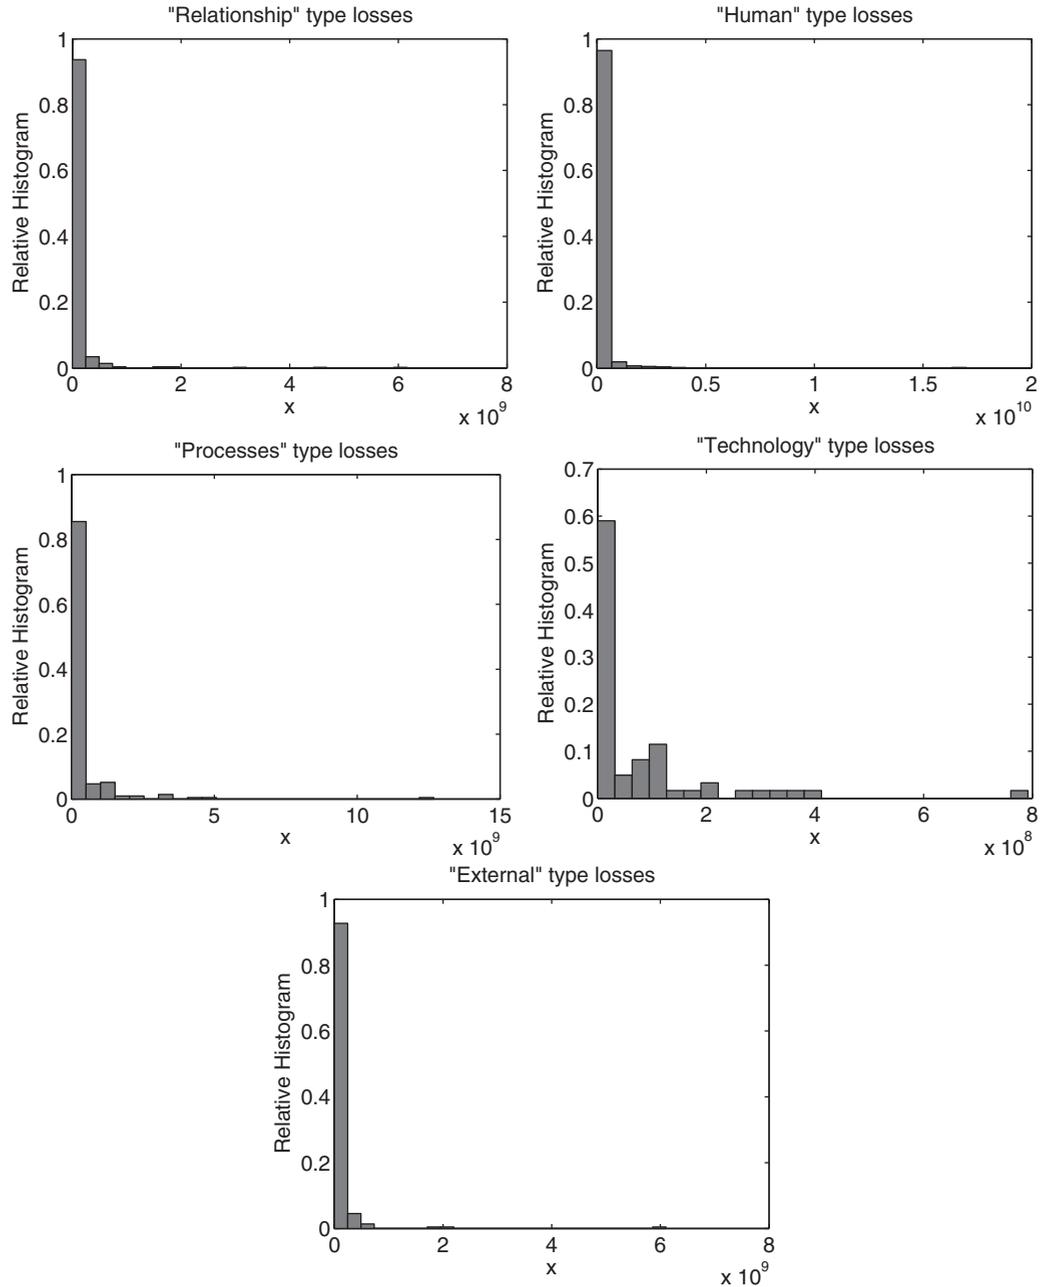

Figure 13 Relative Frequency Histograms of Operational Loss Data in Müller Study

data. The estimation procedure used in the study was somewhat simplified for two reasons. First, different banks used different minimum truncation levels for their internal data, roughly between €6,000 to €10,000. This issue was ignored in the estimation process. Sec-

ond, the data across all participating banks were pooled together without any consideration given for bank characteristics such as size.

Table 4 reproduces the sample descriptive statistic (based on 1,000 bootstrapped samples generated from the original data), MLE

parameter estimates (based on the original data), and goodness-of-fit test statistics¹⁹ for the lognormal and Gumbel distributions.²⁰ Other considered distributions showed a poor fit. Although lognormal and Gumbel fitted the main body of the data rather well, they performed poorly in the upper tail, according to Moscadelli. This was confirmed by the test statistic values above the 90% critical values, meaning that it is unlikely that the data come from a selected distribution at the 90% confidence level.

He further performs the analysis of the data using the extreme value theory argument for modeling high losses with the GPD, finding that GPD outperforms other considered distributions. He also confirms the findings from other empirical studies that operational losses follow a very heavy-tailed distribution.

De Fontnouvelle-Rosengren-Jordan Study of 2002 LDCE Operational Loss Data

The dataset examined in Moscadelli was also analyzed by de Fontnouvelle, Rosengren, and Jordan (2006). They limited their analysis to the data collected from six banks, and

performed the analysis on the bank-by-bank basis, rather than pooling the data as was done in Moscadelli. For confidentiality reasons, only the data belonging to the four business lines—Trading and Sales (BL1), Retail Banking (BL2), Payment and Settlement (BL3), and Asset Management (BL4)—and six loss types—Internal Fraud (LT1), External Fraud (LT2), Employment Practices and Workplace Safety (LT3), Clients, Products and Business Practices (LT4), and Execution, Delivery and Process Management (LT5)—were included in the analysis.

The following distributions were considered for the study: exponential, Weibull, lognormal, gamma, loggamma (i.e., log of data is gamma-distributed), 1-parameter Pareto, Burr, and loglogistic.²¹ The distributions were fitted using the MLE method. Overall, heavy-tailed distributions—Burr, loggamma, loglogistic, and 1-parameter Pareto—fit the data very well, while thin-tailed distributions' fit is poor, as expected. In particular, losses of LT3 are well fit by most of the heavy-tailed distributions and lognormal. In many cases, the estimated parameters would be unreasonable, for example resulting in a negative mean loss. For some

Table 5 Sample Descriptive Statistics, Parameter Estimates, and Goodness-of-Fit Tests in the Lewis Study

1. Sample Description		
Mean (£)		151,944.04
Median (£)		103,522.90
St.dev. (£)		170,767.06
Skewness		2.84

BL and LT data sets, the models failed the χ^2 goodness-of-fit test for all considered cases. Hence, de Fontnouvelle, Rosengren, and Jordan performed additional analysis using the extreme value theory and fitting the GPD to the data exceeding a high threshold.²²

Lewis Study of Legal Liability Loss Data

Lewis (2004) reports his findings for a sample (in British pounds) of legal liability losses (from an undisclosed source), consisting of 140 points.²³ He fits the normal, exponential, and Weibull distributions²⁴ to the data and compares the fit. Table 5 shows the descriptive statistics for the sample, the MLE parameters for three fitted distributions, and the values of the AD goodness-of-fit statistic. The data are highly leptokurtic and significantly right-skewed. As expected, the normal distribution results in a very poor fit, and the Weibull distribution seems the most reasonable assumption,

based on the lowest value of the AD test statistic.

Studies with Simulated Data

A number of studies on operational risk that have appeared in literature were using simulated rather than real data. We present a few examples here.

Reynolds-Syer Study

Reynolds and Syer (2003) apply a nonparametric approach to modeling operational loss severity. They use a hypothetical sample of six-year internal operational loss data of a firm, with a total of 293 observations. The summary of input data is given in Table 6. Using the sample of historic data, sampling is repeated a large number of times, and 1,000 simulated years are created. For each year, the simulated losses are summed up. The distribution of yearly aggregated

Table 6 Sample Descriptive Statistics of Loss Data in the Reynolds-Syer Study

Year	# obs.	Total (\$ '000,000)	Average (\$ '000)	St. Dev. (\$ '000)
2000	64	7.55	117.9	109.6
2001	57	6.35	111.3	106.2
2002	52	5.14	98.8	93.7
2003	55	5.29	96.1	88.0
2004	43	3.86	89.7	78.5
2005	45	3.41	75.7	68.5

Source: Reynolds and Syer (2003), p. 204.

operational losses is assumed to follow the resulting empirical distribution.

Rosenberg-Schuermann Study

Rosenberg and Schuermann (2006) use a Monte Carlo approach to generate a sample of 200,000 operational losses. For the loss distribution they consider a 1-parameter Pareto distribution with parameter $1/0.65 = 1.5385$. This parameter is based on the average of the exponential parameters²⁵ of 1/0.64 and 1/0.66, obtained for logarithmic losses from the OpRisk Analytics database and OpVantage database, respectively, in the empirical study carried out by de Fontnouvelle, DeJesus-Rueff, Jordan, and Rosengren (2003). Recall that since the shape parameter is less than one, then such Pareto distribution has a finite mean but an infinite variance. To guarantee the existence of the first two moments, Rosenberg and Schuermann set a log-loss greater than 1,000 standard deviations equal to a loss of 1,000 standard deviations.

KEY POINTS

- Broadly, one can classify the approaches to model operational loss magnitudes into two groups: nonparametric approach and parametric approach.
- Under the nonparametric approach, one can either model the losses using the empirical distribution function, or one can fit a smooth curve to the histogram of the data and analyze the properties of the curve instead.
- Under the parametric approach, one can fit one (or more) of common parametric distributions directly to the data (and compare them).
- Because of the specific nature of the operational loss data, the distributions that are most likely to find application to modeling the losses are those that are right-skewed and are defined only on the positive values of the underlying random variable. These distributions include the exponential, lognormal, Weibull, gamma, beta, Pareto, Burr, and mixture distributions.
- Operational risk managers are concerned with finding a model that would capture the “tail events.” Common distributions are classified into two categories depending on the heaviness of the right tail: light-tailed and heavy-tailed. In operational risk modeling, light-tailed distributions should be used with caution.
- There have been several empirical studies with operational loss data. Two types of empirical studies are distinctive: studies that use real loss data and studies that use simulated data. Generally, most of the studies suggest that heavy-tailed loss distributions (such as lognormal or Pareto) best describe operational loss magnitudes.

NOTES

1. An example is cubic spline approximation as is done in Rosenberg and Schuermann (2006). Useful references on this approach include Silverman (1986) and Scott (1992).
2. See Rosenberg and Schuermann (2006).
3. See Cizek, Härdle, and Weron (2005).
4. To be more precise, for a discrete random variable it is called probability mass function.
5. The lognormal distribution was proposed by the Basel Committee for the operational risk modeling in 2001.
6. $\Gamma(a)$ is the complete gamma function, $\Gamma(a) = \int_0^\infty t^{a-1} e^{-t} dt$. When a is an integer, then $\Gamma(a) = (a - 1)!$
7. See Madan and Unal (2004) and Kremer (1998).
8. See Mittnik and Rachev (1993a, 1993b).
9. $\Gamma(a; b)$ is the incomplete gamma function defined as $\Gamma(a; b) = \frac{1}{\Gamma(a)} \int_0^b t^{a-1} e^{-t} dt$.
10. In this case, the gamma distribution is called the Erlang distribution.
11. $I(x; \alpha, \beta)$ is the regularized beta function equal to $\int_0^x u^{\alpha-1} (1-u)^{\beta-1} du \times \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)}$.
12. See Cizek, Härdle, and Weron (2005).

13. See Klugman, Panjer, and Willmot (2004).
14. See Klugman, Panjer, and Willmot (2004).
15. In literature, thin-tailed distributions are also called light-tailed distributions, and heavy-tailed distributions are also called fat-tailed distributions. We will use the corresponding terms interchangeably.
16. Original dataset is available from Cruz (2002), Chapter 3, p. 57.
17. Note that the density specification for the exponential and Weibull distributions in Cruz (2002) are different. We report the parameter values based on the specifications of the density functions as presented in this entry.
18. The KS values reported in Table 3 should be further scaled by \sqrt{n} (n being the sample length) if we want to compare the goodness of fit across samples of different lengths.
19. The test statistics are unadjusted to the length of data.
20. The Gumbel distribution is light-tailed and has density $f(x) = \frac{1}{\sigma} \exp\left\{-\frac{x-\mu}{\sigma} - \exp\left\{-\frac{x-\mu}{\sigma}\right\}\right\}$, defined on $x \in \Re$. The support allows for negative loss values, so the Gumbel distribution is unlikely to find much application in operational risk modeling.
21. The density of the loglogistic distribution is $f(x) = ax^{1/b-1}/[b(1+ax^{1/b})^2]$.
22. For the tables with the χ^2 goodness-of-fit statistic values and other details of this empirical study we refer the reader to de Fontnouvelle, Rosengren, and Jordan (2006).
23. Original dataset is available from Lewis (2004), Chapter 7, p. 87.
24. Lewis (2004) does not report the parameter estimates for the Gaussian and Weibull cases. We computed them directly by fitting the distributions to the data.
25. We stated earlier that an exponential transformation of an exponentially distributed random variable follows a 1-parameter Pareto distribution.

Optimization Tools

Introduction to Stochastic Programming and Its Applications to Finance

KORAY D. SIMSEK, PhD

Associate Professor, Sabanci School of Management, Sabanci University

Abstract: Mathematical programming is one of a number of operations research techniques that employs mathematical optimization models to assist in decision making. Mathematical programming includes linear programming, integer programming, mixed-integer programming, nonlinear programming, stochastic programming, and goal programming. Mathematical programming models allow the decision maker to identify the “best” solution. This is in contrast to other mathematical tools that are in the arsenal of decision makers such as statistical models (which tell the decision maker what occurred in the past), forecasting models (which tell the decision maker what might happen in the future), and simulation models (which tell the decision maker what will happen under different conditions). The mean-variance model for portfolio selection as formulated by Markowitz is an example of an application of one type of mathematical programming (quadratic programming). However, in formulating optimization models in many applications in finance, decision makers need to take into consideration the uncertainty about the model’s parameters and the multiperiod nature of the problem faced. To deal with these situations, the technique of stochastic programming is employed.

The dynamic nature of financial decision making requires the use of tools that are capable of capturing the multiperiod nature inherent in problems faced by asset managers in portfolio selection decisions and financial managers in capital budgeting decisions. These tools should be understandable with adequate treatment of uncertainty. They should incorporate practical considerations, such as transaction costs in the case of asset managers. Stochastic programming bears these characteristics. In this entry, we discuss the basics of stochastic program-

ming, give a brief history, and emphasize its importance by comparing the approach to other tools used in finance.

WHAT IS STOCHASTIC PROGRAMMING?

Stochastic programming is nothing but a fancy name for the study of optimal decision making under uncertainty. As opposed to “deterministic,” the term “stochastic” implies that some of the parameters of the problem are random

(that is, not known with certainty); the term “programming” points to links with *mathematical programming* and *optimization algorithms*.

Uncertainty is almost always inherent in real-world decision problems (and even more so in financial planning). As an example, we may consider a bet whose outcome is determined by flipping a coin. In such problems, uncertainty of parameters may be due to the presence of uncertain events (e.g., a coin flip in the previous example) or simply due to lack of reliable data.

In the past, due to computational and informational limitations, optimal decision models were often formulated deterministically by replacing the uncertainties with expectations or best estimates. With contributions from many disciplines, including operations research, and improvements in the information technology (faster hardware and software), stochastic programming is rapidly developing today.

The main features of a stochastic program, which can be viewed as an optimal decision model with explicit consideration of uncertainties, are:

- Random parameters with known (or partially known) distributions.
- Several decision variables with many potential values.
- Discrete time periods for decisions.
- Use of expectations (or other functions of decision variables) for objectives.

The problem structure, constraints, and objectives (risk/reward) are modeled across time along with the uncertainty of events. Future uncertainty is modeled through generating scenarios over time. In other words, the realizations of the uncertain parameters may be (gradually) revealed after some or all of the decisions have been made. High-performance computers take advantage of sophisticated algorithms to determine the optimal decision that will take into account the future uncertainty. As the uncertainty is revealed after each stage, recourse decisions can be made in the light of new information.

The relative importance of these main features contrasts with other decision-making models, such as statistical decision theory, decision analysis, dynamic programming, Markov decision processes, and *stochastic control (SC)*. In contrast to statistical decision theory, stochastic programming has emphasized solution methods and analytical solution properties over procedures for constructing objectives and updating probabilities. Stochastic programs generally have higher dimensions (that is, larger problem size) than SC models, which put more emphasis on control rules and have more restrictive constraint assumptions.

We can see the first forms of decision models that involve uncertainty in the early days of the history of mathematical programming. Beale (1955), Dantzig (1955), and Charnes and Cooper (1959) were the first to propose linear programs with random parameters. Dantzig named his approach “linear programming under uncertainty,” whereas Charnes and Cooper called theirs “chance/probabilistically constrained programming.”

Subsequently, stochastic programming has become a major subfield of mathematical programming with several theoretical developments. For overviews of the literature including algorithms and applications, see Kall and Wallace (1994), Infanger (1994), Ermoliev and Wets (1988), Birge and Louveaux (1997), Wallace and Ziemba (2003), Prékopa (1995), Higle and Sen (1996), Wallace et al. (1996), Censor and Zenios (1997), Wets and Ziemba (1999), Dupačová et al. (2002), Birge et al. (2002), and Ruszczyński and Shapiro (2003).

In general, stochastic optimization models result in large-scale programs since they include a large number of scenarios to reflect all possible outcomes of future uncertainty. Therefore, efforts on the algorithmic developments focused on adaptations of large-scale linear programming methods for special classes of stochastic programs whose structures are exploitable. In other words, emphasis was placed on forming the deterministic equivalent program and

taking advantage of the structure of the resulting formulation. Dantzig and Madansky (1961) introduced Dantzig-Wolfe decomposition as a possible method. One of the most successful approaches has been the application of Benders' decomposition (Benders, 1962) method to stochastic programs, originally developed by Van Slyke and Wets (1969). Birge (1985) extended this idea for multistage stochastic programs. In general, these methods concentrate on linear models. The diagonal quadratic approximation (DQA) algorithm, originally developed for linear programs by Mulvey and Ruszczyński (1992), can handle both quadratic and general convex (or equivalently concave) objective functions with linear constraints, as shown in Berger et al. (1994). The progressive hedging algorithm, developed by Rockafellar and Wets (1991), dualizes the nonanticipativity constraints and, like DQA, iterates over scenarios to force these constraints to be equal. Unlike DQA, there is no quadratic penalty term and all scenarios are coordinated through a master processor. Mulvey and Vladimirou (1991) successfully implemented the progressive hedging algorithm in the context of stochastic networks.

Specialized software packages that employ these methods are much faster than general solvers. Combined with algebraic modeling languages, such as AMPL, these specialized stochastic programming solvers provide efficient means of tackling problems that involve high levels of uncertainty.

Stochastic Programming in Finance

Financial planning represents one of the major application areas of stochastic programming. In fact, it is a natural domain for stochastic programming, since risk needs to be incorporated into investment decisions (portfolio decisions and capital budgeting decisions) and the problem structure is amenable to algebraic constraints and relationships. Deterministic approximations would fail to see the big picture. For example, through stochastic programs, portfolio allocations that would opti-

mize an investor's risk level under several scenarios can be determined; by contrast, because they ignore risk, deterministic programs provide inadequate solutions. Static portfolio selection models, based on Markowitz's mean-variance model (1952), have been proposed in many cases; however, their implementations may result in significant transaction costs and mistimed liquidation of assets. Examples of application of stochastic programming in financial planning can be found in Ziemba and Vickson (1975) and Zenios (1992).

Within finance, stochastic programming applications have greatly increased in recent years, particularly in asset-liability management (ALM). Multistage stochastic programs take into account the dynamic aspects of ALM problems faced by institutional investors. Based on assumptions about the (joint) dynamics of risk factors that are usually described by stochastic processes, representative scenarios for investment strategies are generated. Transactions take place at discrete points in time over a finite planning horizon. Moreover, several constraints (e.g., liability considerations, liquidity restrictions, limits on risk exposure) can be taken into account.

Since multistage programs suffer from an exponential growth in problem size with respect to the number of periods under consideration, the first models for ALM that appeared in the early 1980s [see Kallberg et al. (1982), Kusy and Ziemba (1986)] were restricted to a two-stage structure due to computational limitations. Mulvey and Vladimirou (1992) looked at optimal investment strategies given liabilities in a network environment. At Fannie Mae, Holmer (1994) implemented a system to minimize investment risk while taking into account that firm's retained mortgage portfolio. Advances in computing power, paired with efficient algorithms that are specialized for stochastic programming, help researchers implement and solve very large scale stochastic programs, such as the pension fund model of Gondzio and Kouwenberg (2001), with millions of scenarios.

One of the first successful commercial multistage stochastic programming applications is the Russell-Yasuda Kasai model (see Cariño et al., 1994, 1998; and Cariño and Ziemba, 1998). The model was employed to optimize the investment decisions for a Japanese insurance company over time where investment returns and liabilities are uncertain. The problem is complicated by constraints to meet the random liabilities and legal restrictions on the use of income in Japan.

Other successful commercial applications include the Towers Perrin-Tillinghast ALM system of Mulvey et al. (2000), the fixed income portfolio management models of Zenios (1995) and Beltratti et al. (1999), and the InnoALM system of Geyer and Ziemba (2008). A good number of applications in ALM are provided in Ziemba and Mulvey (1998), Ziemba (2003), and Zenios and Ziemba (2006).

Among other areas in finance, capital budgeting and fixed income portfolio management have been researched extensively using stochastic programming methods. For the former, Lockett and Gear (1975), De et al. (1982), and Turney (1990) are the earliest applications. Bradley and Crane (1972) were the first to propose stochastic programming for bond portfolio management. Zenios and Kang (1993) developed a portfolio immunization strategy in a multi-period stochastic optimization framework. Granville et al. (1994) describe a dual method for an asset-only allocation problem. Many other applications in the fixed income literature exist, including Hiller and Eckstein (1993) and Golub et al. (1995).

STOCHASTIC PROGRAMMING VERSUS OTHER METHODS IN FINANCE

In this section, we compare stochastic programming with other methods applied to financial planning (especially to ALM). First,

we highlight the dynamic aspects of stochastic programming and show its differences with *static models*. Afterward, we briefly discuss *continuous-time models* in finance and compare these models with stochastic programming—a discrete-time approach.

Static versus Dynamic Models in Financial Planning

The most well-known static model for financial planning is, without a doubt, the mean-variance model of Markowitz (1952). In this framework, the minimum-variance portfolio that satisfies a required expected return defines the optimal portfolio. Mulvey (1989) extended this model to account for liabilities by replacing the return measure with the surplus (defined as assets minus liabilities). Others have introduced downside risk measures (e.g., conditional value-at-risk, semivariance, mean absolute deviation, to name a few) to replace variance, recognizing the fact that variance is not a good risk measure for most asset classes (such as derivatives and fixed income securities) and for long-term investors. (See, e.g., Fishburn, 1977, Worzel et al., 1994, and Rockafellar and Uryasev, 2000.) Despite being computationally attractive, static models are inappropriate for long-term investors facing sequential decisions. Single-period models, unlike *dynamic models*, fail to cope with the dynamic aspects of the problem, such as transaction costs.

Among other static models, duration-matching models seem to be interesting, especially for ALM. These models seek to protect the surplus against an interest rate uncertainty. The optimal portfolio of assets is the lowest-cost portfolio whose value and duration are equal to those of liabilities. Applications can be quite successful in certain cases, for example, when a defined benefit pension plan has been terminated and taken over by an insurance company or when the transaction costs are low. However, these models ignore the facts that individual cash inflows and outflows are not matched and that one needs to adjust to the

changes in duration at every stage (which leads to high transaction costs). Therefore, computational and structural advantages of these models are insufficient to justify their drawbacks.

Dynamic models, in contrast, provide substantial flexibility to address the issues faced by long-term investors. They are not as easy to solve and conceptualize as static models; however, as discussed earlier in this entry, the advances in technical aspects of stochastic programming and today's computational power more than make up for these incapacities. Among these methods, dynamic programming seems to be especially interesting from an ALM perspective, as the optimal decisions are obtained in feedback form. However, it suffers from *the curse of dimensionality* as the planning horizon or the uncertainty representation is extended. An alternative method to overcome this problem is to specify a decision rule within the same framework, which also helps handle the transaction costs more easily. Nevertheless, incorporating decision rules leads to nonconvex optimization models (see Mulvey and Simsek, 2002). Fleten et al. (2002) illustrate the superior performance of dynamic models over static models. In the next section, we discuss the two major types of dynamic models.

Continuous-Time Models versus Stochastic Programming

Continuous-time models were introduced to the finance literature by Merton (1969). The variables that define the states of the world are modeled through *stochastic differential equations* (SDEs). Asset prices also follow SDEs whose parameters may be state and/or time dependent. Trading is assumed to occur continuously. Under additional assumptions on investors' preferences (that is, utility functions) and the structure of the economy, an explicit analytical solution can be found for these models by SC techniques. Thus, they provide better insights than the stochastic programming solutions, which are hard to generalize. However,

as Cochrane (2001, p. 28) suggests: "... in the complexity of most practical situations, one often ends up resorting to numerical simulation of a discretized model anyway."

Although some of the SC recommendations are implementable, the model simplifications may render them ineffective. As these models cannot incorporate complex constraints imposed by realistic situations and most investors (e.g., pension funds) do not want to trade continuously, we turn to stochastic programming, which allows decisions to be made at a finite number of discrete points in time.

In most cases, stochastic programming models require the uncertainties be approximated by a scenario tree with a finite number of states of the world at each time. As Kouwenberg and Zenios (2006, p. 291) suggest: "... important practical issues such as transaction costs, multiple state variables, market incompleteness, taxes and trading limits, regulatory restrictions, and corporate policy requirements can be handled *simultaneously* within the framework." This huge practical advantage, unfortunately, comes at a significant cost: curse of dimensionality. As analytical solutions are not possible, stochastic programming models need to be solved via numerical optimization. The model size explodes as the size of the state space or the number of decision stages increases. In recent years, this drawback has been substantially overcome through the development of new algorithms and the advances in computing power. Still, one should be careful about incorporating too much detail into a stochastic programming model, not because of the computational disadvantages but mainly to avoid confusing the decision maker, since SP solutions are hard to generalize.

It is, however, interesting to note that the continuous-time models have been the focus of research in the financial economics literature, whereas models in the operation research literature are mostly stated in discrete time. As Berger (1995) points out, there have been several successful applications of SC, such as the

Black-Scholes option pricing formula (Black and Scholes, 1973) and the continuous-time capital asset pricing model (Merton, 1973). See also Constantinides (1986), Dumas and Luciano (1991), and Shreve and Soner (1991) for SC applications with practical considerations such as transaction costs.

A GENERAL MULTISTAGE STOCHASTIC PROGRAMMING MODEL FOR FINANCIAL PLANNING

To illustrate the use of stochastic programming, we provide in this section a multistage stochastic program to tackle a long-term investment problem. We formulate the deterministic equivalent of the stochastic program and we discuss the issue of modeling the uncertain parameters on *scenario generation* methods.

Model Formulation

Here, we define the multiperiod investment problem as a multistage stochastic program. The basic model is a variant of Mulvey et al. (1997), with special attention to transaction costs.

To define the model, we divide the entire planning horizon T into two discrete time intervals T_1 and T_2 , where $T_1 = \{0, 1, \dots, \tau\}$ and $T_2 = \{\tau + 1, \dots, T\}$. The former corresponds to periods in which investment decisions are made. Period τ defines the end of the planning horizon. We focus on the investor's position at the beginning of period τ . Decisions occur at the beginning of each time stage. Much flexibility exists. An active trader might see his time interval as short as minutes, whereas a pension plan adviser will be more concerned with much longer planning periods such as the dates between the annual board of directors' meetings. It is possible for the steps to vary over time—short intervals at the beginning of the planning period and longer intervals toward the end. T_2 handles the horizon at time τ by calculating economic

and other factors beyond period τ up to period T . The investor renders passive decisions after the end of period τ .

Asset classes are defined by set $A = \{1, 2, \dots, I\}$, with category 1 representing cash. The remaining asset classes can include growth and value stocks, bonds, real estate, hedge funds, or private equity. The asset classes should track well-defined market segments. Ideally, the co-movements between pairs of asset class returns would be relatively low so that diversification can be done across the asset classes.

In multiperiod models, uncertainty is represented by a set of distinct realizations, called *scenarios*, $s \in S$. The scenarios may reveal identical values for the uncertain quantities up to a certain period; that is, they share common information history up to that period. We address the representation of the information structure through nonanticipativity constraints, which require that variables sharing a common history, up to time period t , must be set equal to each other (see equation (7) below).

We assume that the portfolio is rebalanced at the beginning of each period. Alternatively, we could simply make no transaction except to reinvest any dividend and interest—a buy-and-hold strategy. For convenience, we also assume that the cash flows are reinvested in the generating asset class and all the borrowing (if any) is done on a single-period basis.

For each $i \in A$, $t \in T_1$, and $s \in S$, we define the following parameters and decision variables.

Parameters

- $r_{i,t}^s$ = $1 + \rho_{i,t}^s$, where $\rho_{i,t}^s$ is the percent return for asset i , in time period t , under scenario s (projected by a stochastic scenario generator, for example, see Mulvey et al. [2000]).
- π_s Probability that scenario s occurs, $\sum_{s \in S} \pi_s = 1$.
- w_0 Wealth at the beginning of time period 0.
- $\sigma_{i,t}$ Transaction costs incurred in rebalancing asset i at the beginning of period t (symmetric transaction costs are assumed, that is, cost of selling equals cost of buying).
- β_i^s Borrowing rate in period t , under scenario s .

Decision Variables

- $x_{i,t}^s$ Amount of money in asset class i , at the beginning of time period t , under scenario s , after rebalancing.
- $v_{i,t}^s$ Amount of money in asset class i , at the beginning of time period t , under scenario s , before rebalancing.
- w_t^s Total wealth at the beginning of time period t , under scenario s .
- $p_{i,t}^s$ Amount of asset i purchased for rebalancing in period t , under scenario s .
- $d_{i,t}^s$ Amount of asset i sold for rebalancing in period t , under scenario s .
- b_t^s Amount of money borrowed at the beginning of period t , under scenario s .

$$v_{i,t}^s = r_{i,t-1}^s x_{i,t-1}^s \quad \forall s \in S, t = 1, \dots, \tau, i \in A \quad (4)$$

$$x_{i,t}^s = v_{i,t}^s + p_{i,t}^s (1 - \sigma_{i,t}) - d_{i,t}^s \quad \forall s \in S, i \in A/\{1\}, t = 1, \dots, \tau \quad (5)$$

$$x_{1,t}^s = v_{1,t}^s + \sum_{i \neq 1} d_{i,t}^s (1 - \sigma_{i,t}) - \sum_{i \neq 1} p_{i,t}^s - b_{t-1}^s (1 + \beta_{t-1}^s) + b_t^s \quad \forall s \in S, t = 1, \dots, \tau \quad (6)$$

$$x_{i,t}^s = x_{i,t}^{s'} \quad \forall s \text{ and } s' \text{ with identical past up to time } t, t = 1, \dots, \tau \quad (7)$$

Given these definitions, we present the deterministic equivalent of the stochastic asset-only allocation problem.

$$\text{Max EU}(w_\tau^s) = \sum_{s \in S} \pi_s U(w_\tau^s) \quad (1)$$

subject to

$$\sum_{i \in A} x_{i,0}^s = w_0 \quad \forall s \in S \quad (2)$$

$$\sum_{i \in A} x_{i,\tau}^s = w_\tau \quad \forall s \in S \quad (3)$$

A generalized network investment model is presented in Figure 1. This figure depicts the flows across time for each of the asset classes. While all constraints cannot be put into a network model, the graphical form is easy for asset managers to comprehend. General linear and nonlinear programs are now readily available for solving the resulting problem. However, a network may have computational advantages for extremely large problems, such as security level models.

As with single-period models, the nonlinear objective function (1) can take several

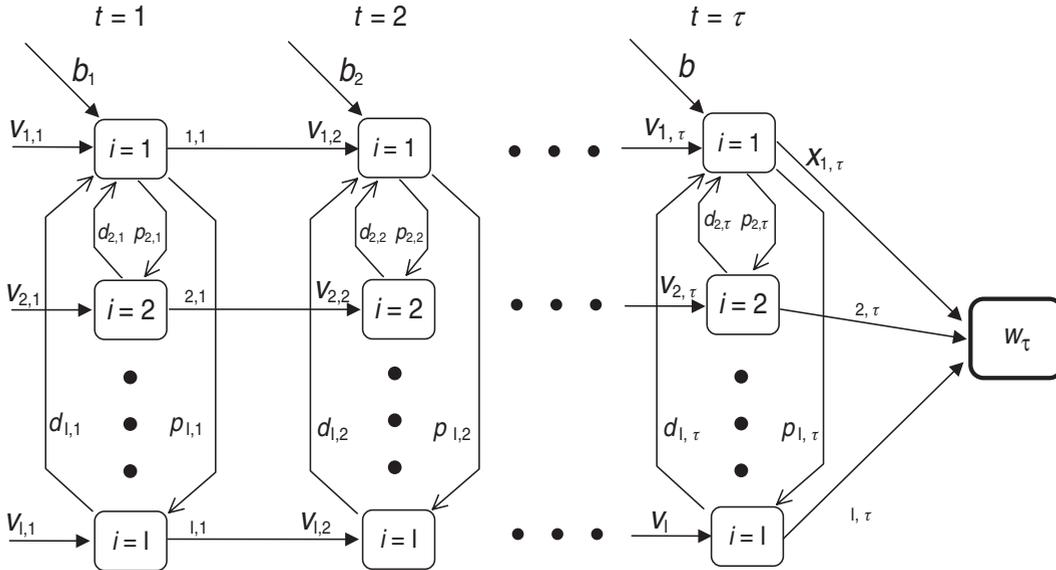

Figure 1 Network Representation for Each Scenario, $s \in S$

different forms. If the classical return-risk function is employed, then (1) becomes $\text{Max } Z = \eta \times \text{Mean}(w_\tau) - (1 - \eta) \times \text{Risk}(w_\tau)$, where $\text{Mean}(w_\tau)$ is the expected total wealth and $\text{Risk}(w_\tau)$ is the risk of the total wealth across the scenarios at the beginning of period τ . Parameter η indicates the relative importance of risk as compared with the expected value. This objective leads to an efficient frontier at period τ by allowing alternative values of η in the range $[0,1]$. It can be shown that a viable alternative to the mean-risk framework is the von Neumann-Morgenstern expected utility of wealth at the beginning of period τ .

Let's review the six constraints:

1. Constraint (2) guarantees that the total initial investment equals the initial wealth.
2. Constraint (3) represents the total wealth in the beginning of period τ . This constraint can be modified to include assets, liabilities, and investment goals, in which case the modified result is referred to as the "surplus wealth" (Mulvey, 1989). Many investors render investment decisions without reference to their liabilities or investment goals. Mulvey (1989) incorporates the notion of surplus wealth into the mean-variance and the expected utility models to address liabilities in the context of asset allocation strategies.
3. Constraint (4) depicts the wealth $v_{i,t}^s$ accumulated at the beginning of period t before rebalancing in asset i .
4. Constraint (5) gives the flow balance constraint for all assets except cash for all periods. This constraint guarantees that the amount invested in period t equals the net wealth for the asset.
5. Constraint (6) represents the flow balancing constraint for cash.
6. Constraints (7) are the nonanticipativity constraints.

The preceding constraints ensure that the scenarios with the same past will have identical decisions up to that period. While these constraints are numerous, solution algorithms take

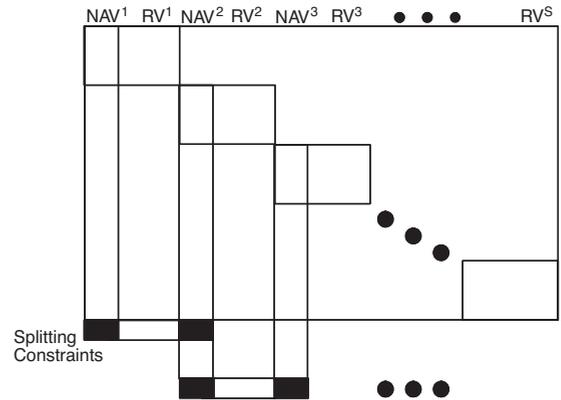

Figure 2 Split Variable Formulation (NAV: Nonanticipativity Variables, RV: Remaining Variables)

advantage of their simple structure. See Birge and Louveaux (1997), Dantzig and Infanger (1993), Kall and Wallace (1994), and Mulvey and Ruszczyński (1995), for example.

Figure 2 depicts the constraint structure for a split variable formulation of the stochastic asset allocation problem. This formulation has proven successful for solving the model using techniques such as the progressive hedging algorithm of Rockafellar and Wets (1991) and the DQA algorithm by Mulvey and Ruszczyński (1995). The split variable formulation can be beneficial for direct solvers that use the interior point method. Given today's powerful PCs, the nonlinear optimization system can be solved in a direct fashion for realistic-size implementations.

By substituting constraint (7) back into constraints (2) to (6), we obtain a standard form of the stochastic allocation problem. Constraints for this formulation exhibit a dual block diagonal structure for two-stage stochastic programs and a nested structure for general multi-stage problems. This formulation may be better for some direct solvers. The standard form of the stochastic program possesses fewer decision variables than the split variable model and is the preferred structure by many researchers in the field. This model can be solved by means of decomposition methods, for example, the

L-shaped method (a specialization of Benders' algorithm). (See Birge and Louveaux, 1997; Consigli and Dempster, 1998; Dantzig and Infanger, 1993; and Kouwenberg and Zenios, 2006.)

As shown by Consigli and Dempster (1998), Dantzig and Infanger (1993), Mulvey et al. (2000), Ziemba and Mulvey (1998), and Ziemba (2003), a multistage model can provide superior performance over single-period models.

Modeling Future Uncertainties (Scenario Generation)

To model future uncertainty in our financial planning problem, we utilize a representative set of scenarios. In this section, we review the procedures for scenario generation and give details about the approach described.

In most cases, stochastic programming models require that the future uncertainties are approximated by a scenario tree with a finite number of states of the world at each time. The planning horizon is divided into T time periods (generally years for pension planning).

In most cases, stochastic programming models require that the future uncertainties are approximated by a scenario tree with a finite number of states of the world at each time. The planning horizon is divided into T time periods (generally years for pension planning). A sample scenario tree of three periods and nine scenarios is depicted in Figure 3. The root of the tree represents the current state of the world. A scenario is defined as a single branch from the root to any leaf of the tree (e.g., the boldfaced path corresponds to scenario 4). Thus, all of the parameter uncertainties are depicted along this branch. Each node represents a state of the world under a given scenario at a given time; for instance, the boldfaced node corresponds to the set of uncertainties at the end of period 2 under scenario 4. The stochastic program will determine an optimal decision for each node of the scenario tree, given the information available at that point. As there are multiple succeeding nodes, the optimal decisions will be determined without exploiting hindsight. A stochastic programming model will find the optimal policy that will fit the current state of the world and the decision maker in each node, while anticipating the op-

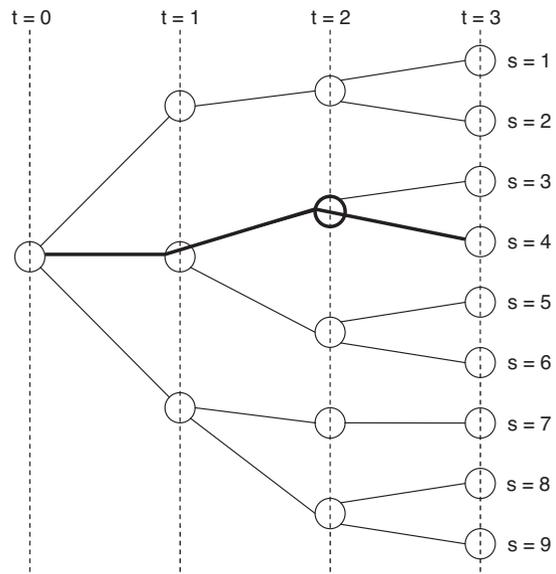

Figure 3 A Three-Period Scenario Tree

timal adjustment of the policy later on as the tree evolves and more information is revealed.

Generating scenario trees to represent the evolution of future uncertainty is a two-step process. Figure 4 depicts a diagram of the process.

The first step involves the construction of a stochastic forecasting model. This involves choosing a model that would be appropriate for the uncertain variables and calibrating the parameters of this model using historical data.

The simplest approach, bootstrapping historical data, eliminates the need for a mathematical model (see, e.g., Grauer and Hakansson, 1982). Among mathematical models, stochastic differential equations and time series analysis are two commonly used techniques to generate anticipatory scenarios. Our preference is to employ the former technique, in which a

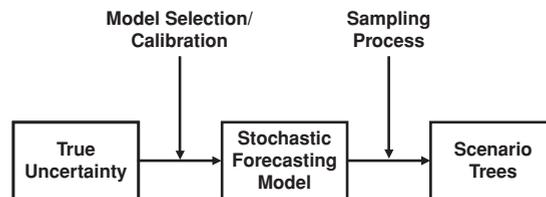

Figure 4 From Historical Data to Scenario Trees

sequence of economic factors (e.g., gross domestic product, corporate earnings, interest rates, and inflation) drive the state variables (see Mulvey [1996] for the details). The parameters of the SDEs for the economic factors and asset returns can be calibrated using historical data. A standard variance reduction method, antithetic variates, can be employed to improve the accuracy of the model's recommendations. Indirect inference methods for calibrating the parameters of the resulting stochastic system can be employed (see Gouriéroux et al., 1993).

The next step involves the discretization of the scenarios generated by the stochastic forecasting model in the first step. To avoid any computational disadvantages, this has to be done using a small number of nodes, which in turn will lead to approximation errors. There are several methods to achieve this depending on the models employed in the first step (see Hoyland and Wallace, 2001; Kouwenberg and Zenios, 2006; Grebeck, Rachev, and Fabozzi, 2009; and Ziemba, 2003). We first create discretized sample paths by moment-matching, using the cascaded SDE structure in the first step. Then, we convert these sample paths to a scenario tree by clustering (see Dupáčová et al., 2002). We begin by grouping similar first stage values of the sample paths into clusters, and then continue sequentially through each stage.

For an ALM system, one needs to generate scenarios for the liability side as well as the asset side. Obviously, both components are driven by economic factors. Liabilities are affected by actuarial predictions as well. When modeling the asset returns, one may need to use sentiment or expert judgment to improve the range of scenarios.

The future value of the liabilities can be especially tricky to project for institutions, such as pension plans, where the liabilities consist of several contracts and therefore the valuation is affected by various sources of uncertainty. For a typical pension plan, one can simulate the future status of the participants by making assumptions about the retirement rates, resigna-

tion frequency, promotion/demotion probabilities, and the mortality rate. Once this is done, the interest rates are forecasted and used to calculate the present value of the liabilities.

When modeling the asset returns, the economic factors that drive the primary asset-class returns are projected as a first step, which would then be followed by the projection of returns for these primary assets. More complex assets would be the last to be modeled in this setup. Alternatively, one can model all uncertain variables at once through one big set of multivariate time-series models.

KEY POINTS

- Stochastic programming is an operations research method for optimal decision making under uncertainty and bears suitable characteristics for modeling and solving financial planning applications, such as asset-liability management, capital budgeting, and fixed income portfolio management.
- The main features of a stochastic program are: random parameters with known (or partially known) distributions; several decision variables with many potential values; multiple discrete time periods for decisions; use of expectations (or other functions of decision variables) for objectives.
- Stochastic programs typically have larger problem size than stochastic control models, which put more emphasis on control rules and have more restrictive constraint assumptions.
- Stochastic programming models generally require that the future uncertainties are approximated by a scenario tree with a finite number of states of the world at each time.
- Multiperiod stochastic programs with a large number of parameters and scenarios result in large-scale deterministic-equivalent programs. Specialized software packages combined with algebraic modeling languages are utilized to efficiently tackle these problems.

Abstract: As the use of quantitative techniques has become more widespread in the investment industry, the issue of how to handle portfolio estimation and model risk has grown in importance. Robust optimization is a technique for incorporating estimation errors directly into the portfolio optimization process, and is typically applied in conjunction with robust statistical estimation methods. The robust optimization approach uses the distribution from the estimation process to find a portfolio allocation in one single optimization, while keeping the computational costs low. Robust portfolios tend to be less sensitive to estimation errors, offer some improved portfolio performance, and often have lower turnover ratios.

The concepts of *portfolio optimization* and diversification have been instrumental in the understanding of financial markets and the development of financial decision making. The major breakthrough came in 1952 with the publication of Harry Markowitz's theory of portfolio selection. Markowitz suggested that sound financial decision making is a quantitative trade-off between risk and return. His work spurred a vast amount of research on quantifying market behavior, and one of the main practical consequences of his theory was the

acceptance of the notion that diversification reduces portfolio risk.

Sixty years after Markowitz's seminal work, substantial advances have been made in the theory and practice of portfolio management. Today, quantitative techniques for forecasting asset returns, portfolio allocation, risk measurement, trading and rebalancing, to mention a few, have a major presence in the financial industry. Their proliferation has been facilitated by the decreased cost of computing power and the increased availability of

sophisticated and specialized software that allows investors to incorporate their forecasts about the future direction of markets into disciplined analytical frameworks.

As the use of quantitative techniques has become widespread in the investment industry, the consideration of estimation risk and model risk has grown in importance. For example, Bayesian techniques and robust estimation of model parameters are now common in financial applications. Most recently, practitioners have begun incorporating the uncertainty introduced by estimation errors directly into the portfolio optimization process by mathematical techniques referred to as robust optimization. Contrary to the traditional approach, in which inputs to the portfolio allocation framework are treated as deterministic, robust portfolio optimization incorporates the notion that inputs have been estimated with errors. In this case, the inputs are not the traditional forecasts, such as expected returns and asset covariances, but rather *uncertainty sets* containing these point estimates (e.g., confidence intervals around the forecasts).

In this entry, we survey the area of robust optimization and its applications in portfolio management. We begin by explaining the main ideas behind the robust optimization approach, and discuss the relationship between robust optimization and other robust methods for portfolio management. Next, we review some important developments in robust optimization applications, and conclude with a discussion of future directions in *robust portfolio management*.

THE ROBUST OPTIMIZATION APPROACH

Introduced in the operations research literature by Ben-Tal and Nemirovski (1998) and El Ghaoui and Lebret (1997), modern robust optimization allows a portfolio manager to solve a robust formulation of the portfolio optimization problem with one single call to an optimization

solver in about the same time as the classical portfolio optimization problem. The resulting optimal portfolio allocations tend to be more stable and less sensitive to changes in model parameters.

Consider the classical mean-variance portfolio allocation problem:

$$\begin{aligned} \max_{\mathbf{w}} \quad & \boldsymbol{\mu}'\mathbf{w} - \lambda \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{1} = 1 \end{aligned}$$

where $\boldsymbol{\mu}$ is the vector of expected returns (alphas) for N assets in the investment universe, $\boldsymbol{\Sigma}$ is the asset-asset covariance matrix, \mathbf{w} is the N -dimensional vector of portfolio weights, λ is the risk aversion coefficient, and $\mathbf{1}$ is a vector of ones. This optimization problem simply states that the optimal portfolio weights should be chosen so that the expected portfolio return less the portfolio risk (scaled by the risk aversion coefficient) is as large as possible. The equality constraint ensures that the portfolio weights add up to one.

As demonstrated, for instance, by Black and Litterman (1992), a small change in the expected asset returns can result in large changes in the optimal portfolio allocation. In other words, the classical portfolio optimization problem is not robust with respect to small changes in its inputs. Since in practice expected returns and asset covariances cannot be measured exactly but have to be estimated—sometimes with large errors—it is important in applications that uncertainty resulting from estimation errors be taken into account.

One way to make the optimization problem robust with respect to estimation errors is to require that the optimal solution remains optimal for all values of the expected returns that are “close” to the estimates of expected returns $\hat{\boldsymbol{\mu}}$. We can express this requirement in the optimization problem as follows: Instead of using the estimate $\hat{\boldsymbol{\mu}}$ of $\boldsymbol{\mu}$, we consider a set of vectors that are close to the estimate $\hat{\boldsymbol{\mu}}$, and solve the optimization problem for all vectors in this set. The idea here is that the expected returns may

have been estimated with some error, but that the estimates are not too far away from the true expected returns. Mathematically, this idea is incorporated in the definition of an uncertainty set for $\hat{\boldsymbol{\mu}}$,

$$U_\delta(\hat{\boldsymbol{\mu}}) = \{\boldsymbol{\mu} \mid |\mu_i - \hat{\mu}_i| \leq \delta_i, i = 1, \dots, N\} \quad (1)$$

In words, the set $U_\delta(\hat{\boldsymbol{\mu}})$ contains all vectors $\boldsymbol{\mu} = (\mu_1, \dots, \mu_N)$ such that each component μ_i is in the interval $[\hat{\mu}_i - \delta_i, \hat{\mu}_i + \delta_i]$, and is often referred to as a “box” uncertainty set. From a statistical point of view, these intervals can be chosen to be certain confidence intervals around each point estimate $\hat{\mu}_i$.

We solve a modification of the original optimization problem such that even if $\boldsymbol{\mu}$ takes its worst possible value within the uncertainty set, the allocation remains optimal. Namely, we solve the max-min portfolio optimization problem

$$\begin{aligned} \max_{\mathbf{w}} \quad & \left\{ \min_{\boldsymbol{\mu} \in U_\delta(\hat{\boldsymbol{\mu}})} \{\boldsymbol{\mu}'\mathbf{w}\} - \lambda \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \right\} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{t} = 1 \end{aligned}$$

At first sight, this optimization problem looks complicated, as we have to minimize the objective function with respect to $\boldsymbol{\mu}$ over the specified uncertainty set and, simultaneously, maximize the objective function with respect to \mathbf{w} to find the optimal allocation. However, as we will see shortly, this problem can be reformulated into an equivalent maximization problem with respect to only \mathbf{w} . First, let us understand what this model implies from an intuitive perspective.

Observe that this model incorporates the notion of aversion to estimation error in the following sense. When the interval $[\hat{\mu}_i - \delta_i, \hat{\mu}_i + \delta_i]$ for the expected return of the i th asset is large, meaning that the expected return has been estimated with large estimation error, then the minimization problem over $\boldsymbol{\mu}$ is less constrained. Consequently, the minimum will be smaller than it would be in situations when the interval for $\hat{\mu}_i$ is smaller. Obviously, when

the interval is small enough, the minimization problem will be so tightly constrained that it would deliver a solution that is close to the optimal solution of the classical portfolio optimization problem in which estimation errors are ignored. In other words, it is the size of the intervals (in general, the size of the uncertainty set) that controls the aversion to the uncertainty that comes from estimation errors.

The robust version of the classical portfolio optimization problem is obtained by solving the max-min problem above, and for this model is easy to derive without any involved mathematics. Namely, it is

$$\begin{aligned} \max_{\mathbf{w}} \quad & \hat{\boldsymbol{\mu}}'\mathbf{w} - \delta'|\mathbf{w}| - \lambda \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{t} = 1 \end{aligned}$$

where $|\mathbf{w}|$ denotes the absolute value of the entries of the vector of weights \mathbf{w} . To gain some intuition, notice that if the weight of asset i in the portfolio is negative, the worst-case expected return for asset i is $\hat{\mu}_i + \delta_i$ (we lose the largest amount possible). If the weight of asset i in the portfolio is positive, then the worst-case expected return for asset i is $\hat{\mu}_i - \delta_i$ (we gain the smallest amount possible). Observe that $\hat{\mu}_i w_i - \delta_i |w_i|$ equals $(\hat{\mu}_i - \delta_i) w_i$ if the weight w_i is positive and $(\hat{\mu}_i + \delta_i) w_i$ if the weight w_i is negative. Hence, the mathematical expression in the objective agrees with our intuition: It minimizes the worst-case expected portfolio return. In this robust version of the mean-variance formulation, assets whose mean return estimates are less accurate (have a larger estimation error δ_i) are therefore penalized in the objective function, and will tend to have a smaller weight in the optimal portfolio allocation.

This optimization problem has the same computational complexity as the nonrobust mean-variance formulation—namely, it can be stated as a quadratic optimization problem. The latter can be achieved by using a standard trick that allows us to get rid of the absolute values for the weights. The idea is to introduce an N -dimensional vector of additional variables $\boldsymbol{\psi}$ to replace the absolute values, and to write an

equivalent version of the optimization problem,

$$\begin{aligned} \max_{\mathbf{w}, \boldsymbol{\psi}} \quad & \hat{\boldsymbol{\mu}}' \mathbf{w} - \boldsymbol{\delta}' \boldsymbol{\psi} - \lambda \mathbf{w}' \boldsymbol{\Sigma} \mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}' \mathbf{1} = 1 \\ & \psi_i \geq w_i; \psi_i \geq -w_i, i = 1, \dots, N \end{aligned}$$

Therefore, incorporating considerations about the uncertainty in the estimates of the expected returns in this example has virtually no computational cost.

We can view the effect of this particular “robustification” of the mean-variance portfolio optimization formulation in two different ways. On the one hand, we see that the values of the expected returns for the different assets have been adjusted downwards in the objective function of the optimization problem. That is, the robust optimization model “shrinks” the expected return of assets with large estimation error. On the other hand, we can interpret the additional term in the objective function as a “risk-like” term that represents penalty for estimation error. The size of the penalty is determined by the investor’s aversion to estimation risk, and is reflected in the magnitude of the deltas.

More complicated specifications for uncertainty sets have more involved mathematical representations, but can still be selected so that they preserve an easy computational structure for the robust optimization problem. For example, a frequently used uncertainty set is

$$U_\delta(\hat{\boldsymbol{\mu}}) = \{ \boldsymbol{\mu} | (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}})' \boldsymbol{\Sigma}_\mu^{-1} (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}}) \leq \delta^2 \} \quad (2)$$

where $\boldsymbol{\Sigma}_\mu$ is the covariance matrix of estimation errors for the vector of expected returns $\boldsymbol{\mu}$. This uncertainty set represents the requirement that the scaled sum of squares (scaled by the inverse of the covariance matrix of estimation errors) between all elements in the set and the point estimates $\hat{\mu}_1, \hat{\mu}_2, \dots, \hat{\mu}_N$ can be no larger than δ^2 . We note that this uncertainty set cannot be interpreted as individual confidence intervals around each point estimate. Instead, those familiar with statistics will notice that this uncertainty set captures the idea of a joint confidence region used, for example, in

Wald tests. In practice, the covariance matrix of estimation errors is often assumed to be diagonal. For this particular case, the set contains all vectors of expected returns that are within a certain number of standard deviations from the point estimate of the vector of expected returns, and the resulting robust portfolio optimization problem would protect the investor if the vector of expected returns is indeed within that range.

Selecting Uncertainty Sets from Statistical Procedures

How do we select uncertainty sets for a particular application? In practice, their shape and size are usually based on statistical estimates and probabilistic guarantees. For example, uncertainty set (1) defines an N -dimensional box: It considers possible deviations of the N uncertain parameters from their expected values, and the resulting robust portfolio optimization problem protects against the worst possible realization of each individual parameter separately. Uncertainty set (2) defines an N -dimensional ellipsoid (in two dimensions, an ellipsoid is an ellipse), and is not as conservative as (1). The resulting robust portfolio optimization offers protection from the worst possible joint deviation of the actual expected returns from the forecasts, by considering the correlations between the estimation errors of the uncertain parameters through the covariance matrix $\boldsymbol{\Sigma}_\mu$.

The calibration of the parameters that enter the definition of uncertainty sets is very important. For example, the intervals for $\hat{\boldsymbol{\mu}}$ that define the uncertainty set (1) above can be matched to 95% or 99% confidence intervals for the estimates of the expected returns. The value of the parameter δ in the uncertainty set (2) can be related to probabilistic guarantees, as we will explain later.

The covariance matrix $\boldsymbol{\Sigma}_\mu$ of the errors in the estimated expected asset returns in uncertainty set (2) can be obtained using several different techniques. However, its estimation

can be problematic because of the difficulty in separating the estimation error in expected returns from the inherent variability in actual realized returns (Lee, Stefek, and Zhelenyak, 2006). Specifically, if a portfolio manager forecasts a 5% active return over the next time period, but achieves 1%, he cannot argue that there was a 4% error in his expected return, so evaluating Σ_{μ} from historical data can be tricky.

In theory, if returns in a given sample of size T are assumed to come from a normal distribution, then Σ_{μ} equals $(1/T) \cdot \Sigma$, where Σ is the covariance matrix of asset returns as before. However, experience seems to suggest that this may not be the best method in practice. One issue is that this approach applies only in a world in which returns are stationary. Another important issue is whether the estimate of the asset covariance matrix Σ itself is reliable if it is estimated from a sample of historical data. It is well-known that computing a meaningful asset return covariance matrix requires a large number of observations—many more observations than the number of assets in the portfolio—and even then the sample covariance matrix may contain large estimation errors that produce poor results in the mean-variance optimization. A fix when sufficient data are not available is to compute the estimation errors in expected returns at a factor (e.g., industry, country, sector) level, and use their variances and covariances in the estimation error covariance matrix for the individual asset returns in a manner similar to standard factor models.

Several approximate methods for estimating Σ_{μ} have also been found to work well in practice (Stubbs and Vance, 2005). For example, it has been observed that simpler estimation approaches, such as computing the diagonal matrix containing the variances of the estimates (as opposed to the complete error covariance matrix), often provide most of the benefit in robust portfolio optimization. In addition, standard approaches for estimating expected returns, such as Bayesian statistics and regression-based methods, generate estimates for the estimation

error covariance matrix in the process of generating the estimates themselves.

Uncertainty sets (1) and (2) are both symmetric, that is, the sets are symmetric around the vector of uncertain parameters $\hat{\mu}$. One can also consider asymmetric uncertainty sets that better reflect information about the probability distributions of the uncertain parameters when the probability distributions are skewed (see Natarajan, Pachamanova, and Sim, 2008). Recently, there has been also a substantial interest in developing “structured” uncertainty sets, that is, uncertainty sets that are constructed for a specific purpose. Frequently, structured uncertainty sets based on simple intersections of elementary uncertainty sets are used to minimize the “conservatism” in traditional ellipsoidal or “box” uncertainty sets. We will discuss such uncertainty sets in more detail later in this entry.

Clarifying a Misconception about Robust Optimization

Among practitioners, the notion of robust portfolio optimization is often equated with the robust mean-variance model we just discussed, with uncertainty set (1) or (2) for the expected asset returns. While robust optimization applications frequently involve one form or another of this model, the actual scope of robust optimization can be much broader. We note that the term “robust optimization” refers to the technique of incorporating information about uncertainty sets for the parameters in the optimization model, and not to the specific definitions of uncertainty sets or the choice of which parameters to model as uncertain. For example, we can use the robust optimization methodology to incorporate considerations for uncertainty in the estimate of the covariance matrix in addition to the uncertainty in expected returns, and obtain a different robust portfolio allocation formulation.

Robust optimization can be applied also to portfolio allocation models that are different from the mean-variance framework, e.g.,

Sharpe ratio and value-at-risk optimization (see, for example, Goldfarb and Iyengar, 2003 and Natarajan, Pachamanova, and Sim, 2008). There are numerous useful and reasonable robust formulations, and a complete review is beyond the scope of this entry. We refer interested readers to Fabozzi et al. (2007) for further details.

THE RELATIONSHIP TO BAYESIAN METHODS AND ECONOMIC THEORY

Critics have argued that robust optimization is not really different from shrinkage estimators that combine the minimum variance portfolio with a speculative investment portfolio. Indeed, when using a particular uncertainty set for the expected returns (assuming all other parameters in the mean-variance problem are certain), it can be shown that the optimal mean-variance portfolio weights using robust optimization are a linear combination of the weights of the minimum variance portfolio (which is independent of investor preferences or expected returns) and a mean-variance efficient portfolio. These portfolio weights can also be obtained by solving a standard mean-variance problem with expected return estimates derived from a standard shrinkage estimator with specific shrinkage parameters (see, for example, Garlappi, Uppal, and Wang, 2007 and Scherer, 2005). Robust optimization thus appears to offer a less transparent way to express investor preferences and tolerance to uncertainty than other approaches, such as *Bayesian methods*, in which the shrinkage parameters can be defined explicitly.

In general, however, robust optimization is not necessarily equivalent to shrinkage estimation. For instance, differences are apparent in the presence of additional portfolio constraints. Furthermore, as we mentioned earlier, the robust optimization methodology can be used to account for uncertainty in parameters other than expected asset returns (covariances of asset

returns, for example), making its relationship with Bayesian estimation even less obvious.

The concept of robust optimization has been criticized also from the point of view of classical economic theory (see, for example, Sims, 2001). From a behavioral and decision-making point of view, few individuals have max-min preferences. Indeed, max-min preferences describe the behavior of decision makers who face great ambiguity and thus make choices consistent with the belief that the worst possible outcomes are highly likely. This kind of conservative behavior is not typical of the average investor. The problem of overconservativeness in applying robust optimization, however, can be controlled by modifying the specification of uncertainty sets for the parameters, as we will explain in the following section.

USING ROBUST PORTFOLIO OPTIMIZATION IN PRACTICE

One of the main problems in assessing the practical benefits of the robust optimization approach is that its performance is dependent on the choice (or calibration) of the model parameters, such as the coefficient of aversion to estimation error δ . In a sense, however, this issue is no different from the calibration of standard parameters in the classical portfolio optimization framework, such as the length of the estimation period to use for forecast generation and the choice of the risk aversion coefficient. These and other parameters need to be determined empirically or subjectively.

Note also that other *robust modeling* devices such as Bayesian estimators and the Black-Litterman model (for an overview, see Fabozzi, Focardi, and Kolm, 2006) have similar issues. In particular, for shrinkage estimators, the portfolio manager needs to determine which shrinkage target to use and the size of the shrinkage parameter. In the Black-Litterman model, he needs to provide his confidence in equilibrium as well as his confidence in his views.

The values of the robust formulation parameters can sometimes be matched to probabilistic guarantees. For example, if the estimates of the expected asset returns are assumed to be normally distributed, then there is an $\omega\%$ chance that the estimates will fall in the ellipsoidal set (2) around the manager's estimates $\hat{\mu}$,

$$U_\delta(\hat{\mu}) = \{ \mu \mid (\mu - \hat{\mu})' \Sigma_\mu^{-1} (\mu - \hat{\mu}) \leq \delta^2 \}$$

if δ^2 is assigned the value of the ω th percentile of a χ^2 distribution with degrees of freedom equal to the number of assets in the portfolio. As an example, suppose that there are 15 assets in the asset universe and that all returns are normally distributed. If we choose $\delta^2 = 25$, then 95% of all expected returns will be in the set $U_\delta(\hat{\mu})$.

More generally, if the expected returns can belong to any possible probability distribution, then assigning

$$\delta = \sqrt{\frac{1 - \omega}{\omega}}$$

guarantees that the estimates will fall in the uncertainty set $U_\delta(\hat{\mu})$ with probability at least $\omega\%$ (El Ghaoui, Oks, and Oustry, 2003).

It has been observed that in practice the standard robust mean-variance formulation with the above uncertainty set specification for estimated expected returns may result in portfolio allocations that are too pessimistic. Recall that the traditional robust counterpart tries to find the optimal solution so that constraints containing uncertain coefficients are satisfied for the worst-case realizations of the uncertain parameters. Naturally, the larger the uncertainty set, the greater the chance that the optimal portfolio allocation will be conservative. Therefore, especially in situations in which the worst-case expected returns can be far away from the estimated expected returns, some portfolio performance may be sacrificed. Of course, we can always make a formulation less pessimistic by considering a smaller uncertainty set. For the uncertainty set above, we can achieve this by decreasing the parameter δ . However, there is a recent trend among practitioners to apply more

structured restrictions. We provide an example of a structured uncertainty set next.

When we formulated the robust portfolio optimization problem earlier in this entry, we made the assumption that all of the actual realizations of expected returns could be worse than their expected values. Thus, the net adjustment in the expected portfolio return will always be downwards. While this leads to a more robust problem than the original one, in many instances it may be too pessimistic to assume that all estimation errors go against us. Instead, it may be more reasonable to believe that at least some of the true realizations will be above their expected values. For example, we may make the assumption that there are approximately as many realizations above the estimated values as there are realizations below the estimated values. This condition can be incorporated in the portfolio optimization problem by adding an additional restriction to the uncertainty set (2). Ceria and Stubbs (2006) refer to this adjustment as a "zero net alpha adjustment." Instead of adjusting the alphas of the estimates, we can perform this kind of adjustment also on their standard deviations or variances. It can be shown that the effect of the zero net adjustment is equivalent to modifying the covariance matrix Σ_μ of estimation errors for the expected returns. Tests with real data indicate that robust mean-variance optimization with this kind of adjustment for expected return estimates outperforms classical mean-variance optimization 70% to 80% of the time (Ceria and Stubbs, 2006).

Other structured uncertainty sets include "tiered" uncertainty sets in which some of the uncertain parameters are modeled as "well-behaved," while others are modeled as "misbehaving." The modeler can require protection against a prespecified number of parameters that he believes will "misbehave," that is, which will deviate significantly from their expected values (see, for example, Bienstock, 2006). In the context of portfolio optimization, we would specify "misbehaving" parameters

as those realizations of expected asset returns that are likely to be lower than their estimates.

Effect of Robust Portfolio Optimization Formulations on Performance

As we mentioned earlier, some tests with simulated and real market data indicate that robust optimization, when inaccuracy is assumed in the expected return estimates, outperforms classical mean-variance optimization in terms of total excess return a large percentage (70% to 80%) of the time (Ceria and Stubbs, 2006). Other tests have not been as conclusive (Lee, Stefek, and Zhelenyak, 2006). The factor that accounts for much of the difference is how the uncertainty in parameters is modeled. Therefore, finding a suitable degree of robustness and appropriate definitions of uncertainty sets can have a significant impact on portfolio performance.

Independent tests by practitioners and academics using both simulated and market data appear to confirm that robust optimization generally results in more stable portfolio weights, that is, that it eliminates the extreme corner solutions resulting from traditional mean-variance optimization. Robust mean-variance optimization also appears to improve worst-case portfolio performance, and results in smoother and more consistent portfolio returns. Finally, by preventing large swings in positions, robust optimization frequently makes better use of the turnover budget and risk constraints.

Robust optimization, however, is not a panacea. By using robust portfolio optimization, investors are likely to trade off the optimality of their portfolio allocation in cases in which nature behaves as they predicted for protection against the risk of inaccurate estimation. Therefore, investors using the technique should not expect to do better than classical portfolio optimization when estimation errors have little impact, or when typical scenarios occur. They should, however, expect insurance in scenarios

in which their estimates deviate from the actual realized values by up to the amount they have prespecified in the modeling process.

PRACTICAL CONSIDERATIONS FOR ROBUST PORTFOLIO ALLOCATION

Which type of robust models is best for modeling financial portfolios? The short answer is: It depends. Among others, it depends on the size of the portfolio, the type of assets and their distributional characteristics, the portfolio strategies and trading styles involved, and the existing infrastructure. Sometimes it makes sense to consider a combination of several techniques, such as a blend of Bayesian estimation and robust portfolio optimization. This is an empirical question—indeed, the only way to find out which strategy performs best is through thorough research and testing. A simple step-by-step checklist for robust quantitative portfolio management could include:

1. Risk forecasting: Develop an accurate risk model
2. Return forecasting: Construct robust expected return estimates
3. Classical portfolio optimization: Start with a simple framework
4. Model risk mitigation:
 - a. Minimize estimation risk through the use of robust estimators
 - b. Improve the stability of the optimization framework through robust optimization
5. Extensions

Needless to say, by no means do we claim that this list is complete or that it has to be followed religiously—it is simply provided as a starting point for the quantitative portfolio manager.

In general, the most difficult item in this list is the calculation of robust expected return estimates. Developing profitable trading strategies (“ α generation”) is notoriously hard, but not

impossible. It is important to remember that modern portfolio optimization techniques and fancy mathematics are not going to help at all if the underlying trading strategies are poor.

Implicit in this list is that for each step one needs to perform thorough testing in order to understand the effect of changes and new additions to the model. It is not unusual that quantitative analysts and portfolio managers will have to revisit previous steps as part of the research and development process. For example, it is important to understand the interplay between forecast generation and the reliability of optimized portfolio weights. Introducing a robust optimizer may lead to more reliable, and often more stable, portfolio weights. However, how to make the optimization framework more robust depends on how expected return and risk forecasts are produced. Therefore, sometimes one has to refine or modify basic forecast generation. Identifying the individual and the combined contribution of different techniques is crucial in the development of a successful quantitative framework.

Minimizing estimation risk and improving the reliability of the optimization framework can be done in either order, or sometimes at the same time. The goal of both approaches is of course to improve the overall reliability and performance of the portfolio allocation framework. Some important questions to consider here are: When/why does the framework perform well (poorly)? How sensitive is it to changes in inputs? How does it behave when constraints change? Are portfolio weights intuitive—do they make sense? How high is the turnover of the portfolio over time?

Starting from the simple framework of classical portfolio optimization, many extensions are possible. Typical examples include the introduction of transaction costs models, more complex constraints (e.g., integer constraints such as round lotting or cardinality constraints), different risk measures (e.g., downside risk measures, higher moments), and dynamic and stochastic programming for incorporating in-

tertemporal dependencies. Often, these are problem specific and have to be dealt with on a case-by-case basis.

FUTURE DIRECTIONS

Advances in the mathematical and physical sciences have always had a major impact on finance. In particular, probability theory, statistics, econometrics, and operations research have provided the necessary tools and discipline for the development of modern financial economics and large-scale portfolio management. The substantial advances in the areas of robust estimation and robust optimization during the 1990s have proven to be of significant importance for the practical applicability and reliability of portfolio management and optimization.

From a theoretical perspective, the area of robust optimization is quite mature. By contrast, there are many unanswered questions in the practice of robust portfolio optimization. There is a need for more empirical research in order to provide better guidelines for applying robust optimization in a way that guarantees superior portfolio performance. In particular, practitioners need to understand better (1) the implications of using different types of uncertainty set, (2) the interaction between different forecast generation methods (estimation techniques) and robust optimization, (3) how to calibrate model parameters in the optimization model, and (4) how to deal with the overconservatism inherent in many robust models.

The robust optimization framework offers great flexibility and many new interesting possibilities in portfolio management. For instance, robust portfolio optimization can exploit the notion of statistically equivalent portfolios. Specifically, with robust optimization, a manager can find the best portfolio that (1) minimizes trading costs with respect to the current holdings, and (2) has an expected portfolio return and variance that are statistically equivalent to those of the classical mean-variance

portfolio. Common portfolio constraints, such as transaction cost considerations and tax implications, can be handled efficiently in the robust optimization framework.

Robust optimization has also shown promise as a computationally attractive alternative to classical optimization methods when it comes to multiperiod portfolio management. There are numerous benefits to taking a long-term view of *investment management*. Treating portfolio allocation as a multiperiod problem provides a framework for robust overall portfolio management that takes into consideration the effects of rebalancing, transaction costs, future liabilities, and taxes.

By incorporating multiperiod views on asset behavior in rebalancing models, portfolio managers may be able to reduce their transaction costs, as the portfolio will not be rebalanced unnecessarily often. As a simple example, if a portfolio manager expects asset returns to dip at the next time period, but then recover, he may choose to hold on to the assets in his portfolio in order to minimize transaction costs. However, if the net gain from realizing the tax loss is higher than the expense of the transactions, he may choose to trade for short term benefit despite believing that the portfolio value will recover after two trading periods. These trade-offs are complex to evaluate and model, and traditional optimization techniques for multistage optimization, such as dynamic programming (see, for example, Bertsekas, 1995a) and stochastic programming (see, for example, Wallace and Ziemba, 2005), have not been very successful in this context as they result in computationally intractable problems due to the “curse of dimensionality.” However, if future asset returns are treated as uncertain parameters, and the uncertainty in their estimates is modeled through appropriately chosen uncertainty sets, the resulting portfolio optimization formulations are computationally tractable.

We emphasize that while the focus of this entry has been on the application of robust optimization to portfolio construction, robust

optimization is a powerful and general tool with financial applications that extend well beyond that of portfolio allocation. The robust optimization technique appears promising in enhancing existing models for optimal trading, the computation of hedge ratios, the estimation of econometric models, and quantitative model selection—just to mention a few. Certainly, the future may bring many more.

KEY POINTS

- As the use of quantitative techniques has become widespread in the investment industry, the consideration of estimation risk and model risk has grown in importance.
- In contrast to the traditional approach in which inputs to the portfolio allocation framework are treated as deterministic, robust portfolio optimization incorporates estimation errors in input parameters directly into the optimization process.
- In robust portfolio optimization, the inputs are not the traditional forecasts, such as expected returns and risk, but rather uncertainty sets containing these point estimates (e.g., confidence intervals around the forecasts).
- The robust optimization is a general technique that leads to a more reliable portfolio allocation framework and offers greater flexibility and many new interesting possibilities for the portfolio manager.
- One of the main problems in assessing the practical benefits of the robust optimization approach is that its performance is dependent on the choice (or calibration) of the model parameters, such as the coefficient of aversion to estimation error.
- Which type of robust model is best for modeling financial portfolios depends on, among other things, the size of the portfolio, the type of assets and their distributional characteristics, the portfolio strategies and trading styles involved, and the existing infrastructure.

Abstract: Probability theory is the mathematical approach to formalizing the uncertainty of events. Even though a decision maker may not know which one of the set of possible events may finally occur, with probability theory, a decision maker has the means of providing each event with a certain probability. Furthermore, it provides the decision maker with the axioms to compute the probability of a composed event in a unique way. The rather formal environment of probability theory translates in a reasonable manner to the problems related to risk and uncertainty in finance such as, for example, the future price of a financial asset. Today, investors may be aware of the price of a certain asset, but they cannot say for sure what value it might have tomorrow. To make a prudent decision, investors need to assess the possible scenarios for tomorrow's price and assign to each scenario a probability of occurrence. Only then can investors reasonably determine whether the financial asset will satisfy an investment objective.

Probability theory serves as the quantification of risk in finance. To estimate probabilistic models, we have to gather and process empirical

data. In this context, we need the tools provided by statistics. In this entry, we introduce the general concepts of probability theory.

HISTORICAL DEVELOPMENT OF ALTERNATIVE APPROACHES TO PROBABILITY

Before we introduce the formal definitions, we provide a brief outline of the historical development of probability theory and the alternative approaches since probability is, by no means, unique in its interpretation. We will describe the two most common approaches: relative frequencies and axiomatic system.

Probability as Relative Frequencies

The relative frequencies approach to probability was conceived in 1928 by Richard von Mises (Mises, 1928) and as the name suggests formulates probability as the relative frequencies denoted by $f(x_i)$. This initial idea was extended by Hans Reichenbach (1935). Given large samples, it was understood that $f(x_i)$ was equal to the true probability of value x_i . For example, if $f(x_i)$ is small, then the true probability of value x_i occurring should be small, in general. However, $f(x_i)$ itself is subject to uncertainty. Thus, the relative frequencies might deviate from the corresponding probabilities. For example, if the sample is not large enough, whatever large may be, then it is likely that we obtain a rare set of observations and draw the wrong conclusion with respect to the underlying probabilities.

This point can be illustrated with a simple example. Consider throwing a six-sided dice 12 times. Intuitively, one would expect the numbers 1 through 6 to occur twice each, since this would correspond to the theoretical probabilities of $1/6$ for each number. But since so many different outcomes of this experiment are very likely possible, one might observe relative frequencies of these numbers different from $1/6$. So, based on the relative frequencies, one might draw the wrong conclusion with respect to the true underlying probabilities of the according values. However, if we increase the repetitions from 12 to 1,000, for example, with a high de-

gree of certainty, the relative frequency of each number will be pretty close to $1/6$.

The reasoning of von Mises and Reichenbach was that since extreme observations are unlikely given a reasonable sample size, the relative frequencies will portray the true probabilities with a high degree of accuracy. In other words, probability statements based on relative frequencies were justifiable since, in practice, highly unlikely events could be ruled out.

In the context of our dice example, they would consider unlikely that certain numbers appeared significantly more often than others if the series of repetitions is, say, 1,000. But still, who could guarantee that we do not accidentally end up throwing 300 1s, 300 2s, 400 3s, and nothing else?

The approach of von Mises becomes relevant, again, in the context of estimating and hypothesis testing. For now, however, we will not pay any further attention to it but turn to the alternative approach to probability theory.

Axiomatic System

Introduced by Andrei N. Kolmogorov in 1933, the axiomatic system abstracted probability from relative frequencies as obtained from observations and instead treated probability as purely mathematical. The variables were no longer understood as the quantities that could be observed but rather as some theoretical entities "behind the scenes." Strict rules were set up that controlled the behavior of the variables with respect to their likelihood of assuming values from a predetermined set. So, for example, consider the price of a stock, say General Electric (GE). GE's stock price as a variable is not what you can observe but a theoretical quantity obeying a particular system of probabilities. What you observe is merely realizations of the stock price with no implication on the true probability of the values since the latter is given and does not change from sample to sample. The

relative frequencies, however, are subject to change depending on the sample.

We illustrate the need for an axiomatic system due to the dependence of relative frequencies on samples using our dice example. Consider the chance of occurrence of the number 1. Based on intuition, since there are six different “numbers of dots” on a dice, the number 1 should have a chance of $1/6$, right? Suppose we obtain the information based on two samples of 12 repetitions each, that is, $n_1 = n_2 = 12$. In the following table, we report the absolute frequencies, a_i , representing how many times the individual numbers of dots 1 through 6 were observed.

Number of Dots	Absolute Frequencies a_i	
	Sample 1	Sample 2
1	4	1
2	1	1
3	3	1
4	0	1
5	1	1
6	3	7
Total	12	12

That is, in sample 1, 1 dot was observed 4 times while, in sample 2, 1 dot was observed only once, and so on.

From the above observations, we obtain the following relative frequencies

Number of Dots	Relative Frequencies $f(x_i)$	
	Sample 1	Sample 2
1	0.3333	0.0833
2	0.0833	0.0833
3	0.2500	0.0833
4	0.0000	0.0833
5	0.0833	0.0833
6	0.2500	0.5833
Total	1.0000	1.0000

That is, in sample 1, 1 dot was observed 33.33% of the time while in sample 2, 1 dot was observed 8.33% of the time, and so on. We see that both samples lead to completely different results about the relative frequencies for the

number of dots. But, as we will see, the theoretical probability is $1/6 = 0.1667$, for each value 1 through 6. So, returning to our original question of the chance of occurrence of 1 dot, the answer is still $1/6 = 0.1667$.

In finance, the problem arising with this concept of probability is that, despite the knowledge of the axiomatic system, we do not know for sure what the theoretical probability is for each value. We can only obtain a certain degree of certainty as to what it approximately might be. This insight must be gained from estimation based on samples and, thus, from the related relative frequencies. So, it might appear reasonable to use as many observations as possible. However, even if we try to counteract the sample-dependence of relative frequencies by using a large number of observations, there might be a change in the underlying probabilities exerting additional influence on the sample outcome. For example, during the period of a bull market, the probabilities associated with an upward movement of some stock price might be higher than under a bear market scenario.

Despite this shortcoming, the concept of probability as an abstract quantity as formulated by Kolmogorov (1933) has become the standard in probability theory.

SET OPERATIONS AND PRELIMINARIES

Before proceeding to the formal definition of probability, randomness, and random variables we need to introduce some terminology.

Set Operations

A set is a combination of *elements*. Usually, we denote a set by some capital (uppercase) letter, for example S , while the elements are denoted by lowercase letters such as a, b, c, \dots or a_1, a_2, \dots . To indicate that a set S consists of exactly the elements a, b, c , we write $S = \{a, b, c\}$. If we want to say that element a belongs to S , the notation used is that $a \in S$ where \in means “belongs

to." If, instead, a does not belong to S , then the notation used is $a \notin S$ where \notin means "does not belong to."

A type of set such as $S = \{a,b,c\}$ is said to be *countable* since we can actually count the individual elements a , b , and c . A set might also consist of all real numbers inside of and including some bounds, say a and b . Then, the set is equal to the interval from a to b , which would be expressed in mathematical notation as $S = [a,b]$. If either one bound or both do not belong to the set, then this would be written as either $S = (a,b]$, $S = [a,b)$, or $S = (a,b)$, respectively, where the parentheses denote that the value is excluded. An interval is an *uncountable* set since, in contrast to a countable set $S = \{a,b,c\}$, we cannot count the elements of an interval.¹

We now present the operators used in the context of sets. The first is *equality* denoted by $=$ and intuitively stating that two sets are equal, that is, $S_1 = S_2$, if they consist of the same elements. If a set S consists of no elements, it is referred to as an *empty set* and is denoted by $S = \emptyset$. If the elements of S_1 are all contained in S_2 , the notation used is $S_1 \subset S_2$ or $S_1 \subseteq S_2$. In the first case, S_2 also contains additional elements not in S_1 while, in the second case, the sets might also be equal. For example, let $S_1 = \{a,b\}$ and $S_2 = \{a,b,c\}$, then $S_1 \subset S_2$. The operator \subseteq would indicate that S_2 consists of, at least, a and b . Or, let $M_1 = [0,1]$ and $M_2 = [0.5,1]$, then $M_2 \subset M_1$.

If we want to join a couple of sets, we use the *union operator* denoted by \cup . For example, let $S_1 = \{a,b\}$ and $S_2 = \{b,c,d\}$, then the union would be $S_1 \cup S_2 = \{a,b,c,d\}$. Or, let $M_1 = [0,1]$ and $M_2 = [0.5,1]$, then $M_2 \cup M_1 = [0,1] = M_1$.² If we join n sets S_1, S_2, \dots, S_n with $n \geq 2$, we denote the union by $\cup_{i=1}^n S_i$.

The opposite operator to the union is the *difference* denoted by the \setminus symbol. If we take the difference between set S_1 and set S_2 , that is, $S_1 \setminus S_2$, we discard from S_1 all the elements that are common to both S_1 and set S_2 . For example, let $S_1 = \{a,b\}$ and $S_2 = \{b,c,d\}$, then $S_1 \setminus S_2 = \{a\}$.

To indicate that we want to single out elements that are contained in several sets simul-

taneously, then we use the *intersection operator* \cap . For example, with the previous sets, the intersection would be $S_1 \cap S_2 = \{b\}$. Or, let $M_1 = [0,1]$ and $M_2 = [0.5,1]$, then $M_1 \cap M_2 = [0.5,1] = M_2$. Instead of the \cap symbol, one sometimes simply writes $S_1 S_2$ to indicate intersection.

If two sets contain no common elements (i.e., the intersection is the empty set), then the sets are said to be *pairwise disjoint*. For example, the sets $S_1 = \{a,b\}$ and $S_2 = \{c,d\}$ are pairwise disjoint since $S_1 \cap S_2 = \emptyset$. Or, let $M_1 = [0,0.5)$ and $M_2 = [0.5, 1]$, then $M_1 \cap M_2 = \emptyset$. If we intersect n sets S_1, S_2, \dots, S_n with $n \geq 2$, we denote the intersection by $\cap_{i=1}^n S_i$.

The *complement* to some set S is denoted by \bar{S} . It is defined as $S \cap \bar{S} = \emptyset$ and $S \cup \bar{S} = \Omega$. That is, the complement \bar{S} is the remainder of Ω that is not contained in S .

Right-Continuous and Non-decreasing Functions

Next we introduce two concepts of functions that should be understood in order to appreciate probability theory: right-continuous function and non-decreasing function.

A function f is right-continuous at \tilde{x} if the limit from the right of the function values coincides with the actual value of f at \tilde{x} . Formally, that is $\lim_{x \rightarrow \tilde{x}} f(x) = f(\tilde{x})$. We illustrate this in Figure 1. At the abscissae x_1 and x_2 , the function f jumps to $f(x_1)$ and $f(x_2)$ respectively.³ After each jump, the function remains at the new level for some time. Hence, approaching x_1 from the right, that is, for higher x -values, the function f approaches $f(x_1)$ smoothly. This is not the case when approaching x_1 from the left since f jumps at x_1 and, hence, deviates from the left-hand limit. The same reasoning applies to f at abscissa x_2 . A function is said to be a *right-continuous function* if it is right-continuous at every value on the x -axis.

A function f is said to be a *non-decreasing function* if it never assumes a value smaller than any value to the left. We demonstrate this using Figure 2. We see that while, in the different sections

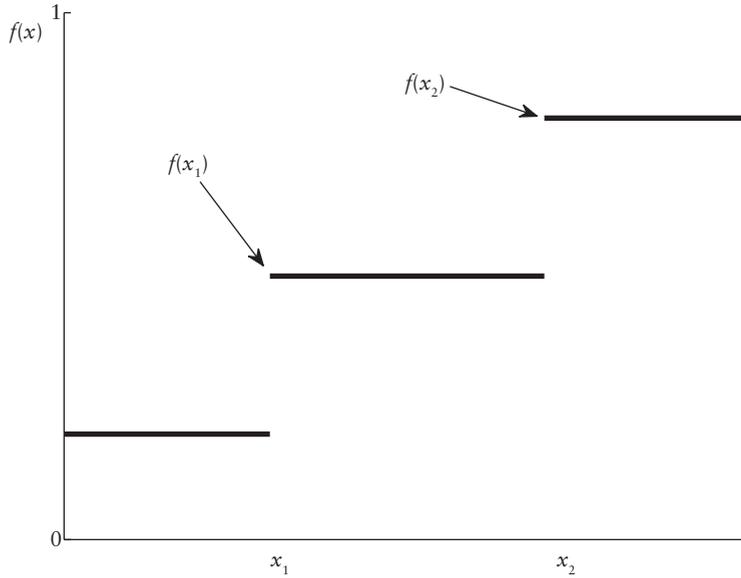

Figure 1 Demonstration of Right-Continuity of Some Hypothetical Function f at Values x_1 and x_2

A, B, and C, f might grow at different rates, it never decreases. Even for x -values in section B, f has zero and thus a nonnegative slope.

Outcome, Space, and Events

Before we dive into the theory, we will use examples that help illustrate the concept be-

hind the definitions that follow later in this entry.

Let us first consider again the number of dots of a dice. If we throw it once, we observe a certain value, that is, a realization of the abstract number of dots, say 4. This is one particular outcome of the random experiment. We will denote the outcomes by ω and a particular

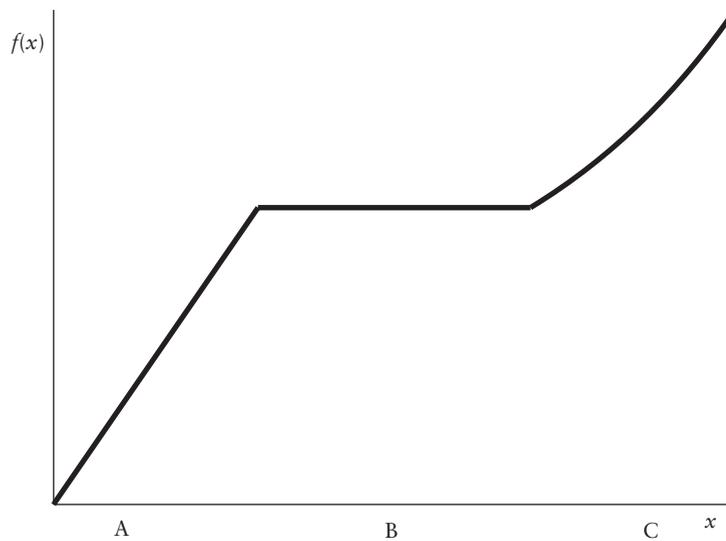

Figure 2 Hypothetical Non-decreasing Function f

outcome i will be denoted by ω_i . We might just as well have realized 2, for example, which would represent another outcome. All feasible outcomes, in this experiment, are given by

$$\omega_1 = 1 \quad \omega_2 = 2 \quad \omega_3 = 3 \quad \omega_4 = 4 \quad \omega_5 = 5 \quad \omega_6 = 6$$

The set of all feasible outcomes is called *space* and is denoted by Ω . In our example, $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_4, \omega_5, \omega_6\}$.

Suppose that we are not interested in the exact number of points but care about whether we obtain an odd or an even number, instead. That is, we want to know whether the outcome is from $A = \{\omega_1, \omega_3, \omega_5\}$ —that is, the set of all odd numbers—or $B = \{\omega_2, \omega_4, \omega_6\}$ —the set of all even numbers. The sets A and B are both contained in Ω ; that is, both sets are *subsets* of Ω . Any subsets of Ω are called *events*. So, we are interested in the events “odd” and “even” number of dots. When individual outcomes are treated as events, they are sometimes referred to as *elementary events* or *atoms*.

All possible subsets of Ω are given by the so-called *power set* 2^Ω of Ω . A power set of Ω is a set containing all possible subsets of Ω including the empty set \emptyset and Ω , itself.⁴

For our dice example, the power set is given in Table 1. With the aid of this power set, we are able to describe all possible events such as, for example, the number of dots less than 3 (i.e., $\{\omega_1, \omega_2\}$) or the number of dots either 1 or greater than or equal to 4 (i.e., $\{\omega_1, \omega_4, \omega_5, \omega_6\}$).

The power set has an additional pleasant feature. It contains any union of arbitrarily many events as well as any intersection of arbitrarily many events. Because of this, we say that 2^Ω is *closed under countable unions* and *closed under countable intersections*. Unions are employed to express that at least one of the events has to occur. We use intersections when we want to express that the events have to occur simultaneously. The power set also contains the complements to all events.

As we will later see, all these properties of the power set are features of a σ -*algebra* (in words: sigma-algebra), often denoted by \mathbb{A} .

Now consider an example where the space Ω is no longer countable. Suppose that we are analyzing the daily logarithmic returns for a common stock or common stock index. Theoretically, any real number is a feasible outcome for a particular day’s return.⁵ So, events are characterized by singular values as well as closed or open intervals on the real line. For example, we might be interested in the event E that the S&P 500 stock index return is “at least 1%.” Using the notation introduced earlier, this would be expressed as the half-open interval $E = [0.01, \infty)$.⁶ This event consists of the uncountable union of all outcomes between 0.01 and ∞ . Now, as the sets containing all feasible events, we might take, again, the power set of the real numbers, that is, 2^Ω with $\Omega = (-\infty, \infty) = \mathbb{R}$.⁷ But, for theoretical reasons

Table 1 The Power Set of the Example Number of Dots of a Dice

$$2^\Omega = \{\emptyset, \{\omega_1\}, \{\omega_2\}, \{\omega_3\}, \{\omega_4\}, \{\omega_5\}, \{\omega_6\}, \{\omega_2, \omega_3\}, \{\omega_2, \omega_4\}, \{\omega_2, \omega_5\}, \{\omega_2, \omega_6\}, \dots$$

$$\{\omega_3, \omega_4\}, \{\omega_3, \omega_5\}, \{\omega_3, \omega_6\}, \{\omega_4, \omega_5\}, \{\omega_4, \omega_6\}, \{\omega_5, \omega_6\}, \{\omega_1, \omega_2, \omega_3\},$$

$$\{\omega_1, \omega_2, \omega_4\}, \{\omega_1, \omega_2, \omega_5\}, \{\omega_1, \omega_2, \omega_6\}, \{\omega_1, \omega_3, \omega_4\}, \{\omega_1, \omega_3, \omega_5\}, \{\omega_1, \omega_3, \omega_6\},$$

$$\{\omega_1, \omega_4, \omega_5\}, \{\omega_1, \omega_4, \omega_6\}, \{\omega_1, \omega_5, \omega_6\}, \{\omega_2, \omega_3, \omega_4\}, \{\omega_2, \omega_3, \omega_5\}, \{\omega_2, \omega_3, \omega_6\}, \dots$$

$$\{\omega_2, \omega_4, \omega_5\}, \{\omega_2, \omega_4, \omega_6\}, \{\omega_2, \omega_5, \omega_6\}, \{\omega_3, \omega_4, \omega_5\}, \{\omega_3, \omega_4, \omega_6\}, \{\omega_3, \omega_5, \omega_6\},$$

$$\{\omega_4, \omega_5, \omega_6\}, \{\omega_1, \omega_2, \omega_3, \omega_4\}, \{\omega_1, \omega_2, \omega_3, \omega_5\}, \{\omega_1, \omega_2, \omega_3, \omega_6\}, \{\omega_1, \omega_2, \omega_4, \omega_5\},$$

$$\{\omega_1, \omega_2, \omega_4, \omega_6\}, \{\omega_1, \omega_2, \omega_5, \omega_6\}, \{\omega_1, \omega_3, \omega_4, \omega_5\}, \{\omega_1, \omega_3, \omega_4, \omega_6\},$$

$$\{\omega_1, \omega_3, \omega_5, \omega_6\}, \{\omega_1, \omega_4, \omega_5, \omega_6\}, \{\omega_2, \omega_3, \omega_4, \omega_5\}, \{\omega_2, \omega_3, \omega_4, \omega_6\},$$

$$\{\omega_2, \omega_3, \omega_5, \omega_6\}, \{\omega_2, \omega_4, \omega_5, \omega_6\}, \{\omega_3, \omega_4, \omega_5, \omega_6\}, \{\omega_1, \omega_2, \omega_3, \omega_4, \omega_5\},$$

$$\{\omega_1, \omega_2, \omega_3, \omega_4, \omega_6\}, \{\omega_1, \omega_2, \omega_3, \omega_5, \omega_6\}, \{\omega_1, \omega_2, \omega_4, \omega_5, \omega_6\},$$

$$\{\omega_1, \omega_3, \omega_4, \omega_5, \omega_6\}, \{\omega_1, \omega_3, \omega_4, \omega_5, \omega_6\}, \Omega\}$$

Note: The notation $\{\omega_i\}$ for $i = 1, 2, \dots, 6$ indicates that the outcomes are treated as events.

beyond the scope of this entry, that might cause trouble.

Instead, we take a different approach. To design our set of events of the uncountable space Ω , we begin with the inclusion of the events “any real number,” which is the space Ω , itself, and “no number at all,” which is the empty set \emptyset . Next, we include all events of the form “less than or equal to a ,” for any real number a , that is, we consider all half-open intervals $(-\infty, a]$, for any $a \in \mathbb{R}$. Now, for each of these $(-\infty, a]$, we add its complement $\overline{(-\infty, a]} = \Omega \setminus (-\infty, a] = (a, \infty)$, which expresses the event “greater than a .” So far, our set of events contains \emptyset, Ω , all sets $(-\infty, a]$, and all the sets (a, ∞) . Furthermore, we include all possible unions and intersections of everything already in the set of events as well as of the resulting unions and intersections themselves. By doing this, we guarantee that any event of practical relevance of an uncountable space is considered by our set of events.

With this procedure, we construct the Borel σ -algebra, \mathbb{B} . This is the collection of events we will use any time we deal with real numbers.

The events from the respective σ -algebra of the two examples can be assigned probabilities in a unique way, as we will see.

The Measurable Space

Let us now express the ideas from the previous examples in a formal way. To describe a random experiment, we need to formulate

1. Outcomes ω
2. Space Ω
3. σ -algebra \mathbb{A}

Definition 1—Space: The space Ω contains all outcomes. Depending on the outcomes ω , the space Ω is either countable or uncountable.

Definition 2— σ -algebra: The σ -algebra \mathbb{A} is the collection of events (subsets of Ω) with the following properties:

- a. $\Omega \in \mathbb{A}$ and $\emptyset \in \mathbb{A}$.
- b. If event $E \in \mathbb{A}$ then $\bar{E} \in \mathbb{A}$.

- c. If the countable sequence of events $E_1, E_2, E_3, \dots \in \mathbb{A}$ then $\cup_{i=1}^{\infty} E_i \in \mathbb{A}$ and $\cap_{i=1}^{\infty} E_i \in \mathbb{A}$.

Definition 3—Borel σ -algebra: The σ -algebra formed by $\emptyset, \Omega = \mathbb{R}$, intervals $(\infty, a]$ for some real a , and countable unions and intersections of these intervals is called a *Borel σ -algebra* and denoted by \mathbb{B} .

Note that we can have several σ -algebrae for some space Ω . Depending on the events we are interested in, we can think of a σ -algebra \mathbb{A} that contains fewer elements than 2^Ω (for countable Ω), or the Borel σ -algebra (for uncountable Ω). For example, we might think of $\mathbb{A} = \{\emptyset, \Omega\}$, that is, we only want to know whether any outcome occurs or nothing at all.⁸ It is easy to verify that this simple \mathbb{A} fulfills all requirements a, b, and c of Definition 2.

Definition 4—Measurable space: The tuple (Ω, \mathbb{A}) with \mathbb{A} being a σ -algebra of Ω is a *measurable space*.

A tuple is the combination of several components. For example, when we combine two values a and b , the resulting tuple is (a, b) , which we know to be a pair. If we combine three values a, b , and c , the resulting tuple (a, b, c) is known as a triplet.

Given a measurable space, we have enough to describe a random experiment. All that is left is to assign probabilities to the individual events. We will do so next.

PROBABILITY MEASURE

We start with a brief discussion of what we expect of a probability or *probability measure*; that is, the following properties:

Property 1: A probability measure should assign each event E from our σ -algebra a nonnegative value corresponding to the chance of this event occurring.

Property 2: The chance that the empty set occurs should be zero since, by definition, it is the improbable event of “no value.”

Property 3: The event that “any value” might occur (i.e., Ω) should be 1 or, equivalently, 100% since some outcome has to be observable.

Property 4: If we have two or more events that have nothing to do with one another that are pairwise disjoint or *mutually exclusive*, and create a new event by uniting them, the probability of the resulting union should equal the sum of the probabilities of the individual events.

To illustrate, let:

- The first event state that the S&P 500 log return is “maximally 5%,” that is, $E_1 = (-\infty, 0.05]$.
- The second event state that the S&P 500 log return is “at least 10%,” that is, $E_2 = [0.10, \infty)$.

Then, the probability of the S&P log return either being no greater than 5% or no less than 10% should be equal to the probability of E_1 plus the probability of E_2 .

Let’s proceed a little more formally. Let (Ω, \mathbb{A}) be a measurable space. Moreover, consider the following definition.

Definition 5—Probability measure: A function P on the σ -algebra \mathbb{A} of Ω is called a *probability measure* if it satisfies:

- a. $P(\emptyset) = 0$ and $P(\Omega) = 1$.
- b. For a countable sequence of events E_1, E_2, \dots in \mathbb{A} that are pairwise disjoint (i.e., $E_i \cap E_j = \emptyset \dots, i \neq j$), we have

$$P\left(\bigcup_{i=1}^{\infty} E_i\right) = \sum_{i=1}^{\infty} P(E_i)$$

This property is referred to as *countable additivity*.

Then we have everything we need to model randomness and chance, that is, we have the space Ω , the σ -algebra \mathbb{A} of Ω , and the probability measure P . This triplet (Ω, \mathbb{A}, P) forms the so called *probability space*.

At this point, we introduce the notion of *P-almost surely* (*P-a.s.*) occurring events. It is imaginable that even though $P(\Omega) = 1$, not all of the outcomes in Ω contribute positive prob-

ability. The entire positive probability may be contained in a subset of Ω while the remaining outcomes form the *unlikely* event with respect to the probability measure P . The event accounting for the entire positive probability with respect to P is called the *certain event with respect to P*. If we denote this event by E_{as} , then we have $P(E_{as}) = 1$ yielding $P(\Omega \setminus E_{as}) = 0$.

There are certain peculiarities of P depending on whether Ω is countable or not. It is essential to analyze these two alternatives since this distinction has important implications for the determination of the probability of certain events. Here is why.

Suppose, first, that Ω is countable. Then, we are able to assign the event $\{\omega_i\}$ associated with an individual outcome, ω_i , a nonnegative probability $p_i = P(\{\omega_i\})$, for all $\omega_i \in \Omega$. Moreover, the probability of any event E in the σ -algebra \mathbb{A} can be computed by adding the probabilities of all outcomes associated with E . That is,

$$P(E) = \sum_{\omega_i \in E} p_i$$

In particular, we have

$$P(\Omega) = \sum_{\omega_i \in \Omega} p_i = 1$$

Let us resume the six-sided dice tossing experiment. The probability of each number of dots 1 through 6 is 1/6 or formally,

$$P(\{\omega_1\}) = P(\{\omega_2\}) = \dots = P(\{\omega_6\}) = 1/6$$

or equivalently,

$$p_1 = p_2 = \dots = p_6 = 1/6$$

Suppose, instead, we have $\Omega = \mathbb{R}$. That is, Ω is uncountable and our σ -algebra is given by the Borel σ -algebra, \mathbb{B} . To give the probability of the events E in \mathbb{B} , we need an additional device, given in the next definition.

Definition 6—Distribution function: A function F is a *distribution function of the probability measure P* if it satisfies the following properties:

- a. F is right-continuous.
- b. F is non-decreasing.

- c. $\lim_{x \rightarrow -\infty} F(x) = 0$ and $\lim_{x \rightarrow \infty} F(x) = 1$.
- d. For any $x \in \mathbb{R}$, we have $F(x) = P((-\infty, x])$.

It follows that, for any interval $(x, y]$, we compute the associated probability according to

$$F(y) - F(x) = P((x, y]) \tag{1}$$

So, in this case we have a function F uniquely related to P from which we derive the probability of any event in \mathbb{B} . Note that in general F is only right-continuous, that is the limit of $F(y)$, when $y > x$ and $y \rightarrow x$, is exactly $F(x)$. At point x , we might have a jump of the distribution $F(x)$. The size of this jump equals $P(\{x\})$. This distribution function can be interpreted in a similar way to the relative empirical cumulative distribution function. That is, we state the probability of our quantity of interest being less than or equal to x .

To illustrate, the probability of the S&P 500 log return being at most 1%, $E = (-\infty, 0.01]$, is given by $F^{\text{S\&P 500}}(0.01) = P((-\infty, 0.01])$,⁹ while the probability of it being between -1% and 1% is

$$F^{\text{S\&P 500}}(0.01) - F^{\text{S\&P 500}}(-0.01) = P((-0.01, 0.01])$$

RANDOM VARIABLE

Now the time has come to introduce the concept of a *random variable*. When we refer to some quantity as being a random variable, we want to express that its value is subject to uncertainty, or randomness. Technically, the variable of interest is said to be *stochastic*. In contrast to a deterministic quantity whose value can be determined with certainty, the value of a random variable is not known until we can observe a realized outcome of the random experiment. However, since we know the probability space (Ω, \mathbb{A}, P) , we are aware of the possible values it can assume.

One way we can think of a random variable denoted by X is as follows. Suppose we have a random experiment where some outcome ω from the space Ω occurs. Then, depending on

this ω , the random variable X assumes some value $X(\omega) = x$, where ω can be understood as input to X . What we observe, finally, is the value x , which is only a consequence of the outcome ω of the underlying random experiment.

For example, we can think of the price of a 30-year Treasury bond as a random variable assuming values at random. However, expressed in a somewhat simple fashion, the 30-year Treasury bond depends completely on the prevailing market interest rate (or yield) and, hence, is a function of it. So, the underlying random experiment concerns the prevailing market interest rate with some outcome ω while the price of the Treasury bond, in turn, is merely a function of ω .

Consequently, a random variable is a function that is completely deterministic and depends on the outcome ω of some random experiment. In most applications, random variables have values that are real numbers.

So, we understand random variables as functions from some space into an image or state space. We need to become a little more formal at this point. To proceed, we will introduce a certain type of function, the *measurable function*, in the following

Definition 7—Measurable function: Let (Ω, \mathbb{A}) and (Ω', \mathbb{A}') be two measurable spaces. That is Ω, Ω' are spaces and \mathbb{A}, \mathbb{A}' their σ -algebrae, respectively. A function $X: \Omega \rightarrow \Omega'$ is \mathbb{A} - \mathbb{A}' -measurable if, for any set $E' \in \mathbb{A}'$, we have

$$X^{-1}(E') \in \mathbb{A}$$

In words, this means that a function from one space to another is measurable if the origin with respect to this function of each image in the σ -algebra of the state space can be traced in the σ -algebra of the domain space. Instead of \mathbb{A} - \mathbb{A}' -measurable, we will, henceforth, use simply *measurable* since, in our statements, it is clear which σ -algebrae are being referred to.

We illustrate this in Figure 3. Function X creates images in Ω' by mapping outcomes ω from

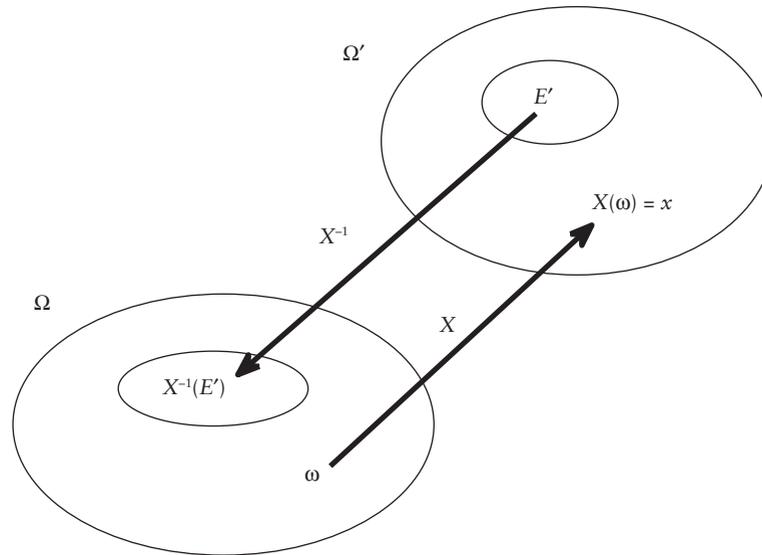

Figure 3 Relationship between Image E' and $X^{-1}(E')$ through the Measurable Function X

Ω with values $X(\omega) = x$ in Ω' . In reverse fashion, for each event E' in the state space with σ -algebra \mathbb{A}' , X^{-1} finds the corresponding origin of E' in σ -algebra \mathbb{A} of the probability space.

Now, we define a random variable X as a measurable function. That means for each event in the state space σ -algebra, \mathbb{A}' , we have a corresponding event in the σ -algebra of the domain space, \mathbb{A} .

To illustrate this, let us consider the example with the dice. Now we will treat the “number of points” as a random variable X . The possible outcome values of X are given by the state space Ω' , namely, $\Omega' = \{1,2,3,4,5,6\}$.¹⁰ The origin or domain space is given by the set of outcomes $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_4, \omega_5, \omega_6\}$. Now, we can think of our random variable X as the function $X: \Omega \rightarrow \Omega'$ with the particular map $X(\omega_i) = i$ with $i = 1, 2, \dots, 6$.

Random Variables on a Countable Space

We will distinguish between random variables on a countable space and on an uncountable space. We begin with the countable case.

The random variable X is a function mapping the countable space Ω into the state space Ω' . The state space Ω' contains all outcomes or values that X can obtain.¹¹ Thus, all outcomes in Ω' are countable images of the outcomes ω in Ω . Between the elements of the two spaces, we have the following relationship.

Let x be some outcome value of X in Ω' . Then, the corresponding outcomes from the domain space Ω are determined by the set

$$X^{-1}(\{x\}) = \{\omega : X(\omega) = x\}$$

In words, we look for all outcomes ω that are mapped to the outcome value x .

For events, in general, we have the relationship

$$X^{-1}(E') = \{\omega : X(\omega) \in E'\}$$

which is the set of all outcomes ω in the domain space that are mapped by X to the event E' in the state space. That leads us to the following definition:

Definition 8—Random variable on a countable space: Let (Ω, \mathbb{A}) and (Ω', \mathbb{A}') be two measurable spaces with countable Ω and Ω' . Then the mapping $X: \Omega \rightarrow \Omega'$ is a *random variable on a countable space* if, for any event $E' \in \mathbb{A}'$

composed of outcomes $x \in \Omega'$, we have

$$\begin{aligned} P^X(E') &= P(\{\omega : X(\omega) \in E'\}) = P(X^{-1}(E')) \\ &= P(X \in E') \end{aligned} \quad (2)$$

We can illustrate this with the following example from finance referred to as the “binomial stock price model.” The random variable of interest will be the price of some stock. We will denote the price of the stock by S . Suppose at the beginning of period t , the price of the stock is \$20 (i.e., $S_t = \$20$). At the beginning of the following period, $t + 1$, the stock price is either $S_{t+1} = \$18$ or $S_{t+1} = \$22$. We model this in the following way.

Let:

- (Ω, \mathbb{A}) and (Ω', \mathbb{A}') be two measurable spaces with $\Omega' = \{\$18, \$22\}$ (i.e., the state space of the period $t + 1$ stock price) and \mathbb{A} (i.e., the corresponding σ -algebra of all events with respect to the stock price in $t + 1$).
- Ω be the space consisting of the outcomes of some random experiment completely influencing the $t + 1$ stock price.
- \mathbb{A} be the corresponding σ -algebra of Ω with all events in the origin space.

Now, we can determine the origin of the event that

$$S_{t+1} = \$18 \text{ by } E_{\text{down}} = \{\omega : S(\omega) = \$18\}$$

and

$$S_{t+1} = \$22 \text{ by } E_{\text{up}} = \{\omega : S(\omega) = \$22\}$$

Thus, we have partitioned Ω into the two events, E_{down} and E_{up} , related to the two period $t + 1$ stock prices. With the probability measure P on Ω , we have the probability space (Ω, \mathbb{A}, P) . Consequently, due to equation (2), we are able to compute the probability $P^S(\$18) = P(E_{\text{down}})$ and $P^S(\$22) = P(E_{\text{up}})$, respectively.

Random Variables on an Uncountable Space

Now let’s look at the case when the probability space (Ω, \mathbb{A}, P) is no longer countable. Recall

the particular way in which events are assigned probabilities in this case.

While for a countable space any outcome ω can have positive probability, that is, $p_\omega > 0$, this is not the case for individual outcomes of an uncountable space. On an uncountable space, we can have the case that only events associated with intervals have positive probability. These probabilities are determined by the distribution function $F(x) = P(X < x) = P(X \leq x)$ according to equation (1).

This brings us to the following definition:

Definition 9—Random variable on a general possibly uncountable space: Let (Ω, \mathbb{A}) and (Ω', \mathbb{A}') be two measurable spaces with, at least, Ω uncountable. The map $X: \Omega \rightarrow \Omega'$ is a *random variable on the uncountable space* (Ω, \mathbb{A}, P) if it is measurable. That is, if, for any $E' \in \mathbb{A}'$, we have

$$X^{-1}(E') \in \mathbb{A}$$

induce probability from (Ω, \mathbb{A}, P) on (Ω', \mathbb{A}') by

$$\begin{aligned} P^X(E') &= p(\{\omega : X(\omega) \in E'\}) = P(X^{-1}(E')) \\ &= P(X \in E') \end{aligned}$$

We call this the *probability law* or distribution of X . Typically, the probability of $X \in E'$ is written using the following notation:

$$P^X(E') = P(X \in E')$$

Very often, we have the random variable X assume values that are real numbers (i.e., $\Omega' = \mathbb{R}$ and $\mathbb{B}' = \mathbb{B}$). Then, the events in the state space are characterized by countable unions and intersections of the intervals $(-\infty, a]$ corresponding to the events $\{X \leq a\}$, for real numbers a . In this case, we require that to be a random variable, X satisfies

$$\{\omega : X(\omega) \leq a\} = X^{-1}((-\infty, a]) \in \mathbb{B}$$

for any real a .

To illustrate, let’s use a call option on a stock. Suppose in period t we purchase a call option on a certain stock expiring in the next period $T = t + 1$. The strike price, denoted by K , is \$50.

Then as the buyer of the call option, in $t + 1$ we are entitled to purchase the stock for \$50 no matter what the market price of the stock (S_{t+1}) might be. The value of the call option at time $t + 1$, which we denote by C_{t+1} , depends on the market price of the stock at $t + 1$ relative to the strike price (K). Specifically,

- If S_{t+1} is less than K , then the value of the option is zero, that is, $C_{t+1} = 0$
- If S_{t+1} is greater than K , then the value of the option is equal to $S_{t+1} - K$

Let (Ω, \mathbb{A}, P) be the probability space with the stock price in $t + 1$; that is, $S_{t+1} = s$ representing the uncountable real-valued outcomes. So, we have the uncountable probability space $(\Omega, \mathbb{A}, P) = (\mathbb{R}, \mathbb{B}, P)$. Assume that the price at $t + 1$ can take any nonnegative value. Assume further that the probability of exactly s is zero (i.e., $P(S_{t+1} = s) = 0$), that is, the distribution function of the price at $T = 1$ is continuous. Let the value of the call option in $T = t + 1$, C_{t+1} , be our random variable mapping from Ω to Ω' . Since the possible values of the call option at $t + 1$ are real numbers, the state space is uncountable as well. Hence, we have $(\Omega', \mathbb{A}') = (\mathbb{R}, \mathbb{B})$. C_{t+1} , to be a random variable, is a \mathbb{B} - \mathbb{B}' -measurable function.

Now, the probability of the call becoming worthless is determined by the event in the origin space that the stock price falls below K . Formally, that equals

$$\begin{aligned} P^{C_{t+1}}(0) &= P(C_{t+1} \leq 0) = P(S_{t+1} \leq K) \\ &= P((-\infty, K]) \end{aligned}$$

since the corresponding event in \mathbb{A} to a 0 value for the call option is $(-\infty, K]$. Equivalently, $C_{t+1}^{-1}(\{0\}) = (-\infty, K]$. Any positive value c of C_{t+1} is associated with zero probability since we have

$$P^{C_{t+1}}(c) = P(C_{t+1} = c) = P(S_{t+1} = c + K) = 0$$

due to the relationship $C_{t+1} = S_{t+1} - K$ for $S_{t+1} > K$.

KEY POINTS

- Events in a mathematical probabilistic sense represent sets of values. They are used to describe a certain situation such as an asset price being below some benchmark value.
- A probability measure is a function that assigns each event a unique probability between zero and one. With respect to this probability measure an event is P-almost sure if it is assigned probability one, while an unlikely event is one with zero probability.
- A random variable is a function assuming values from a given set of values at random. The probability of the random variables assuming certain values is determined by the probability measure.
- A distribution function is uniquely related to the probability measure. It assigns real numbers values between zero and one. At any real number, it represents the probability that a random variable assumes values of at most this number.
- Stochastic is the Greek term for random. It is often used in probability theory to describe that something is not deterministic, that is, known with certainty in advance.

NOTES

1. Suppose we have the interval $[1,2]$, that is all real numbers between 1 and 2. We cannot count all numbers inside of this interval since, for any two numbers such as, for example, 1 and 1.001, 1.0001, or even 1.000001, there are always infinitely many more numbers that lie between them.
2. Note that in a set, we do not consider an element more than once.
3. By *abscissa* we mean a value on the horizontal x -axis.
4. For example, let $\Omega = \{1,2,3\}$, then the power set $2^\Omega = \{\emptyset, \{1\}, \{2\}, \{3\}, \{1,2\}, \{1,3\}, \{2,3\}, \Omega\}$. That is, we have included all possible combinations of the original elements of Ω .

5. Let us assume, for now, that we are not restricted to a few digits due to measurement constraints or quotes conventions in the stock market. Instead, we consider being able to measure the returns to any degree of precision.
6. By convention, we never include ∞ since it is not a real number.
7. The symbol \mathbb{R} is just a mathematical abbreviation for the real numbers.
8. The empty set is interpreted as the *improbable event*.
9. We use the index in $F^{\text{S\&P } 500}$ to emphasize that this distribution function is unique to the probability of events related to the S\&P 500 log returns.
10. Note that we do not define the outcomes of number of dots as nominal or even rank

data anymore, but as numbers. That is 1 is 1, 2 is 2, and so on.

11. Theoretically, Ω' does not have to be countable; that is, it could contain more elements than X can assume values. But we restrict ourselves to countable state spaces Ω' consisting of exactly all the values of X .

Abstract: Discrete probability distributions are needed whenever the random variable is to describe a quantity that can assume values from a countable set, either finite or infinite. A discrete probability distribution (or law) is quite intuitive in that it assigns certain values positive probabilities adding up to one, while any other value automatically has zero probability. In general, neglecting some of the mathematical rigor, discrete distributions can be understood from the insight gained from descriptive statistics. For example, the random number of defaults in a bond portfolio inside of a given period of time can be modeled with a discrete probability distribution. Another example is given by sampling when we are interested in whether an observation belongs to a certain group. Also, simple stock price models are based on discrete laws where the stock price can only change to one of a finite number of possible values.

Discrete random variables are random variables on the countable space. We present the most important discrete random variables used in finance and their *probability distribution* (also called *probability law*): Bernoulli, binomial, hypergeometric, multinomial, Poisson, and discrete uniform.

Appendix A provides a summary of the discrete distributions covered.

DISCRETE LAW

In order to understand the distributions discussed in this entry, we will explain the general concept of a *discrete law*. Based on the knowledge of countable probability spaces, we introduce the random variable on the countable space as the discrete random variable. To fully comprehend the discrete random variable, it is necessary to become familiar with the

process of assigning probabilities to events in the countable case. Furthermore, the cumulative distribution function will be presented as an important representative of probability. It is essential to understand the mean and variance parameters. Wherever appropriate, we draw analogies to descriptive statistics for a facilitation of the learning process.

Random Variable on the Countable Space

Recall the probability space (Ω, \mathbb{A}, P) where Ω is a countable space. The probability of any event E is given by

$$P(E) = \sum_{\omega_i \in E} p_i$$

with the p_i being the probabilities of the individual outcomes ω_i in the event E . Remember that the random variable X is the mapping from Ω into Ω' such that the state space Ω' is countable. (We denote random variables by capital letters, such as X , whereas the outcomes are denoted by small letters, such as x_i .) Thus, the probability of any event E' in the state space has probability

$$P(X \in E') = P^X(E') = \sum_{\omega_i: X(\omega_i) \in E'} p_i$$

since E' is associated with the set

$$\{\omega_i : X(\omega_i) \in E'\}$$

through X . The probability of each individual outcome of X yields the discrete probability law of X . It is given by $P(X = x_i) = p_i^X$, for all $x_i \in \Omega'$.

Only for individual discrete values x is the probability p^X positive. This is similar to the empirical frequency distribution with positive relative frequency f_i at certain observed values. If we sort the $x_i \in \Omega$ in ascending order, analogous to the empirical relative cumulative frequency distribution

$$F_{emp}^f(x) = \sum_{x_i \leq x} f_i$$

we obtain the *discrete cumulative distribution (cdf)* of X ,

$$F^X(x) = P(X \leq x) = \sum_{x_i \leq x} p_i^X$$

That is, we express the probability that X assumes a value no greater than x .

Suppose we want to know the probability of obtaining at most 3 dots when throwing a dice. That is, we are interested in the *cdf* of the random variable number of dots, at the value $x = 3$. We obtain it by

$$F^X(3) = p_1 + p_2 + p_3 = 1/6 + 1/6 + 1/6 = 0.5$$

where the p_i denote the respective probabilities of the number of dots less than or equal to 3. A graph of the *cdf* is shown in Figure 1.

Mean and Variance

The sample mean and variance are sample dependent statistics. Here we present the mean and variance of the distribution as parameters where the probability space can be understood as the analog to the population.

To illustrate, we use the random variable number of dots obtained by tossing a dice. Since we treat the numbers as numeric values, we are able to perform transformations and computations with them. By throwing a dice several times, we would be able to compute a sample average based on the respective outcome. So, a question could be: What number is theoretically expected? In our discussion below, we see how to answer that question.

Mean

The mean is the population equivalent to the sample average of a quantitative variable. In order to compute the sample average, we sum up all observations and divide the resulting value by the number of observations, which we will denote by n . Alternatively, we sum over all values weighted by their relative frequencies.

This brings us to the mean of a random variable. For the mean of a random variable,

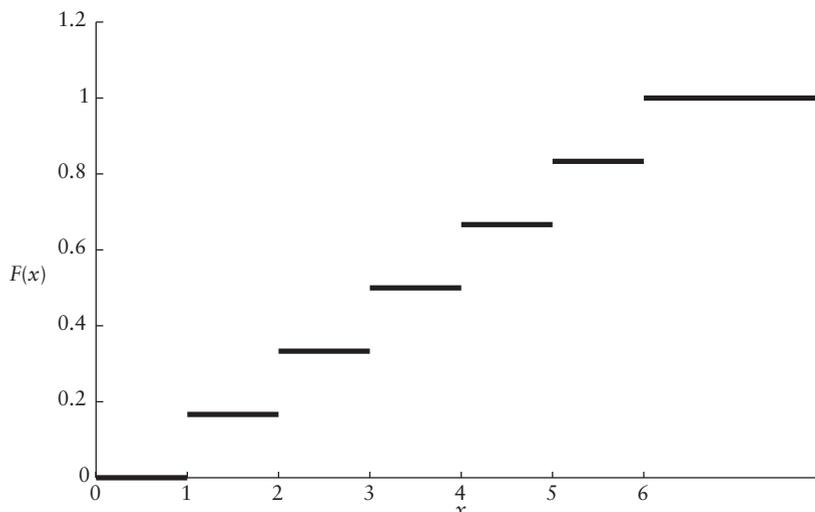

Figure 1 Cumulative Distribution Function of Number of Dots Appearing from Tossing a Dice

we compute the accumulation of the outcomes weighted by their respective probabilities; that is,

$$E(X) = \sum_{x_i \in \Omega} x_i \cdot p_i^X \quad (1)$$

given that equation (1) is finite. (Often, the mean is denoted as the parameter μ .) If the mean is not finite, then the mean is said to not exist. The mean equals the expected value of the random variable X . However, as we will see in the following examples, the mean does not actually have to be equal to one of the possible outcomes.

For the number of dots on the dice example, the expected value is

$$E(X) = \sum_{i=1}^6 i \cdot p_i \frac{1}{6} \sum_{i=1}^6 i = 21/6 = 3.5$$

So, on average, one can expect a value of 3.5 for the random variable, despite the fact this is not an obtainable number of dots. How can we interpret this? If we were to repeat the dice tossing many times, record for each toss the number of dots observed, then, if we averaged over all numbers obtained, we would end up with an average very close if not identical to 3.5.

Let's move from the dice tossing example to look at a binomial stock price model. With the

stock price S at the end of period 1 being either $S_1 = \$18$ or $S_1 = \$22$, we have only these two outcomes with positive probability each. We denote the probability measure of the stock price at the end of period 1 by $P^S(\cdot)$. At the beginning of the period, we assume the stock price to be $S_0 = \$20$. Furthermore, suppose that up- and down-movements are equally likely; that is, $P^S(18) = 1/2$ and $P^S(22) = 1/2$. So we obtain

$$E(S) = 1/2 \cdot \$18 + 1/2 \cdot \$22 = \$20$$

This means on average, the stock price will remain unchanged even though \$20 is itself not an obtainable outcome.

We can think of it this way. Suppose we observed some stock over a very long period of time and the probabilities for up- and down-movements did not change. Furthermore suppose that each time the stock price was \$20 at the beginning of some period, we recorded the respective end-of-period price. Then, we would finally end up with an average of these end-of-period stock prices very close to if not equal to \$20.

Variance

Just like in the realm of descriptive statistics, we are interested in the dispersion or spread of the data. For this, we introduce the *variance* as

a measure. Our focus is on the variance as a parameter of the random variable's distribution.

A sample measure of spread gives us information on the average deviation of observations from their sample mean. With the help of the variance, we intend to determine the magnitude we have to theoretically expect of the squared deviation of the outcome from the mean. Again, we use squares to eliminate the effect from the signs of the deviations as well as to emphasize larger deviations compared to smaller ones, just as we have done with the sample variance.

For the computation of the expected value of the squared deviations, we weight the individual squared differences of the outcomes from the mean with the probability of the respective outcome. So, formally, we define the variance of some random variable X to be

$$\sigma_X^2 = \text{Var}(X) = \sum_{x_i \in \Omega} (x_i - E(X))^2 p_i^X \quad (2)$$

For example, for the number of dots obtained from tossing a dice, we obtain the variance

$$\begin{aligned} \sigma_X^2 &= \text{Var}(X) = \sum_{i=1}^6 (i - E(X))^2 p_i^X \\ &= \frac{1}{6} [(1 - 3.5)^2 + (2 - 3.5)^2 + \dots + (6 - 3.5)^2] \\ &= 2.9167 \end{aligned}$$

Thus, on average, we have to expect a squared deviation from the mean by roughly 2.9.

The *standard deviation* is simply the square root of the variance. Formally, the standard deviation is given by

$$\sigma_X = \sqrt{\text{Var}(X)}$$

The standard deviation appeals to intuition because it is a quantity that is of the same scale as the random variable X . In addition, it helps in assessing where the probability law assigns its probability mass. A rule of thumb is that at least 75% about the probability mass is assigned to a vicinity of the mean that extends two standard deviations in each direction from the mean. Furthermore, this rule states that in at least 89% of the times, a value will occur that lies in a vicinity of the mean of three standard deviations in each direction.

For the number of dots obtained from tossing a dice, since the variance is 2.9167, the standard deviation is

$$\sigma_X = \sqrt{2.9167} = 1.7078$$

In Figure 2, we display all possible outcomes 1 through 6 indicated by the \circ symbol, including the mean of $E(X) = 3.5$. We extend a vicinity about the mean of length $\sigma_X = 1.7078$, indicated by the "+" symbol, to graphically

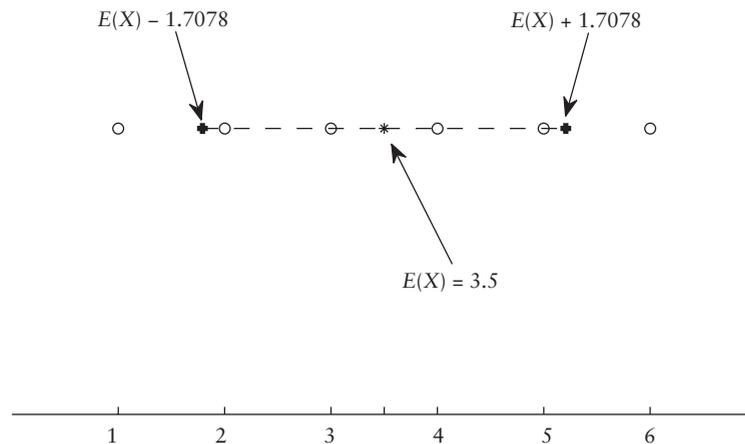

Figure 2 Relation Between Standard Deviation ($\sigma = 1.7078$) and Scale of Possible Outcomes $1, 2, \dots, 6$ Indicated by the \circ Symbol

relate the magnitude of the standard deviation to the possible values of X .

BERNOULLI DISTRIBUTION

In the remainder of this entry, we introduce the most common discrete distributions used in finance. We begin with the simplest one, the *Bernoulli distribution*.

Suppose we have a random variable X with two possible outcomes. That is, we have the state space $\Omega' = \{x_1, x_2\}$. The distribution of X is given by the probability for the two outcomes, that is,

$$p_1^X = p \text{ and } p_2^X = 1 - p$$

Now, to express the random experiment of drawing a value for X , all we need to know is the two possible values in the state space and parameter p representing the probability of x_1 . This situation is represented concisely by the Bernoulli distribution. This distribution is denoted $B(p)$ where p is the probability parameter.

Formally, the Bernoulli distribution is associated with random variables that assume the values $x_1 = 1$ and $x_2 = 0$, or $\Omega' = \{0, 1\}$. That is why this distribution is sometimes referred to as the “zero-one distribution.” One usually sets the parameter p equal to the probability of x_1 such that

$$p = P(X = x_1) = P(X = 1)$$

The mean of a Bernoulli distributed random variable is

$$E(X) = 0 \cdot (1 - p) + 1 \cdot p = p \quad (3)$$

and the variance is

$$\begin{aligned} \text{Var}(X) &= (0 - p)^2 \cdot (1 - p) + (1 - p)^2 \cdot p \\ &= p \cdot (1 - p) \end{aligned} \quad (4)$$

The Bernoulli random variable is commonly used when one models the random experiment where some quantity either satisfies a certain criterion or not. For example, it is employed when it is of interest whether an item is intact or broken. In such applications, we assign the

outcome “success” the numerical value 1 and the outcome “failure” the numerical value 0, for example. Then, we model the random variable X describing the state of the item as Bernoulli distributed.

Consider the outcomes when flipping a coin: head or tail. Now we set head equal to the numerical value 0 and tail equal to 1. We take X as the Bernoulli distributed random variable describing the side of the coin that is up after the toss. What should be considered a fair coin? It would be one where in 50% of the tosses, head should be realized and in the remaining 50% of the tosses, tail should be realized. So, a fair coin yields

$$p = 1 - p = 0.5$$

According to equation (3), the mean is then $E(X) = 0.5$ while, according to equation (4), the variance is $\text{Var}(X) = 0.25$. Here, again, the mean does not represent a possible value x from the state space Ω' . We can interpret it in the following way: Since 0.5 is halfway between one outcome (0) and the other outcome (1), the coin is fair because the mean is not inclined to either outcome.

As another example, we will take a look at credit risk modeling by considering the risk of default of a corporation. Default occurs when the corporation is no longer able to meet its debt obligations. a priori, default occurring during some period is uncertain and, hence, is treated as random. Here, we view the corporation’s failure within the next year as a Bernoulli random variable X . When the corporation defaults, $X = 0$ and in the case of survival, $X = 1$. For example, a corporation may default within the next year with probability

$$P(X = 0) = 1 - p = 1 - e^{-0.04} = 0.0392$$

and survive with probability

$$P(X = 1) = p = e^{-0.04} = 0.9608$$

We can, of course, extend the prerequisites of the Bernoulli distribution to a more general case; that is, we may choose values for the two

outcomes, x_1 and x_2 , of the random variable X different from 0 and 1. Then, we set the parameter p equal to either one of the probabilities $P(X = x_1)$ or $P(X = x_2)$. The distribution yields mean

$$E(X) = x_1 \cdot p + x_2 \cdot (1 - p)$$

and variance

$$\text{Var}(X) = (x_1 - E(X))^2 \cdot p + (x_2 - E(X))^2 \cdot (1 - p)$$

where we set $p = P(X = x_1)$.

We illustrate this generalization of the Bernoulli distribution in the case of the binomial stock price model. Again, we denote the random stock price at time period 1 by S_1 . Recall that the state space $\Omega' = \{\$18, \$22\}$ containing the two possible values for S_1 . The probability of S_1 assuming value \$18 can be set to

$$P(S_1 = \$18) = p$$

so that

$$P(S_1 = \$22) = 1 - p$$

Hence, we have an analogous situation to a Bernoulli random experiment; however, with $\Omega' = \{\$18, \$22\}$ instead of $\Omega' = \{0, 1\}$.

Suppose that

$$P(S_1 = \$18) = p = 0.4 \text{ and}$$

$$P(S_1 = \$22) = 1 - p = 0.6$$

Then, the mean is

$$E(S_1) = 0.4 \cdot \$18 + 0.6 \cdot \$22 = \$20.4$$

and the variance

$$\begin{aligned} \text{Var}(S_1) &= (\$18 - \$20.4)^2 \cdot 0.4 \\ &\quad + (\$22 - \$20.4)^2 \cdot 0.6 = (\$3.84)^2 \end{aligned}$$

BINOMIAL DISTRIBUTION

Suppose that we are no longer interested in whether merely one single item satisfies a particular requirement such as success or failure. Instead, we want to know the number of items satisfying this requirement in a sample of n items. That is, we form the sum over all items

in the sample by adding 1 for each item that is success and 0 otherwise. For example, it could be the number of corporations that satisfy their debt obligation in the current year from a sample of 30 bond issues held in a portfolio. In this case, a corporation would be assigned 1 if it satisfied its debt obligation and 0 if it did not. We would then sum up over all 30 bond issues in the portfolio.

Now, one might realize that this is the linking of n single Bernoulli trials. In other words, we perform a random experiment with n "independent" and identically distributed Bernoulli random variables, which we denote by $B(p)$. Note that we introduced two important assumptions: independent random variables and identically distributed random variables. Independent random variables or independence is an important statistical concept that requires a formal definition. We will not provide one here. Instead, we will simply relate independence to an intuitive interpretation such as uninfluenced by another factor or factors. So in the Bernoulli trials, we assume independence, which means that the outcome of a certain item does not influence the outcome of any others. By identical distribution we mean that the two random variables' distributions are the same. In our context, it implies that for each item, we have the same $B(p)$ distribution.

This experiment is as if one draws an item from a bin and replaces it into the bin before drawing the next item. Thus, this experiment is sometimes referred to as *drawing with replacement*. All we need to know is the number of trials, n , and the parameter p related to each single drawing. The resulting sum of the Bernoulli random variables is distributed as a *binomial distribution* with parameters n and p and denoted by $B(n, p)$.

Let X be distributed $B(n, p)$. Then, the random variable X assumes values in the state space $\Omega' = \{0, 1, 2, \dots, n\}$. In words, the total X is equal to the number of items satisfying the particular requirement (i.e., having a value of 1). X has some integer value i of at least 0 and at most n .

To determine the probability of X being equal to i , we first need to answer the following question: How many different samples of size n can yield a total of i hits (i.e., realizations of the outcome i)? The notation to represent realizing i hits out of a sample of size n is

$$\binom{n}{i} \tag{5}$$

The expression in equation (5) is called the *binomial coefficient* and is explained in Appendix B of this entry.

Since in each sample the n individual $B(p)$ distributed items are drawn independently, the probability of the sum over these n items is the product of the probabilities of the outcomes of the individual items. We illustrate this in the next example.

Suppose we flip a fair coin 10 times (i.e., $n = 10$) and denote by Y_i the result of the i -th trial. We denote by $Y_i = 1$ that the i -th trial produced head and by $Y_i = 0$ that it produced tail. Assume we obtain the following result

Y_1	Y_2	Y_3	Y_4	Y_5	Y_6	Y_7	Y_8	Y_9	Y_{10}
1	1	0	0	0	1	0	1	1	0

So, we observe $X = 5$ times head. For this particular result that yields $X = 5$, the probability is

$$\begin{aligned} P(Y_1 = 1, Y_2 = 1, \dots, Y_{10} = 0) &= P(Y_1 = 1) \cdot P(Y_2 = 1) \cdot \dots \cdot P(Y_{10} = 0) \\ &= p \cdot p \cdot \dots \cdot (1 - p) \\ &= p^5 \cdot (1 - p)^5 \end{aligned}$$

Since we are dealing with a fair coin (i.e., $p = 0.5$), the above probability is

$$\begin{aligned} P(Y_1 = 1, Y_2 = 1, \dots, Y_{10} = 0) &= 0.5^5 \cdot 0.5^5 \\ &= 0.5^{10} \approx 0.0010 \end{aligned}$$

With

$$\binom{10}{5} = 252$$

different samples leading to $X = 5$, we compute the probability for this value of the total as

$$\begin{aligned} P(X = 5) &= \binom{10}{5} p^5 \cdot (1 - p)^5 \\ &= 252 \cdot 0.5^{10} = 0.2461 \end{aligned}$$

So, in roughly one fourth of all samples of $n = 10$ independent coin tosses, we obtain a total of $X = 5$ 1s (or heads).

From the example, we see that the exponent for p is equal to the value of the total X (i.e., $i = 5$), and the exponent for $1 - p$ is equal to $n - i = 5$.

Let p be the parameter from the related Bernoulli distribution (i.e., $P(X = 1) = p$). The probability of the $B(n, p)$ random variable X being equal to some $i \in \Omega'$ is given by

$$P(X = i) = \binom{n}{i} \cdot p^i \cdot (1 - p)^{n-i}, i = 1, 2, \dots, n \tag{6}$$

For a particular selection of parameters, the probability distribution at certain values can be found in the four tables in Appendix A.

The mean of a $B(n, p)$ random variable is

$$E(X) = n \cdot p \tag{7}$$

and its variance is

$$Var(X) = n \cdot p \cdot (1 - p) \tag{8}$$

Below we will apply what we have just learned to be the binomial stock price model and two other applications.

Application to the Binomial Stock Price Model

Let's extend the binomial stock price model in the sense that we link T successive periods during which the stock price evolves. (The entire time span of length T is subdivided into the adjacent period segments $(0,1], (1,2], \dots, (T - 1, T].$) In each period $(t, t + 1]$, the price either increases or decreases by, say, 10%. The 10% can be intuitively thought of as the variability of the stock price S . Thus, the

corresponding factor by which the price will change from the previous period is 0.9 (down movement) and 1.1 (up movement). Based on this assumption about the price movement for the stock each period, at the end of the period $(t, t + 1]$, the stock price is

$$S_{t+1} = S_t \cdot Y_{t+1}$$

where the random variable Y_{t+1} assumes a value from $\{0.9, 1.1\}$, with 0.9 representing a price decrease of 10% and 1.1 a price increase of 10%. Consequently, in the case of $Y_{t+1} = 1.1$, we have

$$S_{t+1} = S_t \cdot 1.1$$

while, in case of $Y_{t+1} = 0.9$, we have

$$S_{t+1} = S_t \cdot 0.9$$

For purposes of this illustration, let's assume the following probabilities for the down movement and up movement, respectively,

$$P(Y_{t+1} = 1.1) = p = 0.6$$

and

$$P(Y_{t+1} = 0.9) = 1 - p = 0.4$$

After T periods, we have a random total of X up movements; that is, for all periods $(0,1]$, $(1,2]$, \dots , and $(T - 1, T]$, we increment X by 1 if the period related factor $Y_{t+1} = 1.1$, $t = 0, 1, \dots, T - 1$. So, the result is some $x \in \{1, 2, \dots, T\}$. The total number of up movements, X , is a binomial distributed $B(T, p)$ random variable on the probability space $(\Omega', \mathbb{A}', P^X)$ where

1. The state space is $\Omega' = \{1, 2, \dots, T\}$.
2. σ -algebra \mathbb{A}' is given by the power set $2^{\Omega'}$ of Ω' .
3. P^X is denoted by the binomial probability distribution given by

$$P(X = k) = \binom{T}{k} p^k (1 - p)^{T-k}, k = 1, 2, \dots, T$$

with $p = 0.6$.

Consequently, according to equations (7) and (8), we have

$$E(X) = 2 \cdot 0.6 = 1.2$$

and

$$\text{Var}(X) = 2 \cdot 0.6 \cdot 0.4 = 0.48$$

By definition of S_T and X , we know that the evolution of the stock price is such that

$$S_T = S_0 \cdot 1.1^X \cdot 0.9^{T-X}$$

Let us next consider a random variable that is not binomial itself, but related to a binomial random variable. Now, instead of considering the $B(T, p)$ distributed total X , we could introduce, as a random variable, the stock price at T (i.e., S_T). Using an illustration, we will derive the stock price independently of X and, then, emphasize the relationship between S_T and X . Note that S_T is not a binomial random variable.

Let us set $T = 2$. We may start with an initial stock price of $S_0 = \$20$. At the end of the first period, that is, $(0,1]$, we have

$$S_1 = S_0 \cdot Y_1$$

either equal to

$$S_1 = \$20 \cdot 1.1 = \$22$$

or

$$S_1 = \$20 \cdot 0.9 = \$18$$

At the end of the second period, that is, $(1,2]$, we have

$$S_2 = S_1 \cdot Y_2 = \$22 \cdot 1.1 = \$24.20$$

or

$$S_2 = S_1 \cdot Y_2 = \$22 \cdot 0.9 = \$19.80$$

in the case where $S_1 = \$22$, and

$$S_2 = S_1 \cdot Y_2 = \$18 \cdot 1.1 = \$19.80$$

or

$$S_2 = S_1 \cdot Y_2 = \$18 \cdot 0.9 = \$16.20$$

in the case where $S_1 = \$18$.

That is, at time $t + 1 = T = 2$, we have three possible values for S_2 , namely, \$24.20, \$19.80,

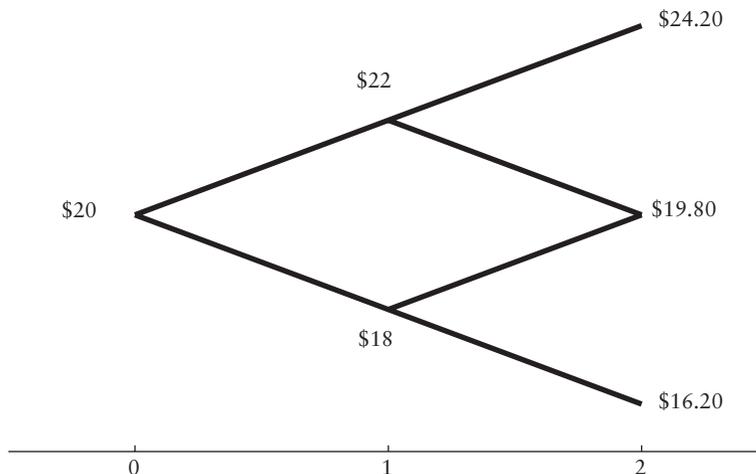

Figure 3 Binomial Stock Price Model with Two Periods

Note: Starting price $S_0 = \$20$. Upward factor $u = 1.1$, downward $d = 0.9$.

and \$16.20. Hence, we have a new state space that we will denote by $\Omega'_S = \{\$16.2, \$19.8, \$24.2\}$. Note that $S_2 = \$19.80$ can be achieved in two different ways: (1) $S_1 = S_0 \cdot 1.1 \cdot 0.9$ and (2) $S_1 = S_0 \cdot 0.9 \cdot 1.1$. The evolution of this pricing process, between time 0 and $T = 2$, can be demonstrated using the *binomial tree* given in Figure 3.

As σ -algebra, we use $\mathbb{A} = 2^{\Omega'_S}$, which is the power set of the state space Ω'_S . It includes events such as, for example, “stock price in $T = 2$ no greater than \$19.80,” defined as $E' = \{S_2 \leq \$19.80\}$.

The probability distribution of S_2 is given by the following

$$\begin{aligned} P(S_2 = \$24.20) &= P(Y_1 = 1.1) \cdot P(Y_2 = 1.1) \\ &= \binom{2}{2} p^2 = 0.6^2 = 0.36 \end{aligned}$$

$$\begin{aligned} P(S_2 = \$19.80) &= P(Y_1 = 0.9) \cdot P(Y_2 = 1.1) \\ &\quad + P(Y_1 = 1.1) \cdot P(Y_2 = 0.9) \\ &= 2(1 - p)p = \binom{2}{1} \cdot 0.4 \cdot 0.6 \\ &= 0.48 \end{aligned}$$

$$\begin{aligned} P(S_2 = \$16.20) &= P(Y_1 = 0.9) \cdot P(Y_2 = 0.9) \\ &= \binom{2}{0} (1 - p)^2 = 0.4^2 = 0.16 \end{aligned}$$

We now have the complete probability space of the random variable S_2 . One can see the connection between S_2 and X by the congruency of the probabilities of the individual outcomes, that is,

$$\begin{aligned} P(S_2 = \$24.20) &= P(X = 2) \\ P(S_2 = \$19.80) &= P(X = 1) \\ P(S_2 = \$16.20) &= P(X = 0) \end{aligned}$$

From this, we derive, again, the relationship

$$S_2 = S_0 \cdot 1.1^X \cdot 0.9^{2-X}$$

Thus, even though S_2 , or, generally S_T , is not distributed binomial itself, its probability distribution can be derived from the related binomial random variable X .¹

Application to the Binomial Interest Rate Model

We next consider a binomial interest rate model of short rates, that is, one-period interest rates. Starting in $t = 0$, the short rate evolves over the subsequent two periods as depicted in Figure 4. In $t = 0$, we have $r_0 = 4\%$, which is the short rate for period 1. For the following period, period 2, the short rate is r_1 while finally, r_2 is valid for

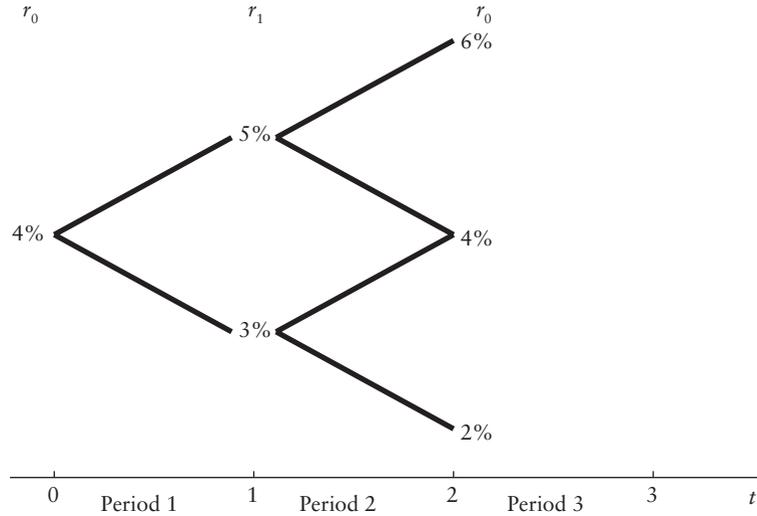

Figure 4 Binomial Interest Rate Model

period 3, from $t = 2$ through $t = 3$. Both r_1 and r_2 are unknown in advance and assume values at random.

As we see, in each of the successive periods, the short rate either increases or decreases by 1% (i.e., 100 basis points). Each movement is assumed to occur with a probability of 50%. So, in period i , $i = 1, 2$, the change in interest rate, Δr_i , has $P(\Delta r_i = 1\%) = p = 0.5$ for an up-movement and $P(\Delta r_i = -1\%) = 1 - p = 0.5$ for a down-movement. For each period, we may model the interest rate change by some Bernoulli random variable where X_1 denotes the random change in period 1 and X_2 that of period 2. The $X_i = 1$ in case of an up-movement and $X_i = 0$ otherwise. The sum of both (i.e., $Y = X_1 + X_2$) is a binomially distributed random variable, precisely $Y \sim B(2, 0.5)$, thus, assuming values 0, 1, or 2.

To be able to interpret the outcome of Y in terms of interest rate changes, we perform the following transformations. A value of $X_i = 1$ yields $\Delta r_i = 1\%$ while $X_i = 0$ translates into $\Delta r_i = -1\%$. Hence, the relationship between Y and r_2 is such that when $Y = 0$, implying two down-movements in a row, $r_2 = r_0 - 2\% = 2\%$. When $Y = 1$, implying one up- and down-movement each, $r_2 = r_0 + 1\% - 1\% = 4\%$. And finally, $Y = 2$ corresponds to two up-movements such

that $r_2 = r_0 + 2\% = 6\%$. So, we obtain the probability distribution:

r_2	$P(r_2)$
2%	$\binom{2}{0} 0.5^0 \cdot 0.5^2 = 0.25$
4%	$\binom{2}{1} 0.5^1 \cdot 0.5^1 = 0.5$
6%	$\binom{2}{2} 0.5^2 \cdot 0.5^0 = 0.25$

HYPERGEOMETRIC DISTRIBUTION

Recall that the prerequisites to obtain a binomial $B(n, p)$ random variable X is that we have n identically distributed random variables Y_i , all following the same Bernoulli law $B(p)$ of which the sum is the binomial random variable X . We referred to this type of random experiment as “drawing with replacement” so that for the sequence of individual drawings Y_i , we always have the same conditions.

Suppose instead that we do not “replace.” Let’s consider the distribution of “drawing without replacement.” This is best illustrated with an urn containing N balls, K of which are

black and $N - K$ are white. So, for the initial drawing, we have the chance of drawing a black ball equal to K/N , while we have the chance of drawing a white ball equal to $(N - K)/N$. Suppose the first drawing yields a black ball. Since we do not replace it, the condition before the second drawing is such that we have $(K - 1)$ black balls and still $(N - K)$ white balls. Since the number of black balls has been reduced by one and the number of white balls is unchanged, the chance of drawing a black ball has been reduced compared to the chance of drawing a white ball; the total is also reduced by one. Hence, the condition is different from the first drawing. It would be similar if instead we had drawn a white ball in the first drawing, however, with the adverse effect on the chance to draw a white ball in the second drawing.

Now suppose in the second drawing another black ball is selected. The chances are increasingly adverse against drawing another black ball in the third trial. This changing environment would be impossible in the binomial model of identical conditions in each trial.

Even if we had drawn first a black ball and then a white ball, the chances would not be the same as at the outset of the experiment before any balls were drawn because the total is now reduced to $N - 2$ balls. So, the chance of obtaining a black ball is now $(K - 1)/(N - 2)$, and that of obtaining a white ball is $(N - K - 1)/(N - 2)$. Mathematically, this is not the same as the original K/N and $(N - K)/N$. Hence, the conditions are altering from one drawing (or trial) to the next.

Suppose now that we are interested in the sum X of black balls drawn in a total of n trials. Let's look at this situation. We begin our reasoning with some illustration given specific values, that is,

$$\begin{aligned} N &= 10 \\ K &= 4 \\ n &= 5 \\ k &= 3 \end{aligned}$$

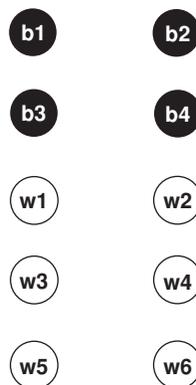

Figure 5 Drawing $n = 5$ Balls without Replacement
Note: $N = 10$, $K = 4$ (black), $n = 5$, and $k = 3$ (black).

The urn containing the black and white balls is depicted in Figure 5. Let's first compute the number of different outcomes we have to consider when we draw $n = 5$ out of $N = 10$ balls regardless of any color. We have 10 different options to draw the first ball; that is, $b1$ through $w6$ in Figure 5. After the first ball has been drawn without replacement, the second ball can be drawn from the urn consisting of the remaining nine balls. After that, the third ball is one out of the remaining eight, and so on until five balls have been successively removed. In total, we have

$$10 \times 9 \times 8 \times 7 \times 6 = 10!/5! = 30,240$$

alternative ways to withdraw the five balls. For example, we may draw $b4, b2, b1, w3$, and $w6$. However, this is the same as $w6, w3, b4, b2$, and $b1$ or any other combination of these five balls. Since we do not care about the exact order of the balls drawn, we have to account for that in that we divide the total number of possibilities (i.e., 30,240) by the number of possible combinations of the very same balls drawn. The latter is equal to

$$5 \times 4 \times 3 \times 2 \times 1 = 5! = 120$$

Thus, we have $30,240/120 = 252$ different nonredundant outcomes if we draw five out of

10 balls. Alternatively, this can be written as

$$252 = \frac{10!}{5! \times 5!} = \binom{10}{5} \quad (9)$$

Consequently, the chance of obtaining exactly this set of balls (i.e., $\{b1, b2, b4, w3, w6\}$) in any order is given by the inverse of equation (9) which is

$$\frac{1}{252} = \frac{1}{\binom{10}{5}} = 0.004 \quad (10)$$

Now recall that we are interested in the chance of obtaining a certain number k of black balls in our sample. So, we have to narrow down the number of possible outcomes given by equation (9) to all samples of size 5 that yield that number k which, here, is equal to 3. How do we do this?

We have a selection of four black balls (i.e., $b1, b2, b3$, and $b4$) to draw from. That gives us a total of $4 \times 3 \times 2 = 4! = 24$ different possibilities to recover $k = 3$ black balls out of the urn consisting of four balls. Again, we do not care about the exact order in which we draw the black balls. To us, it is the same whether we select them, for example, in the order $b1 - b2 - b4$ or $b2 - b4 - b1$, as long as we obtain the set $\{b1, b2, b4\}$. So, we correct for this by dividing the total of 24 by the number of combinations to order these particular black balls; that is,

$$3 \times 2 \times 1 = 3! = 6$$

Hence, the number of combinations of drawing $k = 3$ black balls out of four is

$$24/6 = 4!/3! = 4$$

Next we need to consider the previous number of possibilities of drawing $k = 3$ black balls in combination with drawing $n - k = 2$ white balls. We apply the same reasoning as before to obtain two white balls from the collection of six (i.e., $\{w1, w2, w3, w4, w5, w6\}$). That gives us $6 \times 5/2 = 6!/(2! \times 4!) = 15$ nonredundant options to recover two white balls, in our example.

In total, we have

$$\begin{aligned} 4 \times 15 &= \frac{4 \times 3 \times 2 \times 1}{3 \times 2 \times 1} \times \frac{6 \times 5 \times 4 \times 3 \times 2 \times 1}{2 \times 1 \times 4 \times 3 \times 2 \times 1} \\ &= \frac{4!}{3! \times 1!} \times \frac{6!}{2! \times 4!} = \binom{4}{3} \times \binom{6}{2} = 60 \end{aligned}$$

different possibilities to obtain three black and two white balls in a sample of five balls. All these 60 samples have the same implication for us (i.e., $k = 3$). Combining these 60 possibilities with a probability of 0.004 as given by equation (10), we obtain as the probability for a sum of $k = 3$ black balls in a sample of $n = 5$

$$60/252 = 0.2381$$

Formally, we have

$$P(X = 3) = \frac{\binom{4}{3} \binom{6}{2}}{\binom{10}{5}} = 0.2381$$

Then, for our example, the probability distribution of X is

$$P(X = k) = \frac{\binom{4}{k} \binom{6}{n-k}}{\binom{10}{5}}, k = 1, 2, 3, 4 \quad (11)$$

(Note that we cannot draw more than four black balls from $b1, b2, b3$, and $b4$.)

Let's advance from the special conditions of the example to the general case; that is, (1) at the beginning, some nonnegative integer N of black and white balls combined, (2) the overall number of black balls $0 \leq K \leq N$, (3) the sample size $0 \leq n \leq N$, and (4) the number $0 \leq k \leq n$ of black balls in the sample.

In equation (11), we have the probability of k black balls in the sample of $n = 5$ balls. We dissect equation (9) into three parts: the denominator and the two parts forming the product in the numerator. The denominator gives the number of possibilities to draw a sample of $n = 5$ balls out of $N = 10$ balls, no matter what the combination of black and white. In other words, we choose $n = 5$ out of $N = 10$. The

resulting number is given by the binomial coefficient. We can extend this to choosing a general sample of n drawings out of a population of an arbitrary number of N balls. Analogous to equation (9), the resulting number of possible samples of length n (i.e., n drawings) is then given by

$$\binom{N}{n} \quad (12)$$

Next, suppose we have k black balls in this sample. We have to consider that in equation (11), we chose k black balls from a population of $K = 4$ yielding as the number of possibilities for this the binomial coefficient on the left-hand side in the numerator. Now we generalize this by replacing $K = 4$ by some general number of black balls ($K \leq N$) in the population. The resulting number of choices for choosing k out of the overall K black balls is then,

$$\binom{K}{k} \quad (13)$$

And, finally, we have to draw the remaining $n - k$ balls, which have to be white, from the population of $N - K$ white balls. This gives us

$$\binom{N - K}{n - k} \quad (14)$$

different nonredundant choices for choosing $n - k$ white balls out of $N - K$.

Finally, all we need to do is to combine equations (12), (13), and (14) in the same fashion as equation (11). By doing so, we obtain

$$P(X = k) = \frac{\binom{K}{k} \binom{N - K}{n - k}}{\binom{N}{n}}, \quad k = 1, 2, \dots, n \quad (15)$$

as the probability to obtain a total of $X = k$ black balls in the sample of length n *without replacement*.

Importantly, here, we start out with N balls of which K are black and, after each trial, we do not replace the ball drawn, so that the population

is different for each trial. The resulting random variable is *hypergeometric* distributed with parameters (N, K, n) ; that is, $Hyp(N, K, n)$, and probability distribution given by equation (15).

The mean of a random variable X following a hypergeometric probability law is given by

$$E(X) = n \cdot \frac{K}{N}$$

and the variance of this $X \sim Hyp(N, K, n)$ is given by

$$Var(X) = \sigma^2 = n \cdot \frac{K}{N} \cdot \frac{N - K}{N} \cdot \frac{N - n}{N - 1}$$

The hypergeometric and the binomial distributions are similar, though not equivalent. However, if the population size N is large, the hypergeometric distribution is often approximated by the binomial distribution with equation (6) causing only little deviation from the true probabilities of equation (15).

Application

Let's see how the hypergeometric distribution has been applied in a Federal Reserve Bank of Cleveland study by Humpage (1998) to assess whether U.S. exchange-rate intervention resulted in a desired depreciation of the dollar.

Consider the following scenario. The U.S. dollar is appreciating against a certain foreign currency. This might hurt U.S. exports to the country whose sovereign issues the particular foreign currency. In response, the U.S. Federal Reserve might be inclined to intervene by purchasing that foreign currency to help depreciate the U.S. dollar through the increased demand for foreign currency relative to the dollar. This strategy, however, may not necessarily produce the desired effect. That is, the dollar might continue to appreciate relative to the foreign currency. Let's let an intervention by the Federal Reserve be defined as the purchase of that foreign currency. Suppose that we let the random variable X be number of interventions that lead to success (i.e., depreciation of the

dollar). Given certain conditions beyond the scope of this book, the random variable X is approximately distributed hypergeometric.

This can be understood by the following slightly simplified presentation. Let the number of total observations be N days of which K is the number of days with a dollar depreciation (with or without intervention), and $N - K$ is the number of days where the dollar appreciated or remained unchanged. The number of days the Federal Reserve intervenes is given by n . Furthermore, let k equal the number of days the interventions are successful so that $n - k$ accounts for the unsuccessful interventions. The Federal Reserve could technically intervene on all N days that would yield a total of K successes and $N - K$ failures. However, the actual number of occasions n on which there are interventions might be smaller. The n interventions can be treated as a sample of length n taken from the total of N days without replacement.

The model can best be understood as follows. The observed dollar appreciations, persistence, or depreciations are given observations. The Federal Reserve can merely decide to intervene or not. Consequently, if it took action on a day with depreciation, it would be considered a success and the number of successes available for future attempts would, therefore, be diminished by one. If, on the other hand, the Federal Reserve decided to intervene on a day with appreciation or persistence, it would incur a failure that would reduce the number of available failures left by one. The $N - n$ days there are no interventions are treated as not belonging to the sample.

The randomness is in the selection of the days on which to intervene. The entire process can be illustrated by a chain with N tags attached to it containing either a $+$ or $-$ symbol. Each tag represents one day. A $+$ corresponds to an appreciation or persistence of the dollar on the associated day, while a $-$ to a depreciation. We assume that we do not know the symbol behind each tag at this point.

In total, we have K tags with a $+$ and $N - K$ with a $-$ tag. At random, we flip n of these tags, which is equivalent to the Federal Reserve taking action on the respective days. Upon turning the respective tag upside right, the contained symbol reveals immediately whether the associated intervention resulted in a success or not.

Suppose we have $N = 3,072$ total observations of which $K = 1,546$ represents the number of days with a dollar depreciation, while on $N - K = 1,508$ days the dollar either became more valuable or remained steady relative to the foreign currency.

Again, let X be the hypergeometric random variable describing successful interventions. On $n = 138$ days, the Federal Reserve saw reason to intervene, that is, purchase foreign currency to help bring down the value of the dollar which was successful on $k = 51$ days and unsuccessful on the remaining $n - k = 87$ days. Concisely, the values are given by $N = 3,072$, $K = 1,546$, $N - K = 1,508$, $n = 138$, $k = 51$, and $n - k = 87$.

So, the probability for this particular outcome $k = 51$ for the number of successes X given $n = 138$ trials is

$$P(X = 51) = \frac{\binom{1546}{51} \binom{1508}{87}}{\binom{3072}{138}} = 0.00013429$$

which is an extremely small probability.

Suppose we state the simplifying hypothesis that the Federal Reserve is overall successful if most of the dollar depreciations have been the result of interventions (i.e., purchase of foreign currency). Then, this outcome with $k = 51$ successful interventions given a total of $N - K$ depreciations shows that the decline of the dollar relative to the foreign currency might be the result of something other than a Federal Reserve intervention. Hence, the Federal Reserve intervention might be too vague a forecast of a downward movement of the dollar relative to the foreign currency.

MULTINOMIAL DISTRIBUTION

For our next distribution, the *multinomial distribution*, we return to the realm of drawing with replacement so that for each trial, there are exactly the same conditions. That is, we are dealing with independent and identically distributed random variables. (Once again we note that we are still short of a formal definition of independence in the context of probability theory. We use the term in the sense of “uninfluenced by.”) However, unlike the binomial distribution, let’s change the population so that we have not only two different possible outcomes for one drawing, but a third or possibly more outcomes.

We extend the illustration where we used an urn containing black and white balls. In our extension, we have a total of N balls with three colors: K_w white balls, K_b black balls, and $K_r = N - K_w - K_b$ red balls. The probability of each of these colors is denoted by

$$\begin{aligned} P(Y = \text{white}) &= p_w \\ P(Y = \text{black}) &= p_b \\ P(Y = \text{red}) &= p_r \end{aligned}$$

with each of these probabilities representing the population share of the respective color: $p_i = K_i/N$, for $i = \text{white, black, and red}$. Since all shares combined have to account for all N , we set

$$p_r = 1 - p_b - p_w$$

For purposes of this illustration, let $p_w = p_b = 0.3$ and $p_r = 0.4$. Suppose that in a sample of $n = 10$ trials, we obtain the following result: $n_w = 3$ white, $n_b = 4$ black, and $n_r = n - n_w - n_b = 3$ red. Furthermore, suppose that the balls were drawn in the following order

Y_1	Y_2	Y_3	Y_4	Y_5	Y_6	Y_7	Y_8	Y_9	Y_{10}
r	w	b	b	w	r	r	b	w	b

where the random variable Y_i represents the outcome of the i -th trial. (We denote $w = \text{white}$,

$b = \text{black}$, and $r = \text{red}$.) This particular sample occurs with probability

$$\begin{aligned} P(Y_1 = r, Y_2 = w, \dots, Y_{10} = b) &= p_r \cdot p_w \cdot \dots \cdot p_b \\ &= p_r^3 \cdot p_w^3 \cdot p_b^4 \end{aligned}$$

The last equality indicates that the order of appearance of the individual values, once again, does not matter.

We introduce the random variable X representing the number of the individual colors occurring in the sample. That is, X consists of the three components $X_w, X_b,$ and X_r or, alternatively, $X = (X_w, X_b, X_r)$. Analogous to the binomial case of two colors, we are not interested in the order of appearance, but only in the respective numbers of occurrences of the different colors (i.e., $n_w, n_b,$ and n_r). Note that several different sample outcomes may lead to $X = (n_w, n_b, n_r)$. The total number of different nonredundant samples with $n_w, n_b,$ and n_r is given by the multinomial coefficient introduced in Appendix B, which here yields

$$\binom{n}{n_w \ n_b \ n_r} = \binom{10}{3 \ 3 \ 4} = 4,200$$

Hence, the probability for this value of $X = (k_w, k_b, k_r) = (3, 4, 3)$ is then

$$\begin{aligned} P(X = (3, 4, 3)) &= \binom{10}{3 \ 3 \ 4} \cdot p_w^3 \cdot p_b^4 \cdot p_r^3 \\ &= 4,200 \cdot 0.3^3 \cdot 0.3^4 \cdot 0.4^3 \\ &= 0.0588 \end{aligned}$$

In general, the probability distribution of a multinomial random variable X with k components X_1, X_2, \dots, X_k is given by

$$\begin{aligned} P(X_1 = n_1, X_2 = n_2, \dots, X_k = n_k) \\ = \binom{n}{n_1 \ n_2 \ \dots \ n_k} \cdot p_1^{n_1} \cdot p_2^{n_2} \cdot \dots \cdot p_k^{n_k} \end{aligned} \quad (16)$$

where, for $j = 1, 2, \dots, k$, n_j denotes the outcome of component j and the p_j the corresponding probability.

The means of the k components X_1 through X_k are given by

$$\begin{aligned} E(X_1) &= p_1 \cdot n \\ &\vdots \\ E(X_k) &= p_k \cdot n \end{aligned}$$

and their respective variances by

$$\begin{aligned} \text{Var}(X_1) &= \sigma_1^2 = p_1 \cdot (1 - p_1) \cdot n \\ &\vdots \\ \text{Var}(X_k) &= \sigma_k^2 = p_k \cdot (1 - p_k) \cdot n \end{aligned}$$

Multinomial Stock Price Model

We can use the multinomial distribution to extend the binomial stock price model described earlier. Suppose we are given a stock with price S_0 , in $t = 0$. In $t = 1$, the stock can have either price

$$\begin{aligned} S_1^{(u)} &= S_0 \cdot u \\ S_1^{(l)} &= S_0 \cdot l \\ S_1^{(d)} &= S_0 \cdot d \end{aligned}$$

Let the three possible outcomes be a 10% increase in price ($u = 1.1$), no change in price ($l = 1.0$), and a 10% decline in price ($d = 0.9$). That is, the price either goes up by some factor, remains steady, or drops by some factor. Therefore,

$$\begin{aligned} S_1^{(u)} &= S_0 \cdot 1.1 \\ S_1^{(l)} &= S_0 \cdot 1.0 \\ S_1^{(d)} &= S_0 \cdot 0.9 \end{aligned}$$

Thus, we have three different outcomes of the price change in the first period. Suppose the price change behaved the same in the second period, from $t = 1$ until $t = 2$. So, we have

$$\begin{aligned} S_2^{(u)} &= S_1 \cdot 1.1 \\ S_2^{(l)} &= S_1 \cdot 1.0 \\ S_2^{(d)} &= S_1 \cdot 0.9 \end{aligned}$$

at time $t = 2$ depending on

$$S_1 \in \left\{ S_1^{(u)}, S_1^{(l)}, S_1^{(d)} \right\}$$

Let's denote the random price change in the first period by Y_1 and the price change in the second period by the random variable Y_2 . So, it is obvious that Y_1 and Y_2 independently assume some value in the set $\{u, l, d\} = \{1.1, 1.0, 0.9\}$. After two periods (i.e., in $t = 2$), the stock price is

$$S_2 = S_0 \cdot Y_1 \cdot Y_2 \in \left\{ S_2^{(uu)}, S_2^{(ul)}, S_2^{(ld)} \right\}$$

Note that the random variable S_2 is not multinomially distributed itself. However, as we will see, it is immediately linked to a multinomial random variable.

Since the initial stock price S_0 is given, the random variable of interest is the product $Y_1 \cdot Y_2$, which is in a one-to-one relationship with the multinomial random variable $X = (n_u, n_l, n_d)$ (i.e., the number of up-, zero-, and down-movements, respectively). The state space of $Y_1 \cdot Y_2$ is given by $\{uu, ul, ud, ll, ld, dd\}$. This corresponds to the state space of X , which is given by

$$\Omega' = \{(2, 0, 0), (0, 2, 0), (0, 0, 2), (1, 1, 0), (1, 0, 1), (0, 1, 1)\}$$

Note that since $Y_1 \cdot Y_2$ is a product, we do not consider, for example, ($Y_1 = u, Y_2 = d$) and ($Y_1 = d, Y_2 = u$) separately. With

$$\begin{aligned} P(Y_i = u) &= p^u = 0.25 \\ P(Y_i = l) &= p^l = 0.50 \\ P(Y_i = d) &= p^d = 0.25 \end{aligned}$$

the corresponding probability distribution of X is given in the first two columns of Table 1. We use the multinomial coefficient

$$\binom{n}{n_u \quad n_l \quad n_d}$$

where

$$\begin{aligned} n &= \text{the number of periods} \\ n_u &= \text{the number of up-movements} \\ n_l &= \text{number of zero movements} \\ n_d &= \text{number of down-movements} \end{aligned}$$

Now, if $S_0 = \$20$, then we obtain the probability distribution of the stock price in $t = 2$ as shown in columns 2 and 3 in Table 1. Note that

Table 1 Probability Distribution of the Two-Period Stock Price Model

$X = (n_u, n_l, n_d)$	$P(X = \cdot)$	$S_2 = \cdot$
(2,0,0)	$\binom{2}{2 \ 0 \ 0} p^u p^u = 0.0625$	$S_0 \cdot u^2 = 20 \cdot 1.1^2 = 24.2$
(1,1,0)	$\binom{2}{1 \ 1 \ 0} p^u p^l = 2 \cdot 0.25 \cdot 0.5 = 0.25$	$S_0 \cdot u \cdot l = 20 \cdot 1.1 \cdot 1.0 = 22$
(1,0,1)	$\binom{2}{1 \ 0 \ 1} p^u p^d = 2 \cdot 0.25^2 = 0.125$	$S_0 \cdot u \cdot d = 20 \cdot 1.1 \cdot 0.9 = 19.8$
(0,2,0)	$\binom{2}{0 \ 2 \ 0} p^l p^l = 0.5^2 = 0.25$	$S_0 \cdot l \cdot l = 20 \cdot 1.0^2 = 20$
(0,1,1)	$\binom{2}{0 \ 1 \ 1} p^l p^d = 2 \cdot 0.5 \cdot 0.25 = 0.25$	$S_0 \cdot l \cdot d = 20 \cdot 1.0 \cdot 0.9 = 18$
(0,0,2)	$\binom{2}{0 \ 0 \ 2} p^d p^d = 0.25^2 = 0.0625$	$S_0 \cdot d^2 = 20 \cdot 0.9^2 = 16.2$

In the first and second columns, we have the probability distribution of the two period stock price changes $X = Y_1 \cdot Y_2$ in the multinomial stock price model. In the third column, we have the probability distribution of the stock price S_2 .

the probabilities of the values of S_2 are associated with the corresponding price changes X and, hence, listed on the same lines of Table 1. It is now possible to evaluate the probability of events such as, "a stock price S_2 of, at most, \$22," from the σ -algebra \mathbb{A}' of the multinomial probability space of X . This is given by

$$\begin{aligned}
 P(S_2 \leq \$22) &= P(S_2 = \$16.2) + P(S_2 = \$18) + P(S_2 = \$19.8) \\
 &\quad + P(S_2 = \$20) + P(S_2 = \$22)
 \end{aligned}$$

$$\begin{aligned}
 &= 0.25 + 0.125 + 0.25 + 0.25 + 0.0625 \\
 &= 1 - P(S_2 = \$24.2) \\
 &= 0.9375
 \end{aligned}$$

where the second line is the result of the fact that the sum of the probabilities of all disjoint events has to add up to one. That follows since any event and its complement account for the entire state space Ω' .

In Figure 6, we can see the evolution of the stock price along the different paths.

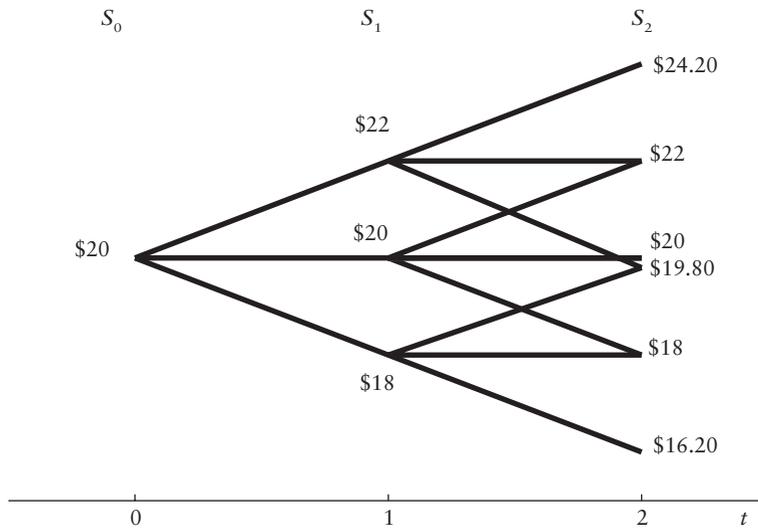

Figure 6 Multinomial Stock Price Model: Stock Price S_2 , in $t = 2$

From equation (1), the expected stock price in $t = 2$ is computed as

$$\begin{aligned} E(S_2) &= \sum_{s \in \Omega'} s \cdot P(S_2 = s) \\ &= \$16.2 \cdot 0.0625 + \$18 \cdot 0.25 + \$19.8 \cdot 0.125 \\ &\quad + \$20 \cdot 0.25 + \$22 \cdot 0.25 + \$24.2 \cdot 0.0625 \\ &= \$20 \end{aligned}$$

So, on average, the stock price will remain unchanged.

POISSON DISTRIBUTION

To introduce our next distribution, consider the following situation. A property and casualty insurer underwrites a particular type of risk, say, automotive damage. Overall, the insurer is interested in the total annual dollar amount of the claims from all policies underwritten. The total is the sum of the individual claims of different amounts. The insurer has to have enough equity as risk guarantee. In a simplified way, the sufficient amount is given by the number of casualties N times the average amount per claim.

In this situation, the insurer's interest is in the total number of claims N within one year. Note that there may be multiple claims per policy. This number N is random because the insurer does not know its exact value at the beginning of the year. The insurer knows, however, that the minimum number of casualties possible is zero. Theoretically, although it is unlikely, there may be infinitely many claims originating from the year of interest.

So far, we have considered the number of claims over the period of one year. It could be of interest to the insurer, however, to know the behavior of the random variable N over a period of different length, say five years, or even the number of casualties related to one month could be of interest. It might be reasonable to assume that there will probably be fewer claims in one month than in one year or five years.

The number of claims, N , as a random variable should follow a probability law that accounts for the length of the period under analysis. In other words, the insurers want to assure that the probability distribution of N gives credit to N being proportional to the length of the period in the sense that if a period is n times as long as another, then the number of claims expected over the longer period should be n times as large, as well.

As a candidate that satisfies these requirements, we introduce the *Poisson distribution* with parameter λ formally expressed as $Poi(\lambda)$. We define that the parameter is a positive real number (i.e., $\lambda > 0$). A Poisson random variable N —that is, $X \sim Poi(\lambda)$ —assumes nonnegative integer values. Formally, N is a function mapping the space of outcomes, Ω , into the state space

$$\Omega' = \{0, 1, 2, \dots\}$$

which is the set \mathbb{N} of the nonnegative integer numbers.

The probability measure of a Poisson random variable N for nonnegative integers $k = 0, 1, 2, \dots$ is defined as

$$P(N = k) = \frac{\lambda^k}{k!} e^{-\lambda} \quad (17)$$

where $e = 2.7183$ is the Euler constant. Here, we have unit period length.

The mean of a Poisson random variable with parameter λ is

$$E(N) = \lambda$$

while its variance is given by

$$Var(N) = \sigma^2 = \lambda \quad (18)$$

So, both parameters, mean and variance, of $N \sim Poi(\lambda)$ are given by the parameter λ .

For a period of general length t , equation (17) becomes

$$P(N = k) = \frac{(\lambda t)^k}{k!} e^{-\lambda t} \quad (19)$$

We can see that the new parameter is now λ_t , accounting for the time proportionality of the distribution of N , that is, $N = N(t)$ is the number of jumps of size 1 in the interval $(0, t)$. The mean changes to

$$EN(t) = \lambda t \quad (20)$$

and analogous to the variance given by (18) is now

$$\text{Var}(N(t)) = \sigma^2(t) = \lambda t \quad (21)$$

We can see by equation (20) that the average number of occurrences is the average per unit of time, λ , times the length of the period, t , in units of time. The same holds for the variance given by equation (21).

The Poisson distribution serves as an approximation of the hypergeometric distribution when certain conditions are met regarding sample size and parameter p .

Application to Credit Risk Modeling for a Bond Portfolio

The Poisson distribution is typically used in finance for credit risk modeling. For example, suppose we have a pool of 100 bonds issued by different corporations. By experience or empirical evidence, we may know that each quarter of a year the expected number to default is two; that is, $\lambda = 2$. Moreover, from prior research, we can approximate the distribution of N by the Poisson distribution, even though, theoretically, the Poisson distribution admits values k greater than 100. What is the number of bonds to default within the next year, on average? According to equation (3), since the mean is $E_{quarter}(N) = \lambda = 2$ per quarter, the mean per year ($t = 4$) is

$$E_{year}(N) = \lambda t = 2 \cdot 4 = 8$$

By equation (20), the variance is 8, from equation (19), the probability of, at most, 10 bonds

to default is given by

$$\begin{aligned} P(N \leq 10) &= P(N = 0) + P(N = 1) + \dots \\ &\quad + P(N = 10) \\ &= e^{-2 \times 4} \cdot \frac{(2 \times 4)^0}{0!} + e^{-2 \times 4} \cdot \frac{(2 \times 4)^1}{1!} + \dots \\ &\quad + e^{-2 \times 4} \cdot \frac{(2 \times 4)^{10}}{10!} \\ &= 0.8159 \end{aligned}$$

DISCRETE UNIFORM DISTRIBUTION

Consider a probability space $(\Omega', \mathbb{A}', P)$ where the state space is a finite set of, say n , outcomes, that is, $\Omega' = \{x_1, x_2, \dots, x_n\}$. The σ -algebra \mathbb{A}' is given by the power set of Ω' .

So far we have explained how drawings from this Ω' may be modeled by the multinomial distribution. In the multinomial distribution, the probability of each outcome may be different. However, suppose that for our random variable X , we have a constant $P(X = x_j) = 1/n$, for all $j = 1, 2, \dots, n$. Since all values x_j have the same probability (i.e., they are equally likely), the distribution is called the *discrete uniform distribution*. We denote this distribution by $X \sim DU_{\Omega'}$. We use the specification Ω' to indicate that X is a random variable on this particular state space.

The mean of a discrete, uniformly distributed random variable X on the state space $\Omega' = \{x_1, x_2, \dots, x_n\}$ is given by

$$E(X) = \sum_{i=1}^n p_i \cdot x_i = \frac{1}{n} \sum_{i=1}^n x_i \quad (22)$$

Note that equation (22) is equal to the arithmetic mean. The variance is

$$\begin{aligned} \text{Var}(X) &= \sum_{i: x_i \in \Omega'} p_i \cdot (x_i - E(X))^2 \\ &= \frac{1}{n} \sum_{i: x_i \in \Omega'} (x_i - E(X))^2 \end{aligned}$$

with $E(X)$ from equation (22).

A special case of a discrete uniform probability space is given when $\Omega' = \{1, 2, \dots, n\}$. The resulting mean, according to equation (22), is then,

$$\begin{aligned} E(X) &= \sum_{i=1}^n p_i \cdot x_i = \frac{1}{n} \sum_{i=1}^n i \\ &= \frac{1}{n} \times \frac{n(n+1)}{2} = \frac{n+1}{2} \end{aligned} \quad (23)$$

For this special case of discrete uniform distribution of a random variable X , we use the notation $X \sim DU(n)$ with parameter n .

Let's once more consider the outcome of a toss of a dice. The random variable number of dots, X , assumes one of the numerical outcomes 1, 2, 3, 4, 5, 6 each with a probability of $1/6$. Hence, we have a uniformly distributed discrete random variable X with the state space $\Omega' = \{1, 2, 3, 4, 5, 6\}$. Consequently, we express this as $X \sim DU(6)$.

Next, we want to consider several independent trials, say $n = 10$, of throwing the dice. By n_1, n_2, n_3, n_4, n_5 , and n_6 , we denote the number of occurrence of the values 1, 2, 3, 4, 5, and 6, respectively. With constant probability $p_1 = p_2 = \dots = p_6 = 1/6$, we have a discrete uniform distribution, that is, $X \sim DU(6)$. Thus, the probability of obtaining $n_1 = 1, n_2 = 2, n_3 = 1, n_4 = 3, n_5 = 1$, and $n_6 = 2$, for example, is

$$\begin{aligned} P(X_1 = 1, X_2 = 1, \dots, X_6 = 2) &= \binom{10}{1 \ 2 \dots 2} \left(\frac{1}{6}\right)^{10} \\ &= \frac{10!}{1! \times 2! \times \dots \times 2!} \cdot \left(\frac{1}{6}\right)^{10} \\ &= 151200 \cdot 0.00000016538 \\ &= 0.0025 \end{aligned}$$

Application to the Multinomial Stock Price Model

Let us resume the stock price model where in $t = 0$ we have a given stock price, say $S_0 = \$20$, where there are three possible outcomes at the end of the period. In the first period, the stock

price either increases to

$$S_1^{(u)} = S_0 \cdot 1.1 = \$22$$

remains the same at

$$S_1^{(l)} = S_0 \cdot 1.0 = \$20$$

or decreases to

$$S_1^{(d)} = S_0 \cdot 0.9 = \$18$$

each with probability $1/3$. Again, we introduce the random variable Y assuming the values $u = 1.1, l = 1.0$, and $d = 0.9$ and, thus, representing the percentage change of the stock price between $t = 0$ and $t + 1 = 1$. The stock price in $t + 1 = 1$ is given by the random variable S_1 on the corresponding state space

$$\Omega_S = \{S_1^{(u)}, S_1^{(l)}, S_1^{(d)}\}$$

Suppose we have $n = 10$ successive periods in each of which the stock price changes by the factors u, l , or d . Let the multinomial random variable $X = (X_1, X_2, X_3)$ represent the total of up-, zero-, and down-movements, respectively. Suppose, after these n periods, we have $n_u = 3$ up-movements, $n_l = 3$ zero-movements, and $n_d = 4$ down-movements. According to equation (16), the corresponding probability is

$$\begin{aligned} P(X_1 = 3, X_2 = 3, X_3 = 4) &= \binom{10}{3 \ 3 \ 4} \left(\frac{1}{3}\right)^{10} \\ &= 4200 \cdot 0.00001935 \\ &= 0.0711 \end{aligned}$$

This probability corresponds to a stock price in $t = 10$ of

$$S_{10} = S_0 \cdot u^3 \cdot l^3 \cdot d^4 = \$20 \cdot 1.1^3 \cdot 1 \cdot 0.9^4 = \$17.47$$

This stock price is a random variable given by

$$S_{10} = S_0 \cdot Y_1 \cdot Y_2 \cdot \dots \cdot Y_{10}$$

where the Y_i are the corresponding relative changes (i.e., factors) in the periods $i = 1, 2, \dots, 10$. Note that S_{10} is not uniformly distributed even though it is a function of the random variables Y_1, Y_2, \dots, Y_{10} because its possible outcomes do not have identical probability.

APPENDIX A LIST OF DISCRETE DISTRIBUTIONS

N that is $k = 1, 2, 3, \dots$ as

$$k! = k \cdot (k - 1) \cdot (k - 2) \cdot \dots \cdot 1$$

For $k = 0$, we define $0! \equiv 1$.

Derivation of the Binomial Coefficient

In the context of the binomial distribution, we form the sum X of n independent and identically distributed Bernoulli random variables Y_i with parameter p or, formally, $Y_i \stackrel{iid}{\sim} B(p)$, $i = 1, 2, \dots, n$. The random variable is then distributed binomial with parameters n and p , i.e., $X \sim B(n, p)$. Since the random variables Y_i have either value 0 or 1, the resulting binomial random variable (i.e., the sum X) assumes some integer value between 0 and n . Let $X = k$ for $0 \leq k \leq n$. Depending on the exact value k , there may be several alternatives to obtain k since, for the sum X , it is irrelevant in which order the individual values of the Y_i appear.

Special Case $n = 3$

We illustrate the special case where $n = 3$ using a $B(3,0.4)$ random variable X ; that is, X is the sum of three independent $B(0.4)$ distributed random variables Y_1, Y_2 , and Y_3 . All possible values for X are contained in the state space $\Omega' = \{0, 1, 2, 3\}$. As we will see, some of these $k \in \Omega'$ can be obtained in different ways.

We start with $k = 0$. This value can only be obtained when all Y_i are 0, for $i = 1, 2, 3$. So, there is only one possibility.

Next we consider $k = 1$. A sum of $X = 1$ can be the result of one $Y_i = 1$ while the remaining two Y_i are 0. We have three possibilities for $Y_i = 1$ since it could be either the first, the second, or the third of the Bernoulli random variables. Then we place the first 0. For this, we have two possibilities since we have two Y_i left that are not equal to 1. Next, we place the second 0, which we have to assign to the remaining Y_i . As an intermediate result, we have $3 \cdot 2 \cdot 1 = 6$

APPENDIX B BINOMIAL AND MULTINOMIAL COEFFICIENTS

In this appendix, we explain the concept of the binomial and multinomial coefficients used in discrete probability distributions.

BINOMIAL COEFFICIENT

The *binomial coefficient* is defined as

$$\binom{n}{k} = \frac{n!}{k!(n - k)!}$$

for some nonnegative integers k and n with $0 \leq k \leq n$. For the binomial coefficient, we use the *factorial* operator denoted by the “!” symbol. A factorial is defined in the set of natural numbers

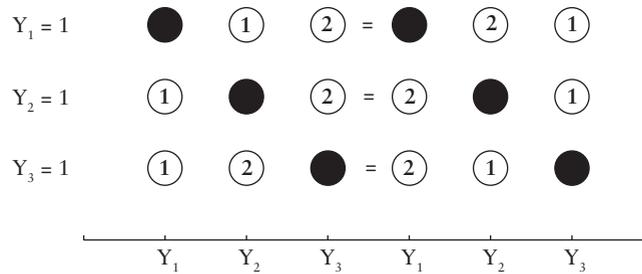

Figure B.1 Three Different Ways to Obtain a Total of $X = \sum_{i=1}^3 Y_i = 1$

Note: The alternatives matched by the = symbol lead to the same outcome, respectively.

possibilities. However, we do not need to differentiate between the two 0 values because it does not matter which of the zeros is assigned first and which second. So, we divide the total number of options by the number of possibilities to place the 0 values (i.e., 2). The resulting number of possible ways to end up with $X = 1$ is

$$\frac{3 \cdot 2 \cdot 1}{2} = \frac{3!}{2! \cdot 1!} = 3$$

For reasons we will make clear later, we introduced the middle term in the above equation.

Let us illustrate this graphically. In Figure B.1, a black ball represents a value $Y_i = 1$ at the i -th drawing while the white numbered circles represent a value of $Y_i = 0$ at the respective i -th drawing with i matching the number in the circle.

Now let $k = 2$. To yield the sum $X = 2$, we need two $Y_i = 1$ and one $Y_i = 0$. So, we have three different positions to place the 0, while the remaining two Y_i have to be equal to 1 automatically. Analogous to the prior case, $X = 1$, we do not need to differentiate between the two 1 values, once the 0 is positioned.

Finally, let $k = 3$. This is accomplished by all three $Y_i = 1$. So, there is only one possibility to obtain $X = 3$.

We summarize these results in Table B.1.

Special Case $n = 4$

We extend the prior case to the case where the random variable X is the sum of four Bernoulli distributed random variables—that is, $Y_i \stackrel{iid}{\sim} B(p), i = 1, 2, 3, 4$ —assuming either value 0 or 1 for each. The resulting sum X is then binomial distributed $B(4, p)$ assuming values k in the state space $\Omega' = \{0,1,2,3,4\}$. Again, we will analyze how the individual values of the sum X can be obtained.

To begin, let us consider the case $k = 0$. As in the prior case $n = 3$, we have only one possibility (i.e., all four Y_i equal to 0, that is, $Y_1 = Y_2 = Y_3 = Y_4 = 0$). This can be seen from the following. Technically, we have four positions to place the first 0. Then, we have three choices to place the second 0. For the third 0, we have two positions available, and one for the last 0. In total, we have

$$4 \times 3 \times 2 \times 1 = 24$$

Table B.1 Different Choices to Obtain $X = k$ when $n = 3$

$k = 0$	$k = 1$	$k = 2$	$k = 3$
$1 = \frac{3!}{0! \times 3!} = \binom{3}{0}$	$3 = \frac{3!}{1! \times 2!} = \binom{3}{1}$	$3 = \frac{3!}{2! \times 1!} = \binom{3}{2}$	$1 = \frac{3!}{3! \times 0!} = \binom{3}{3}$

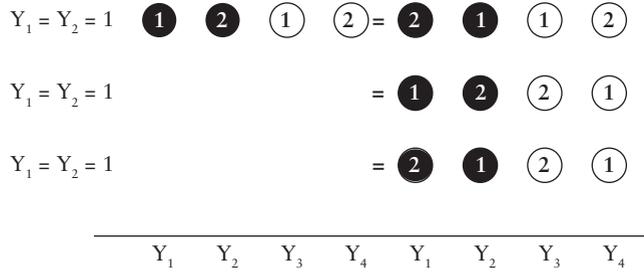

Figure B.2 Four Different Ways to Obtain $Y_1 = Y_2 = 1$

But due to the fact that we do not care about the order of the 0 values, we divide by the total number of options (i.e., 24) and then obtain

$$\frac{4 \times 3 \times 2 \times 1}{4 \times 3 \times 2 \times 1} = \frac{4!}{4!} = 1$$

Next, we derive a sum of $k = 1$. This can be obtained in four different ways. The reasoning is similar to that in the case $k = 1$ for $n = 3$. We have four positions to place the 1. Once the 1 is placed, the remaining Y_i have to be automatically equal to 0. Again, the order of placing the 0 values is irrelevant, which eliminates the redundant options through division of the total number by $3 \times 2 \times 1 = 6$. Technically, we have

$$\frac{4 \times 3 \times 2 \times 1}{3 \times 2 \times 1} = \frac{4!}{3!} = 4$$

For a sum X equal to $k = 2$, we have four different positions to place the first 1. Then, we have three positions left to place the second 1. This yields $4 \times 3 = 12$ different options. However, we do not care which one of the 1 values is placed first since, again, their order is irrelevant. So, we divide the total number by 2 to

indicate that the order of the two 1 values is unimportant. Next, we place the first 0, which offers us two possible positions for the remaining Y_i that are not equal to 1 already. For this, we have two options. In total, we then have

$$\frac{4 \times 3 \times 2 \times 1}{2 \times 1} = \frac{4!}{2!} = 12$$

possibilities. Then, the second 0 is placed on the remaining Y_i . So, there is only one choice for this 0. Because we do not care about the order of placement of the 2 values, we divide by 2. The resulting number of different ways to yield a sum X of $k = 2$ is

$$\frac{4 \times 3 \times 2 \times 1}{2 \times 1 \times 2 \times 1} = \frac{4!}{2! \times 2!} = 6$$

which is illustrated in Figures B.2 through B.7.

A sum of X equal to $k = 3$ is achieved by three 1 values and one 0 value. So, since the order of the 1 values is irrelevant due to the previous reasoning, we only care about where to place the 0 value. We have four possibilities, that is,

$$\frac{4 \times 3 \times 2 \times 1}{3 \times 2 \times 1} = \frac{4!}{3!} = 4$$

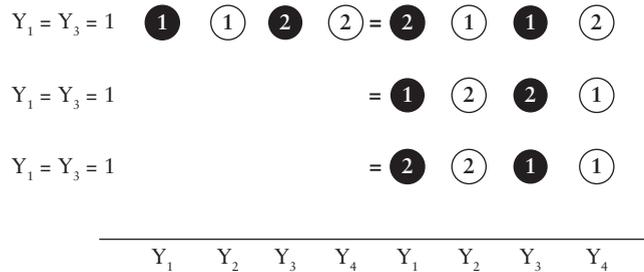

Figure B.3 Four Different Ways to Obtain $Y_1 = Y_3 = 1$

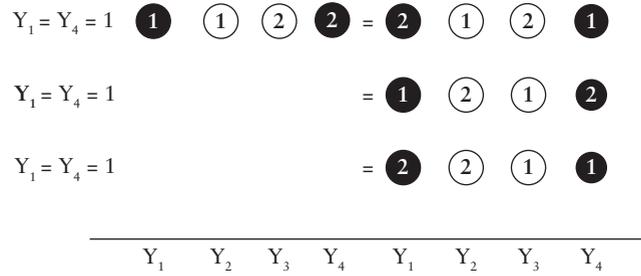

Figure B.4 Four Different Ways to Obtain $Y_1 = Y_4 = 1$

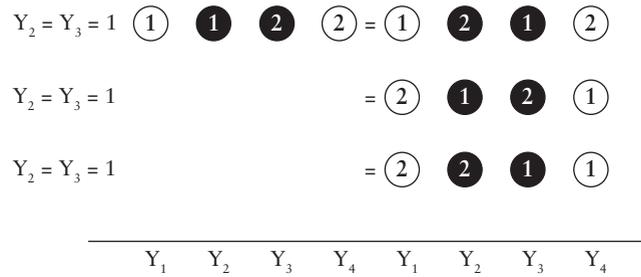

Figure B.5 Four Different Ways to Obtain $Y_2 = Y_3 = 1$

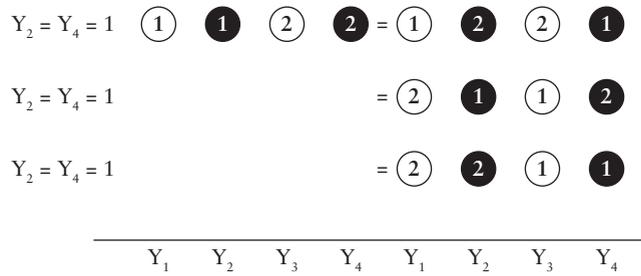

Figure B.6 Four Different Ways to Obtain $Y_2 = Y_4 = 1$

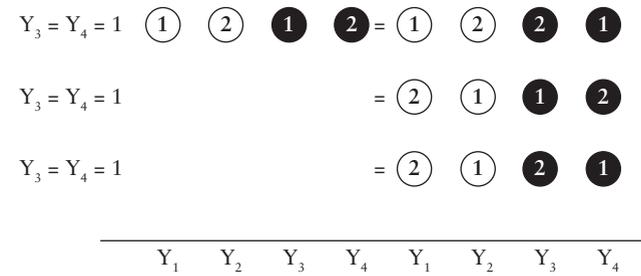

Figure B.7 Four Different Ways to Obtain $Y_3 = Y_4 = 1$

Table B.2 Different Choices to Obtain $X = k$ when $n = 4$

$k = 0$	$k = 1$	$k = 2$	$k = 3$	$k = 4$
$1 = \frac{4!}{0! \times 4!} = \binom{4}{0}$	$4 = \frac{4!}{1! \times 3!} = \binom{4}{1}$	$6 = \frac{4!}{2! \times 2!} = \binom{4}{2}$	$4 = \frac{4!}{3! \times 1!} = \binom{4}{3}$	$1 = \frac{4!}{4! \times 0!} = \binom{4}{4}$

Finally, to obtain $k = 4$, we only have one possible way to do so, as in the case where $k = 0$. Mathematically, this is

$$\frac{4 \times 3 \times 2 \times 1}{4 \times 3 \times 2 \times 1} = \frac{4!}{4!} = 1$$

We summarize the results in Table B.2.

General Case

Now we generalize for any $n \in N$ (i.e., some nonnegative integer number). The binomial random variable X is hence the $B(n, p)$ distributed sum of n independent and identically distributed random variables Y_i

From the two special cases (i.e., $n = 3$ and $n = 4$), it seems that to obtain the number of choices for some $0 \leq k \leq n$, we have $n!$ in the numerator to account for all the possibilities to assign the individual n values to the Y_i , no matter how many 1 values and 0 values we have. In the denominator, we correct for the fact that the order of the 1 values and 0 values is irrelevant. That is, we divide by the number of different orders to place the 1 values on the Y_i that are equal to 1, and also by the number of different orders to assign the 0 values to the Y_i being equal to 0. Therefore, we have $n!$ in the

numerator and $k! \times (n - k)!$ in the denominator. The result is illustrated in Table B.3.

MULTINOMIAL COEFFICIENT

The *multinomial coefficient* is defined as

$$\binom{n}{n_1 \ n_2 \ \dots \ n_k} = \frac{n!}{n_1! \cdot n_2! \cdot \dots \cdot n_k!}$$

for $n_1 + n_2 + \dots + n_k = n$. Sometimes, the multinomial coefficient is referred to as the *polynomial coefficient*.

Assume we have some population of balls with k different colors. Suppose n times we draw some ball and return it to the population such that for each trial (i.e., drawing), we have the identical conditions. Hence, the individual trials are independent of each other. Let Y_i denote the color obtained in the i -th trial for $i = 1, 2, \dots, n$.

How many different possible samples of length n are there? Let us think of the drawings in a different way. That is, we draw one ball after another disregarding color and assign the drawn ball to the trials Y_1 through Y_n in an arbitrary fashion.

Table B.3 Different Choices to Obtain $X = k$ for General n

$k = 0$	$k = 1$	$k = 2$
$1 = \frac{n!}{0! \times n!} = \binom{n}{0}$	$n = \frac{n!}{1! \times (n - 1)!} = \binom{n}{1}$	$\frac{n \times (n - 1)}{2} = \frac{n!}{2! \times (n - 2)!} = \binom{n}{2}$
...	$k = n - 1$	$k = n$
...	$n = \frac{n!}{(n - 1)! \times 1!} = \binom{n}{n - 1}$	$n = \frac{n!}{n! \times 0!} = \binom{n}{n}$

First, we draw a ball with any of the k colors and assign it to one of the n trials, Y_i . Next, we draw the second ball and assign it to one of the remaining $n - 1$ possible trials i as outcome of Y_i . This yields

$$n \times (n - 1)$$

different possibilities. The third ball drawn is assigned to the $n - 2$ trials left so that we have

$$n \times (n - 1) \times (n - 2)$$

possibilities, in total. This is continued until we draw the n th (i.e., the last), color, which can only be placed in the last remaining trial Y_i . In total this yields

$$n \times (n - 1) \times (n - 2) \times \dots \times 2 \times 1 = n!$$

different possibilities of drawing n balls.

The second question is how many different possibilities are there to obtain a sample with the number of occurrences n_1, n_2, \dots , and n_k of the respective colors. Let red be one of these colors and suppose we have a sample with a total of $n_r = 3$ red balls from trials 2, 4, and 7 so that $Y_2 = Y_4 = Y_7 = \text{red}$. The assignment of red to these three trials yields

$$3! = 3 \times 2 \times 1 = 6$$

different orders of assignment. Now, we are indifferent with respect to which of the Y_2, Y_4 , and Y_7 was assigned red first, second, and third. Thus, we divide the total number $n!$ of different samples by $n_r! = 3!$ to obtain only nonredundant results with respect to a red ball. We proceed in the same fashion for the remaining colors and, finally, obtain for the total number of nonredundant samples containing n_1 of color 1, n_2 of color 2, \dots , and n_k of color k

$$\binom{n!}{n_1 n_2 \dots n_k} = \frac{n!}{n_1! \times n_2! \times \dots \times n_k!}$$

which is exactly the multinomial coefficient equation given above.

KEY POINTS

- A discrete law or probability distribution is related to some discrete random variable, that is, a random variable that can assume values from a countable set of values. Typical examples include counts (i.e., the number of items meeting certain requirements) and number of hits.
- The most important discrete random variables used in finance and their probability distribution are the Bernoulli, binomial, hypergeometric, multinomial, Poisson, and discrete uniform.
- The Bernoulli distribution might be the most famous discrete law. It is applied when a random variable can only assume one of two values—0 or 1. A simple example would be the toss of a coin. In financial models, it is applied if it is of interest whether a certain event has occurred (1) or not (0).
- The binomial distribution is the extension of the Bernoulli distribution in the sense that it represents repeated trials where the respective outcomes are either 0 or 1, so that in total we can obtain any integer between 0 and n , where n is the number of Bernoulli trials. A typical example in finance would be given by the binomial stock price model where it is the objective to count the number of improvements of some stock over a given number of periods.
- Drawing with replacement refers to the experiment of repeated trials where each individual trial is conducted under identical conditions as the others and without influencing each other. A prerequisite of the binomial distribution is drawing with replacement.
- The Poisson distribution is related to a discrete random variable that can assume any nonnegative integer value. A typical application is in risk theory when the number of defaults or occurrences of some undesirable event has to be modeled.

NOTE

1. Note that the successive prices S_1, \dots, S_T depend on their respective predecessors. They are said to be *path-dependent*. Only the changes, or factors Y_{t+1} , for each period are independent. In this case, the price S_{t+1} depends only on S_t , however, and not the en-

tire past. This is referred to as the *Markov* property.

Abstract: Continuous probability distributions are needed when the random variable of interest can assume any value inside of one or more intervals of real numbers such as, for example, any number greater than zero. Asset returns, for example, whether measured monthly, weekly, daily, or at an even higher frequency are commonly modeled as continuous random variables. In contrast to discrete probability distributions that assign positive probability to certain discrete values, continuous probability distributions assign zero probability to any single real number. Instead, only entire intervals of real numbers can have positive probability such as, for example, the event that some asset return is not negative. For each continuous probability distribution, this necessitates the so-called probability density, a function that determines how the entire probability mass of one is distributed. The density often serves as the proxy for the respective probability distribution.

In this entry, we introduce the concept of continuous probability distributions. We present the continuous distribution function with its corresponding density function, a function unique to continuous probability laws. In this entry, parameters of location and scale such as the mean and higher moments—variance and skewness—are defined. For a more technical discussion of continuous distributions, see Evans, Hastings, and Peacock (2000) or Johnson, Kotz, and Balakrishnan (1995).

CONTINUOUS PROBABILITY DISTRIBUTION DESCRIBED

Suppose we are interested in outcomes that are no longer countable. Examples of such outcomes in finance are daily logarithmic stock returns, bond yields, and exchange rates. Technically, without limitations caused by rounding to a certain number of digits, we could imagine that any real number could provide a feasible outcome for the daily logarithmic return of some stock. That is, the set of feasible values

that the outcomes are drawn from (i.e., the space Ω) is uncountable. The events are described by continuous intervals such as, for example, $(-0.05, 0.05]$, which, referring to our example with daily logarithmic returns, would represent the event that the return at a given observation is more than -5% and at most 5% .

In the context of continuous probability distributions, we have the real numbers \mathbb{R} as the uncountable space Ω . The set of events is given by the Borel σ -algebra \mathbb{B} , which is based on the half-open intervals of the form $(-\infty, a]$, for any real a . The space \mathbb{R} and the σ -algebra \mathbb{B} form the measurable space (\mathbb{R}, \mathbb{B}) , which we are to deal with throughout this entry.

DISTRIBUTION FUNCTION

To be able to assign a probability to an event in a unique way, in the context of continuous distributions we introduce as a device the *continuous distribution function* $F(a)$, which expresses the probability that some event of the sort $(-\infty, a]$ occurs (i.e., that a number is realized that is at most a). (Formally, an outcome $\omega \in \Omega$ is realized that lies inside of the interval $(-\infty, a]$.) As with discrete random variables, this function is also referred to as the *cumulative distribution function* (*cdf*) since it aggregates the probability up to a certain value.

To relate to our previous example of daily logarithmic returns, the distribution function evaluated at say 0.05 , that is, $F(0.05)$, states the probability of some return of at most 5% . (The distribution function F is also referred to as the *cumulative probability distribution function* (often abbreviated *cdf*) expressing that the probability is given for the accumulation of all outcomes less than or equal to a certain value.)

For values x approaching $-\infty$, F tends to zero, while for values x approaching ∞ , F goes to 1. In between, F is monotonically increasing and right-continuous. More concisely, we list these

properties below:

$$\text{Property 1. } F(x) \xrightarrow{x \rightarrow -\infty} 0$$

$$\text{Property 2. } F(x) \xrightarrow{x \rightarrow \infty} 1$$

$$\text{Property 3. } F(b) - F(a) \geq 0 \text{ for } b \geq a$$

$$\text{Property 4. } \lim_{x \downarrow a} F(x) = F(a)$$

The behavior in the extremes—that is when x goes to either $-\infty$ or ∞ —is provided by properties 1 and 2, respectively. Property 3 states that F should be monotonically increasing (i.e., never become less for increasing values). Finally, property 4 guarantees that F is right-continuous.

Let us consider in detail the case when $F(x)$ is a continuous distribution, that is, the distribution has no jumps. The continuous probability distribution function F is associated with the probability measure P through the relationship

$$F(a) = P((-\infty, a])$$

that is, that values up to a occur, and

$$F(b) - F(a) = P((a, b]) \quad (1)$$

Therefore, from equation (1) we can see that the probability of some event related to an interval is given by the difference between the value of F at the upper bound b of the interval minus the value of F at the lower bound a . That is, the entire probability that an outcome of at most a occurs is subtracted from the greater event that an outcome of at most b occurs. Using set operations, we can express this as

$$(a, b] = (-\infty, b] \setminus (-\infty, a]$$

For example as we have seen, the event of a daily return of more than -5% and, at most, 5% is given by $(-0.05, 0.05]$. So, the probability associated with this event is given by $P((-0.05, 0.05]) = F(0.05) - F(-0.05)$.

In contrast to a discrete probability distribution, a continuous probability distribution always assigns zero probability to countable events such as individual outcomes a_i or unions

thereof such as

$$\bigcup_{i=1}^{\infty} a_i$$

That is,

$$\begin{aligned} P(\{a_i\}) &= 0, \text{ for all } a_i \\ P\left(\bigcup_{i=1}^{\infty} a_i\right) &= 0 \end{aligned} \quad (2)$$

From equation (2), we can apply the left-hand side of equation (1) also to events of the form (a, b) to obtain

$$P((a, b)) = F(b) - F(a) \quad (3)$$

Thus, it is irrelevant whether we state the probability of the daily logarithmic return being more than -5% and at most 5% , or the probability of the logarithmic return being more than -5% and less than 5% . They are the same because the probability of achieving a return of exactly 5% is zero. With a space Ω consisting of uncountably many possible values such as the set of real numbers, for example, each individual outcome is unlikely to occur. So, from a probabilistic point of view, one should never bet on an exact return or, associated with it, one particular stock price.

Since countable sets produce zero probability from a continuous probability measure, they belong to the so-called *P-null sets*. All events associated with *P-null sets* are unlikely events.

So, how do we assign probabilities to events in a continuous environment? The answer is given by equation (3). That, however, presumes knowledge of the distribution function F . The next task is to define the continuous distribution function F more specifically as explained next.

DENSITY FUNCTION

The continuous distribution function F of a probability measure P on (\mathbb{R}, \mathbb{B}) is defined as follows

$$F(x) = \int_{-\infty}^x f(t) dt \quad (4)$$

where $f(t)$ is the *density function* of the probability measure P .

We interpret equation (4) as follows. Since, at any real value x the distribution function uniquely equals the probability that an outcome of at most x is realized, that is, $F(x) = P((-\infty, x])$, equation (4) states that this probability is obtained by integrating some function f over the interval from $-\infty$ up to the value x .

What is the interpretation of this function f ? The function f is the marginal rate of growth of the distribution function F at some point x . We know that with continuous distribution functions, the probability of exactly a value of x occurring is zero. However, the probability of observing a value inside of the interval between x and some very small step to the right Δx (i.e., $[x, x + \Delta x)$) is not necessarily zero. Between x and $x + \Delta x$, the distribution function F increases by exactly this probability; that is, the increment is

$$F(x + \Delta x) - F(x) = P(X \in [x, x + \Delta x)) \quad (5)$$

Now, if we divide $F(x + \Delta x) - F(x)$ from equation (5) by the width of the interval Δx , we obtain the average probability or average increment of F per unit step on this interval. If we reduce the step size Δx to an infinitesimally small step ∂x , this average approaches the *marginal rate of growth* of F at x , which we denote f ; that is,¹

$$\lim_{\Delta x \rightarrow 0} \frac{F(x + \Delta x) - F(x)}{\Delta x} = \frac{\partial F(x)}{\partial x} \equiv f(x) \quad (6)$$

At this point, let us recall the histogram with relative frequency density for class data. Over each class, the height of the histogram is given by the density of the class divided by the width of the corresponding class. Equation (6) is somewhat similar if we think of it this way. We divide the probability that some realization should be inside of the small interval. And, by letting the interval shrink to width zero, we obtain the marginal rate of growth or, equivalently, the

derivative of F . (We assume that F is continuous and that the derivative of F exists.) Hence, we call the *probability density function* or simply the *density function*. Commonly, it is abbreviated as *pdf*.

Now, when we refocus on equation (4), we see that the probability of some occurrence of at most x is given by integration of the density function f over the interval $(-\infty, x]$. Again, there is an analogy to the histogram. The relative frequency of some class is given by the density multiplied by the corresponding class width. With continuous probability distributions, at each value t , we multiply the corresponding density $f(t)$ by the infinitesimally small interval width dt . Finally, we integrate all values of f (weighted by dt) up to x to obtain the probability for $(-\infty, x]$. This, again, is similar to histograms: In order to obtain the cumulative relative frequency at some value x , we compute the area covered by the histogram up to value x .

In Figure 1, we compare the histogram and the probability density function. The histogram

with density h is indicated by the dotted lines while the density function f is given by the solid line. We can now see how the probability $P((-\infty, x^*])$ is derived through integrating the marginal rate f over the interval $(-\infty, x^*]$ with respect to the values t . The resulting total probability is then given by the area A_1 of the example in Figure 1. This is analogous to class data where we would tally the areas of the rectangles whose upper bounds are less than x^* and the part of the area of the rectangle containing x^* up to the dash-dotted vertical line.

Requirements on the Density Function

Given the uncountable space \mathbb{R} (i.e., the real numbers) and the corresponding set of events given by the Borel σ -algebra \mathbb{B} , we can give a more rigorous formal definition of the density function. The *density function* f of probability measure P on the measurable space (\mathbb{R}, \mathbb{B}) with distribution function F is a Borel-measurable

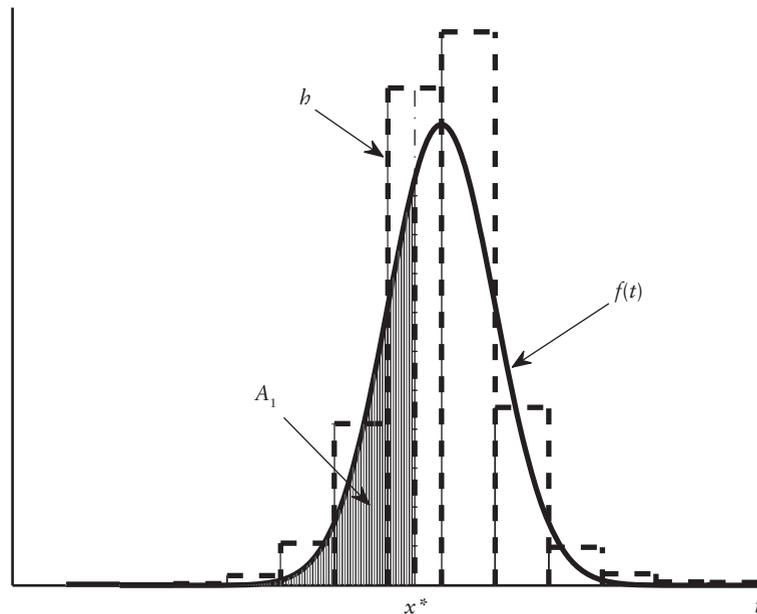

Figure 1 Comparison of Histogram and Density Function

Note: Area A_1 represents probability $P((-\infty, x^*])$ derived through integration of $f(t)$ with respect to t between $-\infty$ and x^*

function f satisfying.

$$P((-\infty, x]) = F(x) = \int_{-\infty}^x f(t)dt \quad (7)$$

with $f(t) \geq 0$, for all $t \in \mathbb{R}$ and

$$\int_{-\infty}^{\infty} f(t)dt = 1$$

By the requirement of Borel-measurability, we simply assume that the real-valued images generated by f have their origins in the Borel σ -algebra \mathbb{B} . Informally, for any value $y = f(t)$, we can trace the corresponding origin(s) t in \mathbb{B} that is (are) mapped to y through the function f . Otherwise, we might incur problems computing the *integral* in equation (7) for reasons that are beyond the scope of this entry.

From definition of the density function given by equation (7), we see that it is reasonable that f be a function that exclusively assumes nonnegative values. Although we have not mentioned this so far, it is immediately intuitive since f is the marginal rate of growth of the continuous distribution function F . At each $t, f(t) \cdot dt$ represents the limit probability that a value inside of the interval $(t, t + dt]$ should occur, which can never be negative. Moreover, we require the in-

tegration of f over the entire domain from $-\infty$ to ∞ to yield 1, which is intuitively reasonable since this integral gives the probability that any real value occurs.

The requirement

$$\int_{-\infty}^{\infty} f(t)dt = 1$$

implies the graphical interpretation that the area enclosed between the graph of f over the entire interval $(-\infty, \infty)$ and the horizontal axis equals one. This is displayed in Figure 2 by the shaded area A . For example, to visualize graphically what is meant by

$$\int_{-\infty}^x f(t)dt$$

in equation (7), we can use Figure 1. Suppose the value x were located at the intersection of the vertical dash-dotted line and the horizontal axis (i.e., x^*). Then, the shaded area A_1 represents the value of the integral and, therefore, the probability of occurrence of a value of at most x . To interpret

$$\int_a^b f(t)dt$$

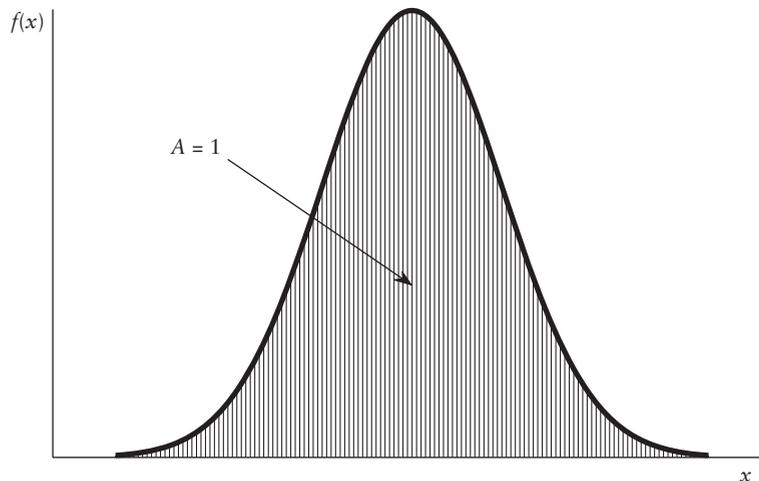

Figure 2 Graphical Interpretation of the Equality $A = \int_{-\infty}^{\infty} f(x)dx = 1$

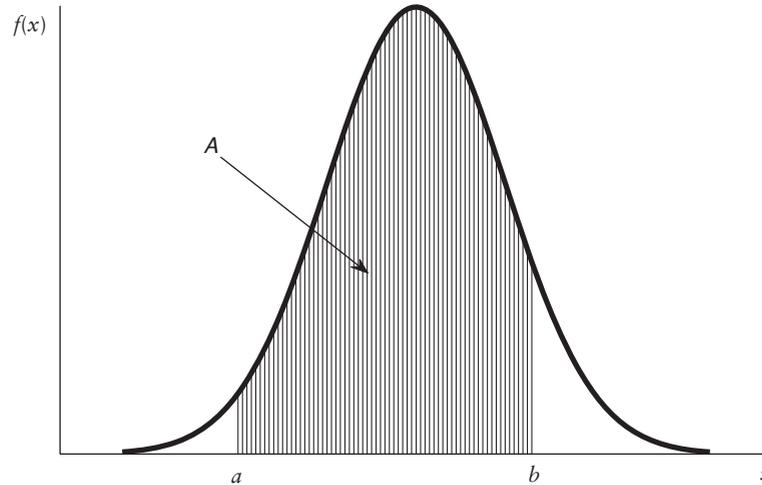

Figure 3 Graphical Interpretation of $A = \int_a^b f(x)dx$

graphically, look at Figure 3. The area representing the value of the interval is indicated by A . So, the probability of some occurrence of at least a and at most b is given by A . Here again, the resemblance to the histogram becomes obvious in that we divide one area above some class, for example, by the total area, and this ratio equates the according relative frequency.

For the sake of completeness, it should be mentioned without indulging in the reasoning behind it that there are probability measures P on (\mathbb{R}, \mathbb{B}) even with continuous distribution functions that do not have density functions as defined in equation (7). But, in our context, we will only regard probability measures with continuous distribution functions with associated density functions so that the equalities of equation (7) are fulfilled.

Sometimes, alternative representations equivalent to equation (7) are used. Typically, the following expressions are used

$$F(x) = \int_{\mathbb{R}} f(t) \cdot 1_{(-\infty, x]} dt \quad (8a)$$

$$F(x) = \int_{-\infty}^{\infty} f(t) \cdot 1_{(-\infty, x]} dt \quad (8b)$$

$$F(x) = \int_{-\infty}^{\infty} P(dt) \quad (8c)$$

$$F(x) = \int_{-\infty}^{\infty} dP(t) \quad (8d)$$

Note that in the first two equalities, (8a) and (8b), the indicator function $1_{(a,b]}$ is used. The last two equalities, (8c) and (8d), can be used even if there is no density function and, therefore, are of a more general form. We will, however, predominantly apply the representation given by equation (7) and occasionally resort to the last two forms above.

We introduce the term *support* at this point to refer to the part of the real line where the density is truly positive, that is, all those x where $f(x) > 0$.

CONTINUOUS RANDOM VARIABLE

So far, we have only considered continuous probability distributions and densities. We yet have to introduce the quantity of greatest interest to us in this entry, the *continuous random variable*. For example, stock returns, bond yields,

and exchange rates are usually modeled as continuous random variables.

Informally stated, a continuous random variable assumes certain values governed by a probability law uniquely linked to a continuous distribution function F . Consequently, it has a density function associated with its distribution. Often, the random variable is merely described by its density function rather than the probability law or the distribution function.

By convention, let us indicate the random variables by capital letters. Recall that any random variable, and in particular a continuous random variable X , is a *measurable function*. Let us assume that X is a function from the probability space $\Omega = \mathbb{R}$ into the *state space* $\Omega' = \mathbb{R}$. That is, origin and image space coincide. The corresponding σ -algebrae containing events of the elementary outcomes ω and the events in the image space $X(\omega)$, respectively, are both given by the Borel σ -algebra \mathbb{B} . Now, we can be more specific by requiring the continuous random variable X to be a $\mathbb{B} - \mathbb{B}$ -measurable real-valued function. That implies, for example, that any event $X \in (a, b]$, which is in \mathbb{B} , has its origin $X^{-1}((a, b])$ in \mathbb{B} , as well. Measurability is important when we want to derive the probability of events in the state space such as $X \in (a, b]$ from original events in the probability space such as $X^{-1}((a, b])$. At this point, one should not be concerned that the theory is somewhat overwhelming. It will become easier to understand once we move to the examples.

COMPUTING PROBABILITIES FROM THE DENSITY FUNCTION

The relationship between the continuous random variable X and its density is given by the following.² Suppose X has density f , then the probability of some event $X \leq x$ or $X \in (a, b]$ is

computed as

$$\begin{aligned} P(X \leq x) &= \int_{-\infty}^x f(t)dt \\ P(X \in (a, b]) &= \int_a^b f(t)dt \end{aligned} \quad (9)$$

which is equivalent to $F(x)$ and $F(b) - F(a)$ respectively, because of the one-to-one relationship between the density f and the distribution function F of X .

As explained earlier, using indicator functions, equation (9) could be alternatively written as

$$\begin{aligned} P(X \leq x) &= \int_{-\infty}^{\infty} 1_{(-\infty, x]}(t) f(t)dt \\ P(X \in (a, b]) &= \int_{-\infty}^{\infty} 1_{(a, b]}(t) f(t)dt \end{aligned}$$

In the following, we will introduce parameters of location and spread such as the mean and the variance, for example. In contrast to the data-dependent statistics, parameters of random variables never change. Some probability distributions can be sufficiently described by their parameters. They are referred to as *parametric distributions*. For example, for the normal distribution we introduce shortly, it is sufficient to know the parameters mean and variance to completely determine the corresponding distribution function. That is, the shape of parametric distributions is governed only by the respective parameters.

LOCATION PARAMETERS

The most important location parameter is the *mean* that is also referred to as the *first moment*. It is the only location parameter presented in this entry.

The mean can be thought of as an average value. It is the number that one would have to

expect for some random variable X with given density function f . The mean is defined as follows: Let X be a real-valued random variable on the space $\Omega = \mathbb{R}$ with Borel σ -algebra \mathbb{B} . The *mean* is given by

$$E(X) = \int_{-\infty}^{\infty} x \cdot f(x) dx \quad (10)$$

in case the integral on the right-hand side of equation (10) exists (i.e., is finite). Typically, the mean parameter is denoted as μ .

In equation (10) that defines the mean, we weight each possible value x that the random variable X might assume by the product of the density at this value, $f(x)$, and step size dx . Recall that the product $f(x) \cdot dx$ can be thought of as the limiting probability of attaining the value x . Finally, the mean is given as the integral over these weighted values. Thus, equation (10) is similarly understood as the definition of the mean of a discrete random variable where, instead of integrated, the probability-weighted values are summed.

DISPERSION PARAMETERS

We turn our focus toward measures of spread or, in other words, dispersion measures. Again, as with the previously introduced measures of location, in probability theory the dispersion measures are universally given parameters. Here, we introduce the moments of higher order, variance, standard deviation, and the skewness parameters.

Moments of Higher Order

It might sometimes be necessary to compute *moments of higher order*. As we already know from descriptive statistics, the mean is the moment of order one. (Alternatively, we often say the *first* moment. For the higher orders k , we consequently might refer to the k -th moment.) However, one might not be interested in the expected value of some quantity itself but of its square. If we treat this quantity as a continu-

ous random variable, we compute what is the *second moment*.

Let X be a real-valued random variable on the space $\Omega = \mathbb{R}$ with Borel σ -algebra \mathbb{B} . The *moment of order k* is given by the expression

$$E(X^k) = \int_{-\infty}^{\infty} x^k \cdot f(x) dx \quad (11)$$

in case the integral on the right-hand side of equation (11) exists (i.e., is finite).

From equation (11), we learn that higher-order moments are equivalent to simply computing the mean of X taken to the k -th power.

Variance

The variance involves computing the expected squared deviation from the mean $E(X) = \mu$ of some random variable X . For a continuous random variable X , the variance is defined as follows: Let X be a real-valued random variable on the space $\Omega = \mathbb{R}$ with Borel σ -algebra \mathbb{B} , then the *variance* is

$$\begin{aligned} \text{Var}(X) &= \int_{-\infty}^{\infty} (x - E(X))^2 \cdot f(x) dx \\ &= \int_{-\infty}^{\infty} (x - \mu)^2 \cdot f(x) dx \quad (12) \end{aligned}$$

in case the integral on the right-hand side of equation (12) exists (i.e., is finite). Often, the variance in equation (12) is denoted by the symbol σ^2 .

In equation (12), at each value x , we square the deviation from the mean and weight it by the density at x times the step size dx . The latter product, again, can be viewed as the limiting probability of the random variable X assuming the value x . The square inflates large deviations even more compared to smaller ones. For some random variable to have a small variance, it is essential to have a quickly vanishing density in the parts where the deviations $(x - \mu)$ become large.

All distributions that we discuss in this entry are parametric distributions. For some of

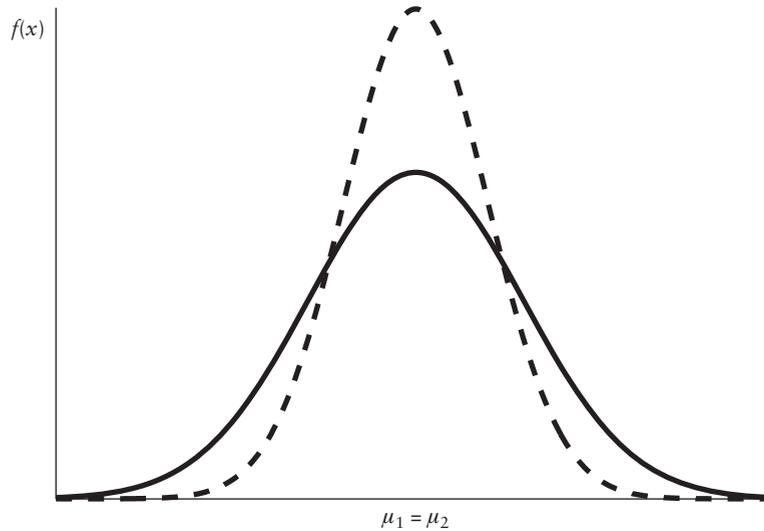

Figure 4 Two Density Functions Yielding Common Means, $\mu_1 = \mu_2$, but Different Variances, $\sigma_1^2 < \sigma_2^2$
 Note: Dashed graph: $\sigma_1^2 = 1$. Solid graph: $\sigma_2^2 = 1.5$.

them, it is enough to know the mean μ and variance σ^2 and consequently, we will resort to these two parameters often. Historically, the variance has often been given the role of risk measure in context of portfolio theory. Suppose we have two random variables R_1 and R_2 representing the returns of two stocks, S_1 and S_2 , with equal means μ_{R_1} and μ_{R_2} , respectively, so that $\mu_{R_1} = \mu_{R_2}$. Moreover, let R_1 and R_2 have variances $\sigma_{R_1}^2$ and $\sigma_{R_2}^2$, respectively, with $\sigma_{R_1}^2 < \sigma_{R_2}^2$. Then, omitting further theory, at this moment, we prefer S_1 to S_2 because of the S_1 's smaller variance. We demonstrate this in Figure 4. The dashed line represents the graph of the first density function while the second one is depicted by the solid line. Both density functions yield the same mean (i.e., $\mu_1 = \mu_2$). However, the variance from the first density function, given by the dashed graph, is smaller than that of the solid graph (i.e., $\sigma_1^2 < \sigma_2^2$). Thus, using variance as the risk measure and resorting to density functions that can be sufficiently described by the mean and variance, we can state that density function for S_1 (dashed graph) is preferable. We can interpret the figure as follows.

Since the variance of the distribution with the dashed density graph is smaller, the probability mass is less dispersed over all x values. Hence, the density is more condensed about the center and more quickly vanishing in the extreme left and right ends, the so-called *tails*. On the other hand, the second distribution with the solid density graph has a larger variance, which can be verified by the overall flatter and more expanded density function. About the center, it is lower and less compressed than the dashed density graph, implying that the second distribution assigns less probability to events immediately near the center. However, the density function of the second distribution decays more slowly in the tails than the first, which means that under the governance of the latter, extreme events are less likely than under the second probability law.

Standard Deviation

The parameter related to the variance is the *standard deviation*. As we know from descriptive statistics described earlier in this book, the standard deviation is the positive square root

of the variance. That is, let X be a real-valued random variable on the space $\Omega = \mathbb{R}$ with Borel σ -algebra \mathbb{B} . Furthermore, let its mean and variance be given by μ and σ^2 , respectively. The standard deviation is defined as

$$\sigma = \sqrt{\text{Var}(X)}$$

For example, in the context of stock returns, one often expresses using the standard deviation the return's fluctuation around its mean. The standard deviation is often more appealing than the variance since the latter uses squares, which are a different scale from the original values of X . Even though mathematically not quite correct, the standard deviation, denoted by σ , is commonly interpreted as the average deviation from the mean.

Skewness

Consider the density function portrayed in Figure 5. The figure is obviously symmetric about some location parameter μ in the sense that $f(-x - \mu) = f(x - \mu)$. Suppose instead that we encounter a density function f of some random variable X that is depicted in Figure 6. This figure is not symmetric about any location parameter. Consequently, some quantity stating the

extent to which the density function is deviating from symmetry is needed. This is accomplished by a parameter referred to as *skewness*. This parameter measures the degree to which the density function leans to either side, if at all.

Let X be a real-valued random variable on the space $\Omega = \mathbb{R}$ with Borel σ -algebra \mathbb{B} , variance σ^2 , and mean $\mu = E(X)$. The skewness parameter, denoted by γ , is given by

$$\gamma = \frac{E\left((x - E(X))^3\right)}{\sigma^{3/2}}$$

The skewness measure given above is referred to as the *Pearson skewness* measure. Negative values indicate skewness to the left (i.e., *left skewed*) while skewness to the right is given by positive values (i.e., *right skewed*).

The design of the skewness parameter follows the following reasoning. In the numerator, we measure the distance from every value x to the mean $E(X)$ of random variable X . To overweight larger deviations, we take them to a higher power than one. In contrast to the variance where we use squares, in the case of skewness we take the third power since three is an odd number and thereby preserves both the signs and directions of the deviations. Due

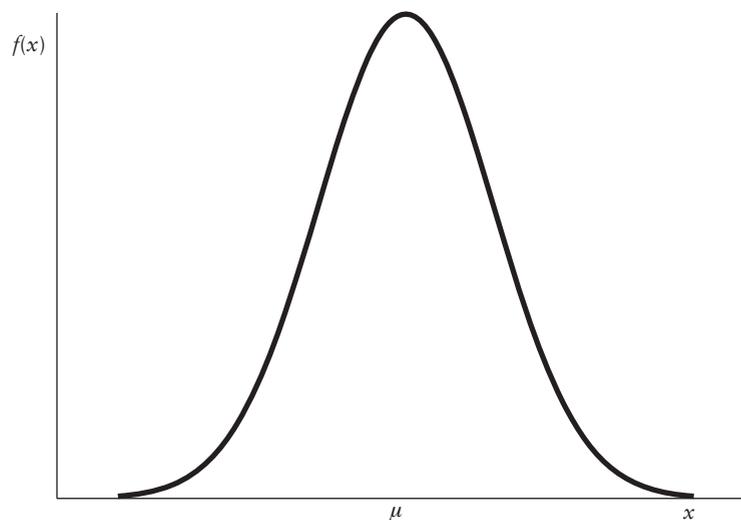

Figure 5 Example of Some Symmetric Density Function $f(x)$

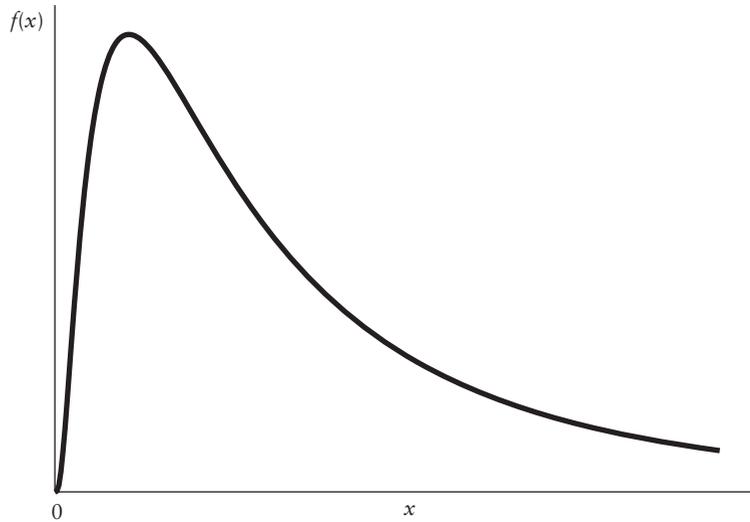

Figure 6 Example of Some Asymmetric Density Function $f(x)$

to this sign preservation, symmetric density functions yield zero skewness since all deviations to the left of the mean cancel their counterparts to the right. To standardize the deviations, we scale them by dividing by the standard deviation, also taken to the third power. So, the skewness parameter is not influenced by the standard deviation of the distributions. If we did not scale the skewness parameter in this way, distribution functions with density functions having large variances would always produce larger skewness even though the density is not really tilted more pronouncedly than some similar density with smaller variance.

We graphically illustrate the skewness parameter γ in Figure 6 for some density function $f(x)$. A density function f that assumes positive values $f(x)$ only for positive real values (i.e., $x > 0$) but zero for $x \leq 0$ is shown in the figure. The random variable X with density function f has mean $\mu = 1.65$. Its standard deviation is computed as $\sigma = 0.957$. The value of the skewness parameter is $\gamma = 0.7224$, indicating a positive skewness. The sign of the skewness parameter can be easily verified by analyzing the density graph. The density peaks just a little to the

right of the leftmost value $x = 0$. Toward the left tail, the density decays abruptly and vanishes at zero. Toward the right tail, things look very different in that f decays very slowly, approaching a level of $f = 0$ as x goes to positive infinity. (The graph is depicted for $x \in [0, 3.3]$.)

KEY POINTS

- A continuous random variable is a random variable that does not only assume values from a set of discrete values but may assume any real value from within one or more intervals. Often, asset returns are modeled as continuous random variables.
- The continuous distribution function is the probability distribution associated with a continuous random variable. It distinguishes itself from the discrete probability distribution in that it gives positive probability only to entire intervals rather than some discrete values only.
- To appreciate continuous random variables, it is necessary to understand the concept of the derivative of some function, which is the marginal rate of growth of some function at a certain point. It can be conceived as the slope

of the function at some point considering only very small increments in the argument of the function away from the point.

- The density function determines how the probability mass of one is distributed across the real line. Hence, it would be counterintuitive if that function were ever negative such that we require it to be nonnegative. Technically, it is the marginal rate of growth of the distribution function at any position or, in other words, its derivative.
- As support of some probability distribution, we define the subset of the real numbers that represents 100% of the probability. For the continuous probability distributions, it is the collection of intervals where the associated probability density is positive.

NOTES

1. The expression $\partial F(x)$ is equivalent to the increment $F(x + \Delta x) - F(x)$ as Δx goes to zero.
2. Sometimes the density of X is explicitly indexed f_x . We will not do so here, however, except where we believe not doing so will lead to confusion. The same holds for its distribution function F .

Abstract: To model the behavior of certain financial assets in a stochastic environment, we can usually resort to a variety of theoretical distributions. Most commonly, probability distributions are selected that are analytically well known. For example, the normal distribution is often the distribution of choice when asset returns are modeled, or the exponential distribution is applied to characterize the randomness of the time between two successive defaults of firms in a bond portfolio. Many other distributions are related to them or built on them in a well-known manner. These distributions often display pleasant features such as stability under summation—meaning that the return of a portfolio of assets whose returns follow a certain distribution again follows the same distribution. However, one has to be careful using these distributions since their advantage of mathematical tractability is often outweighed by the fact that the stochastic behavior of the true asset returns is not well captured by these distributions.

In this entry, we discuss the more commonly used distributions with appealing statistical properties that are used in finance. The distributions discussed are the normal distribution, the chi-square distribution, the Student's t -distribution, the Fisher's F -distribution, the exponential distribution, the gamma distribution (including the special Erlang distribution), the beta distribution, and the log-normal

distribution. Many of the distributions enjoy widespread attention in finance, or statistical applications in general, due to their well-known characteristics or mathematical simplicity. However, as we emphasize, the use of some of them might be ill-suited to replicate the real-world behavior of financial returns. For a more technical discussion of continuous distributions, see Evans, Hastings,

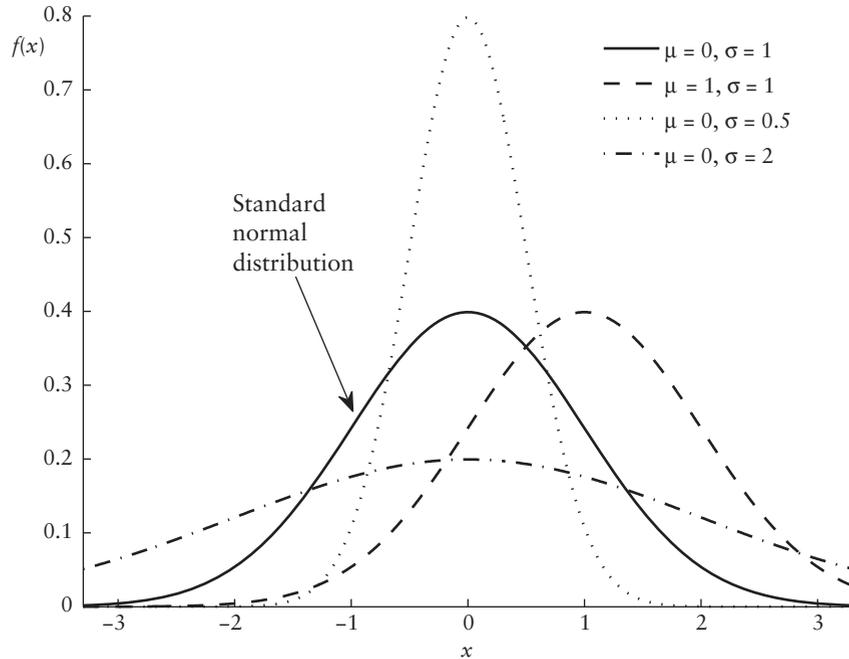

Figure 1 Normal Density Function for Various Parameter Values

and Peacock (2000) or Johnson, Kotz, and Balakrishnan (1995).

NORMAL DISTRIBUTION

The first distribution we discuss is the *normal distribution*. It is the distribution most commonly used in finance despite its many limitations. This distribution, also referred to as the *Gaussian distribution* (named after the mathematician and physicist C. F. Gauss), is characterized by the two parameters: mean (μ) and standard deviation (σ). The distribution is denoted by $N(\mu, \sigma^2)$. When $\mu = 0$ and $\sigma^2 = 1$, then we obtain the *standard normal distribution*.

For $x \in R$, the density function for the normal distribution is given by

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma} \cdot e^{-\frac{(x-\mu)^2}{2\sigma^2}} \quad (1)$$

The density in equation (1) is always positive. Hence, we have support (i.e., positive density) on the entire real line. Furthermore, the density function is symmetric about μ . A plot of the density function for several parameter values is given in Figure 1. As can be seen, the value of μ results in a horizontal shift from 0 while σ inflates or deflates the graph. A characteristic of the normal distribution is that the densities are bell shaped.

A problem is that the distribution function cannot be solved for analytically and therefore has to be approximated numerically. In the particular case of the standard normal distribution, the values are tabulated. Standard statistical software provides the values for the standard normal distribution as well as most of the distributions presented in this entry. The standard normal distribution is commonly denoted by the Greek letter Φ such that we have $\Phi(x) = F(x) = P(X \leq x)$, for some standard normal random variable X . In Figure 2, graphs

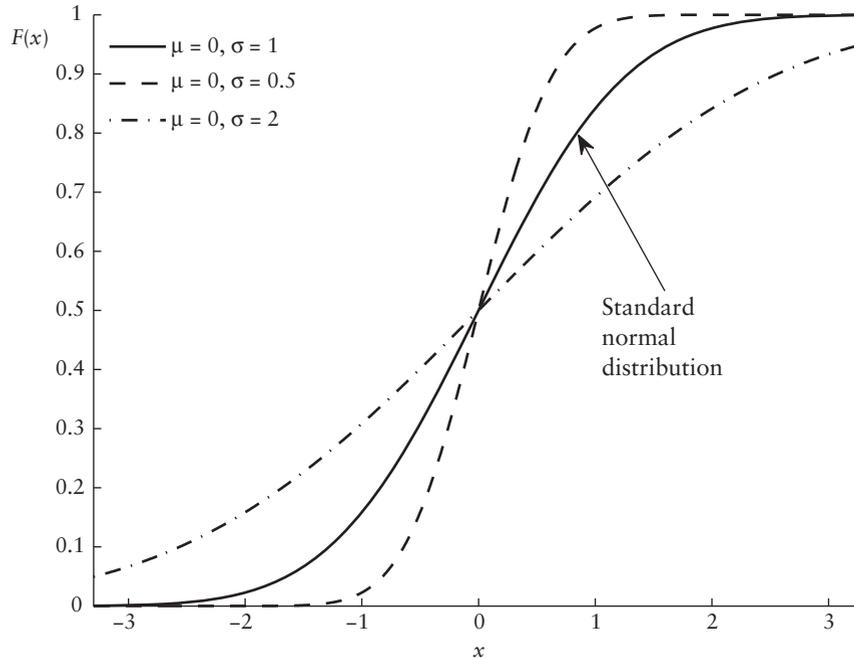

Figure 2 Normal Distribution Function for Various Parameter Values

of the distribution function are given for three different sets of parameters.

Properties of the Normal Distribution

The normal distribution provides one of the most important classes of probability distributions due to two appealing properties that generally are not shared by all distributions:

Property 1. The distribution is *location-scale invariant*.

Property 2. The distribution is *stable under summation*.

Property 1, the location-scale invariance property, guarantees that we may multiply X by b and add a where a and b are any real numbers. Then, the resulting $a + b \cdot X$ is, again, normally distributed, more precisely, $N(a + \mu, b\sigma)$. Consequently, a normal random variable will still be normally distributed if we change the units of measurement. The change into $a + b \cdot X$ can be interpreted as observing the same X , however,

measured in a different scale. In particular, if a and b are such that the mean and variance of the resulting $a + b \cdot X$ are 0 and 1, respectively, then $a + b \cdot X$ is called the *standardization* of X .

Property 2, stability under summation, ensures that the sum of an arbitrary number n of normal random variables, X_1, X_2, \dots, X_n is, again, normally distributed provided that the random variables behave independently of each other. This is important for aggregating quantities.

These properties are illustrated later in the entry.

Furthermore, the normal distribution is often mentioned in the context of the *central limit theorem*. It states that a sum of random variables with identical distributions and being independent of each other results in a normal random variable.¹ We restate this formally as follows:

Let X_1, X_2, \dots, X_n be identically distributed random variables with mean $E(X_i) = \mu$ and $Var(X_i) = \sigma^2$ and do not influence the outcome of each other (i.e., are independent).

Then, we have

$$\frac{\sum_{i=1}^n X_i - n \cdot \mu}{\sigma \sqrt{n}} \xrightarrow{D} N(0, 1) \quad (2)$$

as the number n approaches infinity. The D above the convergence arrow in equation (2) indicates that the distribution function of the left expression converges to the standard normal distribution.

Generally, for $n = 30$ in equation (2), we consider equality of the distributions; that is, the left-hand side is $N(0,1)$ distributed. In certain cases, depending on the distribution of the X_i and the corresponding parameter values, $n < 30$ justifies the use of the standard normal distribution for the left-hand side of equation (2). If the X_i are Bernoulli random variables, that is, $X_i \sim B(p)$, with parameter p such that $n \cdot p \geq 5$, then we also assume equality in the distributions in equation (2). Depending on p , this can mean that n is much smaller than 30.

These properties make the normal distribution the most popular distribution in finance. But this popularity is somewhat contentious, however, for reasons that will be given as we progress in this entry.

The last property we will discuss of the normal distribution that is shared with some other distributions is the bell shape of the density function. This particular shape helps in roughly assessing the dispersion of the distribution due to a rule of thumb commonly referred to as the *empirical rule*. Due to this rule, we have

$$\begin{aligned} P(X \in [\mu \pm \sigma]) &= F(\mu + \sigma) - F(\mu - \sigma) \approx 68\% \\ P(X \in [\mu \pm 2\sigma]) &= F(\mu + 2\sigma) - F(\mu - 2\sigma) \approx 95\% \\ P(X \in [\mu \pm 3\sigma]) &= F(\mu + 3\sigma) - F(\mu - 3\sigma) \approx 100\% \end{aligned}$$

The above states that approximately 68% of the probability is given to values that lie in an interval one standard deviation σ about the mean μ . About 95% probability is given to values within 2σ to the mean, while nearly all probability is assigned to values within 3σ from the mean.

By comparison, the so-called *Chebyshev inequalities* valid for any type of distribution—so not necessarily bell-shaped—yield

$$\begin{aligned} P(X \in [\mu \pm \sigma]) &\approx 0\% \\ P(X \in [\mu \pm 2\sigma]) &\approx 75\% \\ P(X \in [\mu \pm 3\sigma]) &\approx 89\% \end{aligned}$$

which provides a much coarser assessment than the empirical rule as we can see, for example, by the assessed 0% of data contained inside of one standard deviation about the mean.

Applications to Stock Returns

Applying Properties 1 and 2 to Stock Returns

With respect to Property 1, consider an example of normally distributed stock returns r with mean μ . If μ is nonzero, this means that the returns are a combination of a constant μ and random behavior centered about zero. If we were only interested in the latter, we would subtract μ from the returns and thereby obtain a new random variable $\tilde{r} = r - \mu$, which is again normally distributed.

With respect to Property 2, we give two examples. First, let us present the effect of aggregation over time. We consider daily stock returns that, by our assumption, follow a normal law. By adding the returns from each trading day during a particular week, we obtain the week's return as $r_w = r_{Mo} + r_{Tu} + \dots + r_{Fr}$ where r_{Mo} , r_{Tu} , \dots , r_{Fr} are the returns from Monday through Friday. The weekly return r_w is normally distributed as well. The second example applies to portfolio returns. Consider a portfolio consisting of n different stocks, each with normally distributed returns. We denote the corresponding returns by R_1 through R_n . Furthermore, in the portfolio we weight each stock i with w_i , for $i = 1, 2, \dots, n$. The resulting portfolio return $R_p = w_1R_1 + w_2R_2 + \dots + w_nR_n$ is also a normal random variable.

Using the Normal Distribution to Approximate the Binomial Distribution

Consider the binomial stock price model. At time $t = 0$, the stock price was $S_0 = \$20$. At time $t = 1$, the stock price was either up or down by 10% so that the resulting price was either $S_0 = \$18$ or $S_0 = \$22$. Both up- and down-movement occurred with probability $P(\$18) = P(\$22) = 0.5$. Now we extend the model to an arbitrary number of n days. Suppose each day i , $i = 1, 2, \dots, n$, the stock price developed in the same manner as on the first day. That is, the price is either up 10% with 50% probability or down 10% with the same probability. If on day i the price is up, we denote this by $X_i = 1$ and $X_i = 0$ if the price is down. The X_i are, hence, $B(0.5)$ random variables. After, say, 50 days, we have a total of $Y = X_1 + X_2 + \dots + X_{50}$ up-movements. Note that because of the assumed independence of the X_i , that Y is a $B(50, 0.5)$ random variable with mean $n \cdot p = 25$ and variance $n \cdot p \cdot (1 - p) = 12.5$. Let us introduce

$$Z_{50} = \frac{Y - 25}{\sqrt{12.5}}$$

From the comments regarding equation (2), we can assume that Z_{50} is approximately $N(25, 12.5)$ distributed. So, the probability of at most 15 up-movements, for example, is given by $P(Y \leq 15) = \Phi((15 - 25)/\sqrt{12.5}) = 0.23\%$. By comparison, the probability of no more than five up-movements is equal to $P(Y \leq 5) = \Phi((5 - 25)/\sqrt{12.5}) = 0\%$.

Normal Distribution for Logarithmic Returns

As another example, let X be some random variable representing a quantitative daily market dynamic such as new information about the economy. A dynamic can be understood as some driving force governing the development of other variables. We assume that it is normally distributed with mean $E(X) = \mu = 0$ and variance $Var(X) = \sigma^2 = 0.2$. Formally, we would write $X \sim N(0, 0.2)$. So, on average, the value of the daily dynamic will be zero with a standard deviation of $\sqrt{0.2}$. In addition, we introduce a

stock price S as a random variable, which is equal to S_0 at the beginning.

After one day, the stock price is modeled to depend on the dynamic X as follows

$$S_1 = S_0 \cdot e^X$$

where S_1 is the stock price after one day. The exponent X in this presentation is referred to as a *logarithmic return* in contrast to a *multiplicative return* R obtained from the formula $R = S_1/S_0 - 1$. So, for example, if $X = 0.01$, S_1 is equal to $e^{0.01} \cdot S_0$. That is almost equal to $1.01 \cdot S_0$, which corresponds to an increase of 1% relative to S_0 .² The probability of X being, for instance, no greater than 0.01 after one day is given by³

$$\begin{aligned} P(X \leq 0.01) &= \int_{-\infty}^{0.01} f(x) dx \\ &= \int_{-\infty}^{0.01} \frac{1}{\sqrt{2\pi} \sqrt{0.2}} e^{-\frac{x^2}{2 \cdot 0.2}} dx \approx 0.51 \end{aligned}$$

Consequently, after one day, the stock price increases, at most, by 1% with 51% probability, that is, $P(S_1 \leq 1.01 \cdot S_0) \approx 0.51$.

Next, suppose we are interested in a five-day outlook where the daily dynamics X_i , $i = 1, 2, \dots, 5$ of each of the following consecutive five days are distributed identically as X and independent of each other. Since the dynamic is modeled to equal exactly the continuously compounded return—that is logarithmic returns—we refer to X as the return in this entry. For the resulting five-day returns, we introduce the random variable $Y = X_1 + X_2 + \dots + X_5$ as the linear combination of the five individual daily returns. We know that Y is normally distributed from Property 2. More precisely, $Y \sim N(0, 1)$. So, on average, the return tends in neither direction, but the volatility measured by the standard deviation is now $\sqrt{5} \approx 2.24$ times that of the daily return X . Consequently, the probability of Y not exceeding a value of 0.01 is

now,

$$P(Y \leq 0.01) = \int_{-\infty}^{0.01} \frac{1}{\sqrt{2\pi}\sqrt{1}} e^{-\frac{y^2}{2 \cdot 1}} dy \approx 0.50$$

We see that the fivefold variance results in a greater likelihood to exceed the threshold 0.01, that is,

$$\begin{aligned} P(Y > 0.01) &= 1 - P(Y \leq 0.01) \\ &\approx 0.50 > 0.49 \approx P(X > 0.01) \end{aligned}$$

We model the stock price after five days as

$$S_5 = S_0 \cdot e^Y = S_0 \cdot e^{X_1 + X_2 + \dots + X_5}$$

So, after five days, the probability for the stock price to have increased by no more than 1% relative to S_0 is equal to

$$P(S_5 \leq e^{0.01} \cdot S_0) = P(S_5 \leq 1.01 \cdot S_0) \approx 0.50$$

There are two reasons why in finance logarithmic returns are commonly used. First, logarithmic returns are often easier to handle than multiplicative returns. Second, if we consider returns that are attributed to ever shorter periods of time (e.g., from yearly to monthly to weekly to daily and so on), the resulting compounded return after some fixed amount of time can be expressed as a logarithmic return. The theory behind this can be obtained from any introductory book on calculus.

CHI-SQUARE DISTRIBUTION

Our next distribution is the *chi-square distribution*. Let Z be a standard normal random variable, in brief $Z \sim N(0,1)$, and let $X = Z^2$. Then X is distributed chi-square with one degree of freedom. We denote this as $X \sim \chi^2(1)$. The *degrees of freedom* indicate how many independently behaving standard normal random variables the resulting variable is composed of. Here X is just composed of one, namely Z , and therefore has one degree of freedom.

Because Z is squared, the chi-square distributed random variable assumes only non-negative values; that is, the support is on the

nonnegative real numbers. It has mean $E(X) = 1$ and variance $Var(X) = 2$.

In general, the chi-square distribution is characterized by the degrees of freedom n , which assume the values $1, 2, \dots$. Let X_1, X_2, \dots, X_n be n $\chi^2(1)$ distributed random variables that are all independent of each other. Then their sum, S , is

$$S = \sum_{i=1}^n X_i \sim \chi^2(n) \quad (3)$$

In words, the sum is again distributed chi-square but this time with n degrees of freedom. The corresponding mean is $E(X) = n$, and the variance equals $Var(X) = 2 \cdot n$. So, the mean and variance are directly related to the degrees of freedom.

From the relationship in equation (3), we see that the degrees of freedom equal the number of independent $\chi^2(1)$ distributed X_i in the sum. If we have $X_1 \sim \chi^2(n_1)$ and $X_2 \sim \chi^2(n_2)$, it follows that

$$X_1 + X_2 \sim \chi^2(n_1 + n_2) \quad (4)$$

From property (4), we have that chi-square distributions have Property 2; that is, they are stable under summation in the sense that the sum of any two chi-squared distributed random variables is itself chi-square distributed.

The chi-square density function with n degrees of freedom is given by

$$f(x) = \begin{cases} f(x) = \frac{1}{2^{n/2}\Gamma(n/2)} \cdot e^{-x/2} \cdot x^{n/2-1}, & x \geq 0 \\ 0 & x < 0 \end{cases}$$

for $n = 1, 2, \dots$ where $\Gamma(\cdot)$ is the *gamma function*. Figure 3 shows a few examples of the chi-square density function with varying degrees of freedom. As can be observed, the chi-square distribution is skewed to the right.

Application to Modeling Short-Term Interest Rates

As an example of an application of the chi-square distribution, we present a simplified

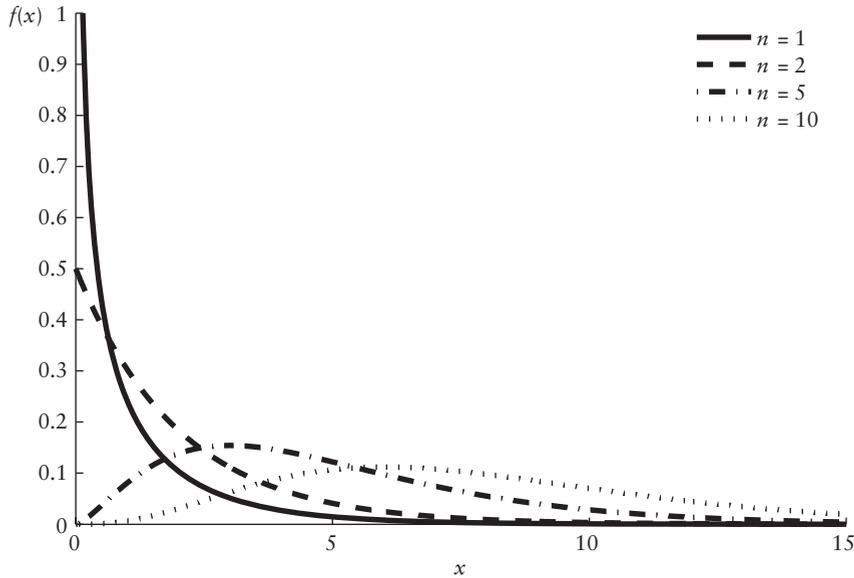

Figure 3 Density Functions of Chi-Square Distributions for Various Degrees of Freedom n

model of short-term interest rates, that is, so-called *short rates*. The short rate given by r_t , at any time t , is assumed to be a nonnegative continuous random variable. Furthermore, we let the short rate be composed of d independent dynamics X_1, X_2, \dots, X_d according to

$$r_t = X_1^2 + X_2^2 + \dots + X_d^2$$

where d is some positive integer number. In addition, each X_i is given as a standard normal random variable independent of all other dynamics. Then, the resulting short rate r_t is chi-square distributed with d degrees of freedom, that is, $r_t \sim \chi^2(d)$.

If we let $d = 2$ (i.e., there are two dynamics governing the short rate), the probability of a short rate between 0 and 1% is 0.5%. That is, we have to expect that on five out of 1,000 days, we will have a short rate assuming some value in the interval $(0, 0.01]$. If, in addition, we had one more dynamic included such that $r_t \sim \chi^2(3)$, then, the same interval would have probability $P(r_t \in (0, 0.01]) \approx 0.03\%$, which is close to being an unlikely event. We see that the more dynam-

ics are involved, the less probable small interest rates such as 1% or less become.

It should be realized, however, that this is merely an approach to model the short rate statistically and not an economic model explaining the factors driving the short rate.

STUDENT'S t -DISTRIBUTION

An important continuous probability distribution when the population variance of a distribution is unknown is the *Students t -distribution* (also referred to as the *t -distribution* and *Student's distribution*).

The t -distribution is a mixture of the normal and chi-square distributions. To derive the distribution, let X be distributed standard normal, that is, $X \sim N(0, 1)$, and S be chi-square distributed with n degrees of freedom, that is, $S \sim \chi^2(n)$. Furthermore, if X and Y are independent of each other (which is to be understood as not influencing the outcome of the other), then

$$Z = \frac{X}{\sqrt{S/n}} \sim t(n) \quad (5)$$

In words, equation (5) states that the resulting random variable Z is Student's t -distributed with n degrees of freedom. The degrees of freedom are inherited from the chi-square distribution of S .

How can we interpret equation (5)? Suppose we have a population of normally distributed values with zero mean. The corresponding normal random variable may be denoted as X . If one also knows the standard deviation of X ,

$$\sigma = \sqrt{\text{Var}(X)}$$

with X/σ , we obtain a standard normal random variable.

However, if σ is not known, we have to use, for example,

$$\sqrt{S/n} = \sqrt{1/n \cdot (X_1^2 + X_2^2 + \dots + X_n^2)}$$

instead where $X_1^2, X_2^2, \dots, X_n^2$ are n random variables identically distributed as X . Moreover, X_1, X_2, \dots, X_n have to assume values independently of each other. Then, the distribution of

$$X/\sqrt{S/n}$$

is the t -distribution with n degrees of freedom, that is,

$$X/\sqrt{S/n} \sim t(n)$$

By dividing by σ or S/n , we generate rescaled random variables that follow a standardized distribution. Quantities similar to $X/\sqrt{S/n}$ play an important role in parameter estimation.

The density function is defined as

$$f(x) = \frac{1}{\sqrt{n \cdot \pi}} \cdot \frac{\Gamma\left(\frac{n+1}{2}\right)}{\Gamma\left(\frac{n}{2}\right)} \cdot \left(1 + \frac{x^2}{n}\right)^{-\frac{n+1}{2}} \quad (6)$$

where the gamma function Γ is incorporated again. The density function is symmetric and has support (i.e., is positive) on all \mathbb{R} .

Basically, the Student's t -distribution has a similar shape to the normal distribution, but thicker tails. For large degrees of freedom n , the Student's t -distribution does not significantly differ from the standard normal distribution. As a matter of fact, for $n \geq 100$, it is practically indistinguishable from $N(0,1)$.

Figure 4 shows the Student's t -density function for various degrees of freedom plotted

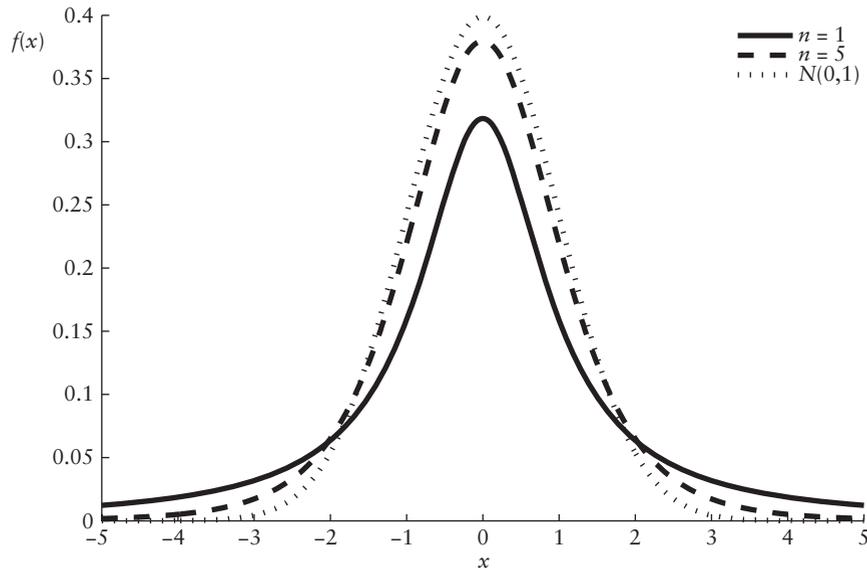

Figure 4 Density Function of the t -Distribution for Various Degrees of Freedom n Compared to the Standard Normal Density Function ($N(0,1)$)

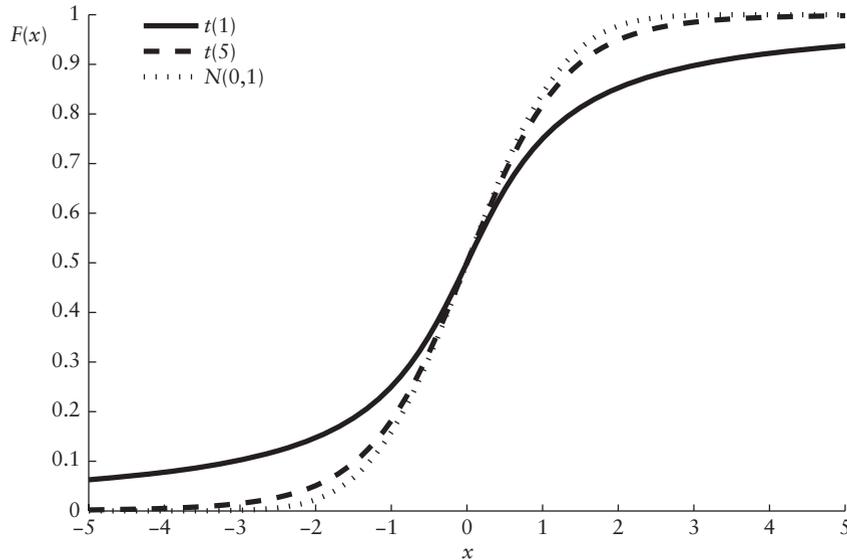

Figure 5 Distribution Function of the t -Distribution for Various Degrees of Freedom n Compared to the Standard Normal Density Function ($N(0,1)$)

against the standard normal density function. The same is done for the distribution function in Figure 5.

In general, the lower the degrees of freedom, the heavier the tails of the distribution, making extreme outcomes much more likely than for greater degrees of freedom or, in the limit, the normal distribution. This can be seen by the distribution function that we depicted in Figure 5 for $n = 1$ and $n = 5$ against the standard normal cumulative distribution function (cdf). For lower degrees of freedom such as $n = 1$, the solid curve starts to rise earlier and approach 1 later than for higher degrees of freedom such as $n = 5$ or the $N(0,1)$ case.

This can be understood as follows. When we rescale X by dividing by $\sqrt{S/n}$ as in equation (5), the resulting $X/\sqrt{S/n}$ obviously inherits randomness from both X and S . Now, when S is composed of few X_i , only, say $n = 3$, such that $X/\sqrt{S/n}$ has three degrees of freedom, there is a lot of dispersion from S relative to the standard normal distribution. By including more independent $N(0,1)$ random variables X_i such that the degrees of freedom increase, S becomes less dispersed. Thus, much uncertainty relative

to the standard normal distribution stemming from the denominator in $X/\sqrt{S/n}$ vanishes. The share of randomness in $X/\sqrt{S/n}$ originating from X alone prevails such that the normal characteristics preponderate. Finally, as n goes to infinity, we have something that is nearly standard normally distributed.

The mean of the Student's t random variable is zero, that is $E(X) = 0$, while the variance is a function of the degrees of freedom n as follows

$$\sigma^2 = \text{Var}(X) = \frac{n}{n-2}$$

For $n = 1$ and 2, there is no finite variance. Distributions with such small degrees of freedom generate extreme movements quite frequently relative to higher degrees of freedom. Precisely for this reason, stock price returns are often found to be modeled quite well using distributions with small degrees of freedom, or alternatively, large variances.

Application to Stock Returns

Let us resume the example at the end of the presentation of the normal distribution. We

consider, once again, the 5-day return Y with standard normal distribution. Suppose that now we do not know the variance. For this reason, at any point in time t , we rescale the observations of Y by

$$\sqrt{\frac{1}{5} \cdot (Y_{-1}^2 + Y_{-2}^2 + \cdots + Y_{-5}^2)}$$

where the $Y_{-1}^2, Y_{-2}^2, \dots, Y_{-5}^2$ are the five independent weekly returns immediately prior to Y . The resulting rescaled weekly returns

$$Z = \frac{Y}{\sqrt{Y_{-1}^2 + Y_{-2}^2 + \cdots + Y_{-5}^2}}$$

then are $t(5)$ distributed. The probability of Y not exceeding a value of 0.01 is now

$$P(Y \leq 0.01) = F(0.01) = 0.5083$$

where F is the cumulative distribution function of the Student's t -distribution with five degrees of freedom. Under the $N(0,1)$, this probability was about the same.

Again, we model the stock price after five days as $S_5 = S_0 \cdot e^Y$ where S_0 is today's price. As we know, when $Y \leq 0.01$, then $S_5 \leq S_0 \cdot e^{0.01} = S_0 \cdot 1.01$. Again, it follows that the stock price increases by at most 1% with probability of about 0.51. So far there is not much difference here between the standard normal and the $t(5)$ distribution.

Let's analyze the stock of American International Group (AIG) in September 2008. During one week, that is, five trading days, the stock lost about 67% of its value. That corresponds to a value of the 5-day return of $Y = -1.0986$ because of $e^Y = e^{-1.0986} = 0.3333 = 1 - 0.6667$. In the $N(0,1)$ model, a decline of this magnitude or even worse would occur with probability

$$P(Y \leq -1.0986) = \Phi(-1.0986) = 13.6\%$$

while under the $t(5)$ assumption, we would obtain

$$P(Y \leq -1.0986) = F(-1.0986) = 16.1\%$$

This is 2.5% more likely in the $t(5)$ model. So, stock price returns exhibiting extreme move-

ments such as that of the AIG stock price should not be modeled using the normal distribution.

F-DISTRIBUTION

Our next distribution is the F -distribution. It is defined as follows. Let $X \sim \chi^2(n_1)$ and $Y \sim \chi^2(n_2)$.

Furthermore, assuming X and Y to be independent, then the ratio

$$F(n_1, n_2) = \frac{X/n_1}{Y/n_2} \quad (7)$$

has an F -distribution with n_1 and n_2 degrees of freedom inherited from the underlying chi-square distributions of X and Y , respectively. We see that the random variable in equation (7) assumes nonnegative values only because neither X nor Y are ever negative. Hence, the support is on the nonnegative real numbers. Also like the chi-square distribution, the F -distribution is skewed to the right.

The F -distribution has a rather complicated looking density function of the form

$$f(x) = \begin{cases} \frac{F\left(\frac{n_1+n_2}{2}\right)}{F\left(\frac{n_1}{2}\right)F\left(\frac{n_2}{2}\right)} \cdot \left(\frac{n_1}{n_2}\right)^{n_1/2} \cdot \frac{x^{n_1/2-1}}{\left[1+x \cdot \frac{n_1}{2}\right]^{\frac{n_1+n_2}{2}}}, & x \geq 0 \\ 0, & x < 0 \end{cases} \quad (8)$$

Figure 6 displays the density function (8) for various degrees of freedom. As the degrees of freedom n_1 and n_2 increase, the function graph becomes more peaked and less asymmetric while the tails lose mass.

The mean is given by

$$E(X) = \frac{n_2}{n_2 - 2}, \quad \text{for } n_2 > 2 \quad (9)$$

while the variance equals

$$\sigma^2 = \text{Var}(X) = \frac{2n_2^2(n_1 + n_2 - 2)}{n_1(n_2 - 2)^2(n_2 - 4)}, \quad \text{for } n_2 > 4 \quad (10)$$

Note that according to equation (9), the mean is not affected by the degrees of freedom n_1 of

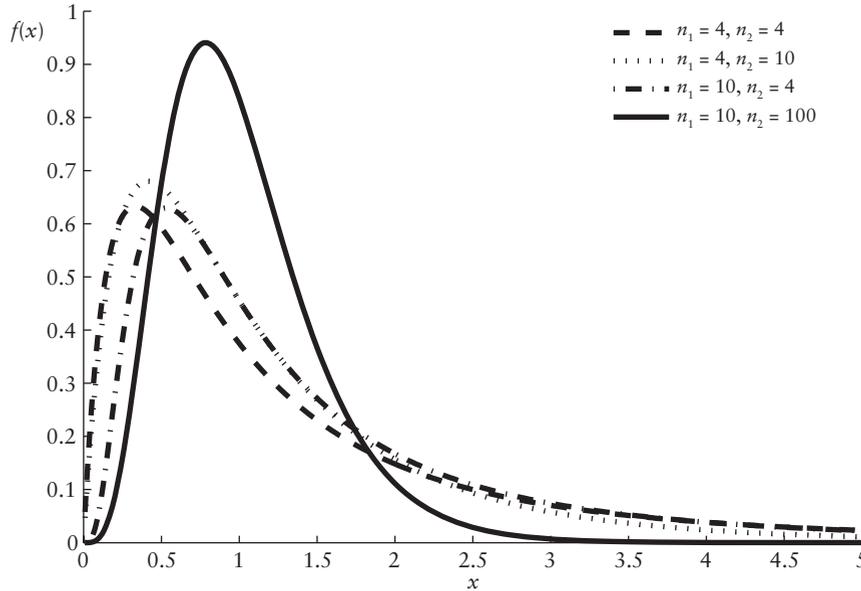

Figure 6 Density Function of the F -Distribution for Various Degrees of Freedom n_1 and n_2

the first chi-square random variable, while the variance in equation (10) is influenced by the degrees of freedom of both random variables.

EXPONENTIAL DISTRIBUTION

The *exponential distribution* is characterized by the positive real-valued parameter λ . In brief, we use the notation $Exp(\lambda)$. An exponential random variable assumes nonnegative values only. The density defined for $\lambda > 0$ by

$$f(x) = \begin{cases} \lambda \cdot e^{-\lambda x}, & x \geq 0 \\ 0 & x < 0 \end{cases}$$

is right skewed. Figure 7 presents the density function for various parameter values λ .

The distribution function is obtained by simple integration as

$$F(x) = 1 - e^{-\lambda x}$$

For identical parameter values as in Figure 7, we have plots of the exponential distribution function shown in Figure 8.

For this distribution, both the mean and variance are relatively simple functions of the pa-

rameter. That is, for the mean

$$E(X) = \frac{1}{\lambda}$$

and for the variance

$$Var(X) = \frac{1}{\lambda^2}$$

There is an inverse relationship between the exponential distribution and the Poisson distribution. Suppose we have a Poisson random variable N with parameter λ , i.e., $N \sim Poi(\lambda)$, counting the occurrences of some event within a time frame of length T . Furthermore, let X_1, X_2, \dots be the $Exp(\lambda)$ distributed interarrival times between the individual occurrences. That is between time zero and the first event, X_1 units of time have passed, between the first event and the second, X_2 units of time have elapsed, and so on. Now, over these T units of time, we expect $T \cdot \lambda = T \cdot E(N)$ events to occur. Alternatively, we have an average of $T/(T \cdot \lambda) = 1/\lambda = E(X)$ units of time to wait between occurrences.

Suppose that by time T we have counted exactly n events. Then the accrued time τ elapsed when the event occurs for the n th time is obtained by the sum of all individual interarrival

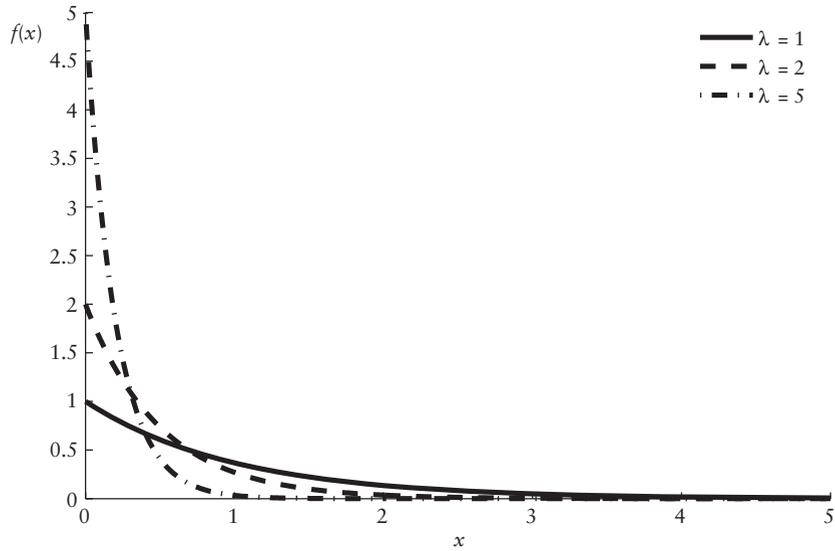

Figure 7 Exponential Density Function for Various Parameter Values λ

times X_1, X_2, \dots, X_n , which cannot be greater than T . Formally

$$\tau = \sum_i^n X_i \leq T \quad (11)$$

A result of this relationship is

$$E(N) = \lambda = \frac{1}{E(X)}$$

The exponential distribution is commonly referred to as a distribution with a “no memory” property in the context of life-span that ends due to some break.

That means that there is no difference in the probability between the following two events. Event one states that the object will live for the first τ units of time after the object’s creation while event two states that the object will

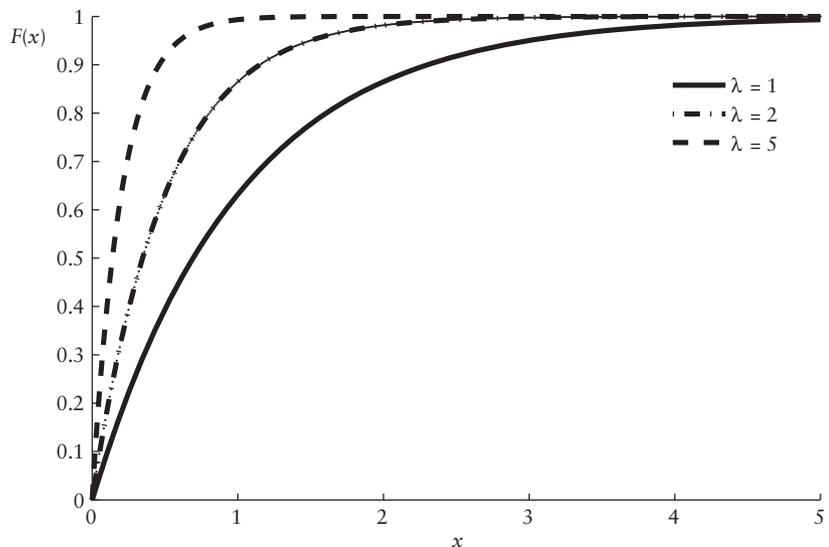

Figure 8 Distribution Function $F(x)$ of the Exponential Distribution for Various Parameter Values λ

continue living for the next τ units of time after it has already survived some t units of time. In other words, if some *interarrival time* or *survival time* (i.e., the time between certain occurrences) is $Exp(\lambda)$ distributed, one starts all over waiting at any given time t provided that the break has not occurred yet. (Technically, these considerations as well as the following equation (12) require the understanding of the notion *conditional distributions*. Here it will suffice to apply pure intuition.) So, for example, let the time until the next default of one of several corporate bonds held in some portfolio be given as an exponential random variable. Then the probability of the first bond defaulting in no more than t units of time given that none have defaulted so far is the same as the probability of the n th bond defaulting after at most t units of time given that $n - 1$ bonds have already defaulted. That is, we only care about the probability distribution of the time of occurrence of the next default regardless of how many bonds have already defaulted.

Finally, an additional property of the exponential distribution is its relationship to the chi-square distribution. Let X be $Exp(\lambda)$. Then X is also chi-square distributed with two degrees of freedom, that is, $X \sim \chi^2(2)$.

Applications in Finance

In applications in finance, the parameter λ often has the meaning of a *default rate*, *default intensity*, or *hazard rate*. This can be understood by observing the ratio

$$\frac{P(X \in (t, t + dt])}{dt \cdot P(X > t)} \quad (12)$$

which expresses the probability of the event of interest such as default of some company occurring between time t and $t + dt$ given that it has not happened by time t , relative to the length of the horizon, dt . Now, let the length of the interval, dt , approach zero, and this ratio in equation (12) will have λ as its limit.

The exponential distribution is often used in credit risk models where the number of defaulting bonds or loans in some portfolio

over some period of time is represented by a Poisson random variable and the random times between successive defaults by exponentially distributed random variables. In general, then, the time until the n th default is given by the sum in equation (11).

Consider, for example, a portfolio of bonds. Moreover, we consider the number of defaults in this portfolio in one year to be some Poisson random variable with parameter $\lambda = 5$, that is, we expect five defaults per year. The same parameter, then, represents the default intensity of the exponentially distributed time between two successive defaults, that is, $\tau \sim Exp(5)$, so that on average, we have to wait $E(\tau) = 1/5$ of a year or 2.4 months. For example, the probability of less than three months (i.e., $1/4$ of a year) between two successive defaults is given by

$$P(\tau \leq 0.25) = 1 - e^{-5 \cdot 0.25} = 0.7135$$

or roughly 71%. Now, the probability of no default in any given year is then

$$P(\tau > 1) = e^{-5 \cdot 1} = 0.0067$$

or 0.67%.

RECTANGULAR DISTRIBUTION

The simplest continuous distribution we are going to introduce is the *rectangular distribution*. Often, it is used to generate simulations of random outcomes of experiments via transformation. If a random variable X is rectangular distributed, we denote this by $X \sim Re(a, b)$ where a and b are the parameters of the distribution.

The support is on the real interval $[a, b]$. The density function is given by

$$f(x) = \begin{cases} \frac{1}{b-a}, & a \leq x \leq b \\ 0 & x \notin [a, b] \end{cases} \quad (13)$$

We see that this density function is always constant, either zero or between the bounds a and b , equal to the inverse of the interval width. Figure 9 displays the density function (13) for some general parameters a and b .

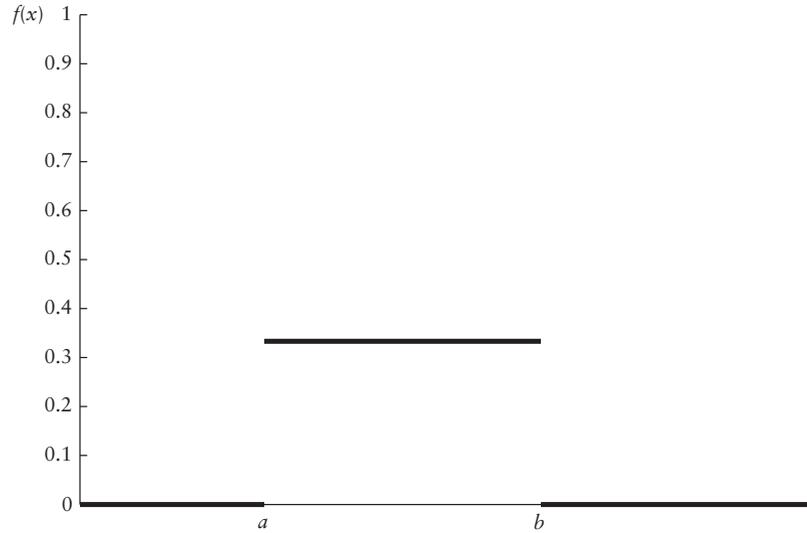

Figure 9 Density Function of a $Re(a, b)$ Distribution

Through integration, the distribution function follows in the form

$$F(x) = \begin{cases} 0 & x < a \\ \frac{1}{b-a} & a \leq x \leq b \\ 1 & x > b \end{cases} \quad (14)$$

The mean is equal to

$$E(X) = \frac{a+b}{2}$$

$$Var(X) = \frac{(b-a)^2}{12}$$

In Figure 10, we have the distribution function given by equation (14) with some general parameters a and b . By analyzing the plot, we can see that the distribution function is not differentiable at a or b , since the derivatives of F do not exist for these values. At any other real

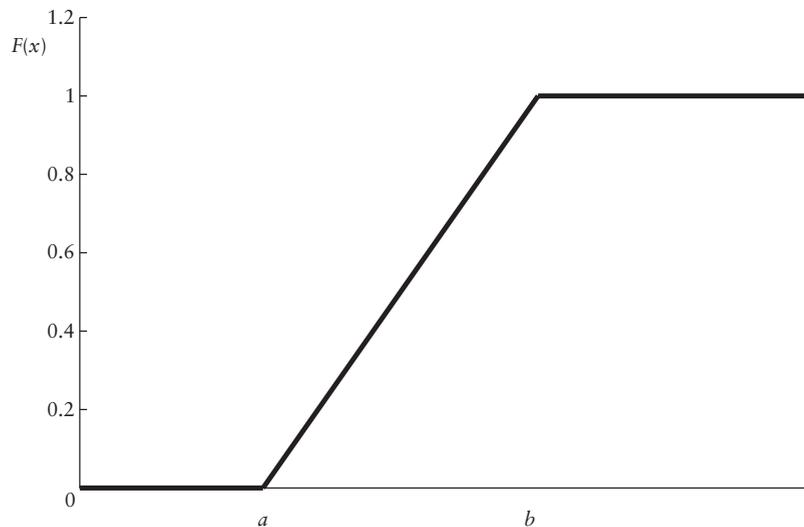

Figure 10 Distribution Function of a $Re(a, b)$ Distribution

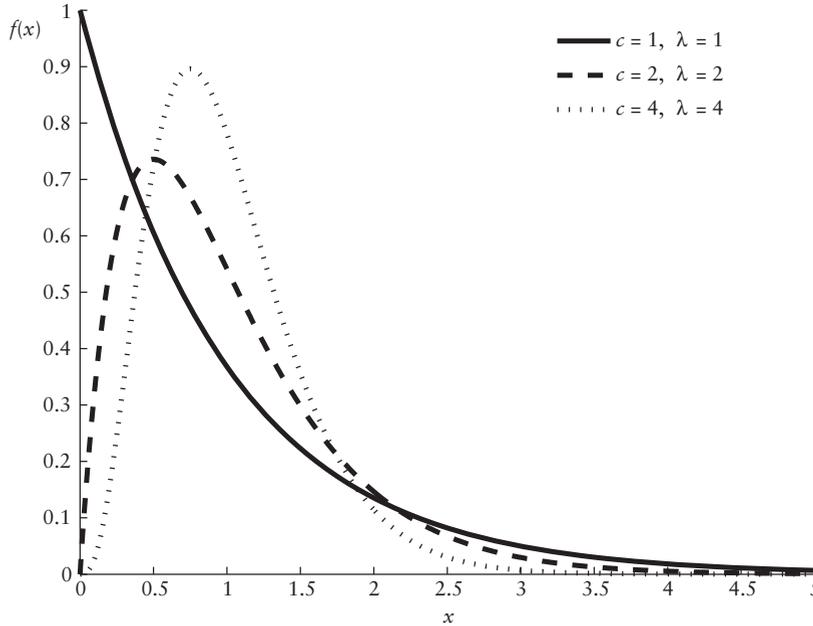

Figure 11 Density Function of a Gamma Distribution $Ga(\lambda, b)$

value x , the derivative exists (being 0) and is continuous. We say in the latter case that f is *smooth* there.

GAMMA DISTRIBUTION

Next we introduce the *gamma distribution* for positive, real-valued random variables. Characterized by two parameters, λ and c , this distribution class embraces several special cases. It is skewed to the right with support on the positive real line. We denote that a random variable X is gamma distributed with parameter λ and c by writing $X \sim Ga(\lambda, c)$ where λ and c are positive real numbers.

The density function is given by

$$f(x) = \begin{cases} \frac{\lambda(\lambda x)^{c-1} \exp\{-\lambda x\}}{\Gamma(c)}, & x > 0 \\ 0 & x \leq 0 \end{cases} \quad (15)$$

with gamma function Γ . A plot of the density function from equation (15) is provided in

Figure 11. The distribution function is

$$F(x) = \begin{cases} 0 & x < 0 \\ \frac{\int_0^{\lambda x} u^{c-1} e^{-u} du}{b^c \Gamma(c)}, & x \geq 0 \end{cases}$$

The mean is

$$E(X) = \frac{c}{\lambda}$$

with variance

$$Var(X) = \frac{c}{\lambda^2}$$

Erlang Distribution

A special case is the *Erlang distribution*, which arises for natural number values of the parameter c , that is, $c \in \mathbb{N}$. The intuition behind it is as follows. Suppose we have c exponential random variables with the same parameter λ , that is, $X_1, X_2, \dots, X_c \sim Exp(\lambda)$ all being independent of each other. Then the sum of these

$$S = \sum_{i=1}^c X_i$$

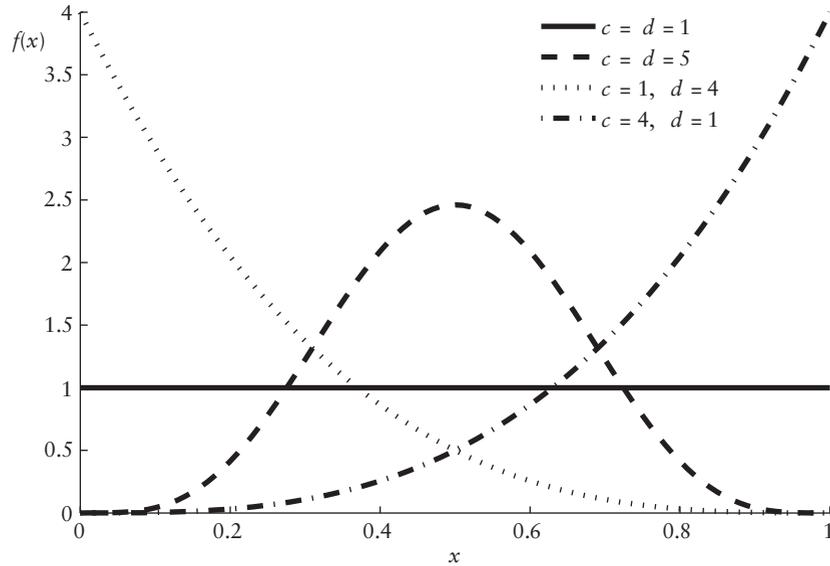

Figure 12 Density Function of a Beta Distribution $Be(c, d)$

is distributed $Ga(\lambda, c)$ such that the resulting distribution function is

$$F(s) = \begin{cases} 0 & s < 0 \\ 1 - e^{-\lambda s} \sum_{i=1}^{c-1} \frac{(\lambda s)^i}{i!}, & s \geq 0 \end{cases}$$

So, when we add the identically $Exp(\lambda)$ distributed interarrival times until the c th default, for example, the resulting combined waiting time is Erlang distributed with parameters c and λ .

BETA DISTRIBUTION

The *beta distribution* is characterized by the two parameters c and d that are any positive real numbers. We abbreviate this distribution by $Be(c, d)$. It has a density function with support on the interval $[0,1]$, that is, only for $x \in [0,1]$ does the density function assume positive values. In the context of credit risk modeling, it commonly serves as an approximation for generating random defaults when the true underlying probabilities of default of certain companies are unknown.

The density function is defined by

$$f(x) = \begin{cases} \frac{1}{B(c, d)} x^{c-1} (1-x)^{d-1}, & 0 \leq x \leq 1 \\ 0 & \text{else} \end{cases}$$

where $B(c, d)$ denotes the *beta function* with parameters c and d . The density function may assume various different shapes depending on c and d . For a few exemplary values, we present the plots in Figure 12. As we can see, for $c = d$, the density function is symmetric about $x = 0.5$.

LOG-NORMAL DISTRIBUTION

Another important distribution in finance is the *log-normal distribution*. It is connected to the normal distribution via the following relationship. Let Y be a normal random variable with mean μ and variance σ^2 . Then the random variable

$$X = e^Y$$

is log-normally distributed with parameters μ and σ^2 . In brief, we denote this distribution by $X \sim Ln(\mu, \sigma^2)$.

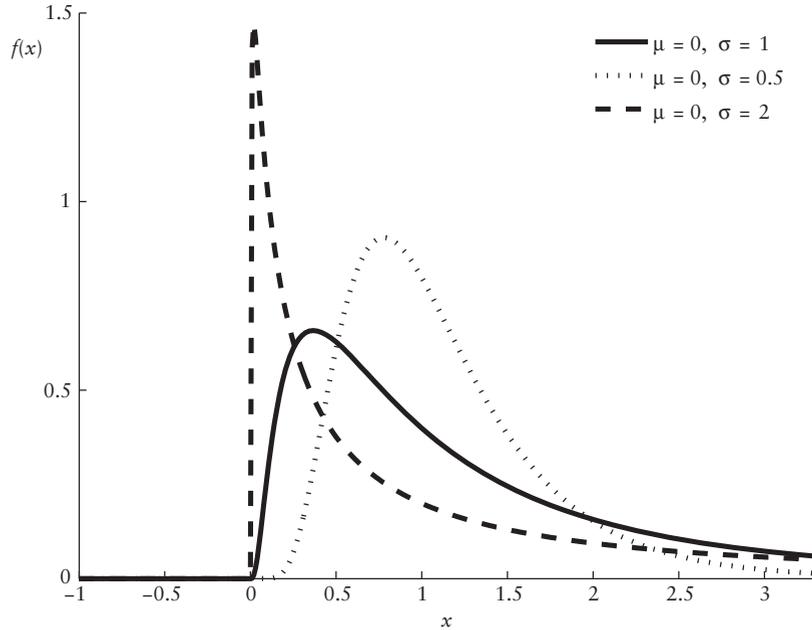

Figure 13 Density Function of the Log-Normal Distribution for Various Values of μ and σ^2

Since the exponential function $e^Y = \exp(Y)$ only yields positive values, the support of the log-normal distribution is on the positive half of the real line only, as will be seen by its density function given by

$$f(x) = \begin{cases} \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{(\ln x - \mu)^2}{2\sigma^2}}, & x > 0 \\ 0 & \text{else} \end{cases} \quad (16)$$

which looks strikingly similar to the normal density function given by (2). Figure 13 depicts the density function for several parameter values.

This density function results in the log-normal distribution function

$$F(x) = \Phi\left(\frac{\ln x - \mu}{\sigma}\right)$$

where $\Phi(\cdot)$ is the distribution function of the standard normal distribution. (This is the result of the one-to-one relationship between the values of a log-normal and a standard normal random variable.) A plot of the distribution function for different parameter values can be found in Figure 14.

Mean and variance of a log-normal random variable are

$$E(X) = e^{(\mu + \sigma^2/2)} \quad (17)$$

and

$$\text{Var}(X) = e^{\sigma^2} (e^{\sigma^2} - 1) e^{2\mu} \quad (18)$$

Application to Modeling Asset Returns

The reason for the popularity of the log-normal distribution is that logarithmic asset returns r have been historically modeled as normally distributed such that the related asset prices are modeled by a log-normal distribution. That is, let P_t denote today's asset price and, furthermore, let the daily return r be $N(\mu, \sigma^2)$. Then in a simplified fashion, tomorrow's price is given by $P_{t+1} = P_t \cdot e^r$ while the percentage change between the two prices, e^r , is log-normally distributed, that is, $Ln(\mu, \sigma^2)$.

The log-normal distribution is closed under special operations as well. If we let the n

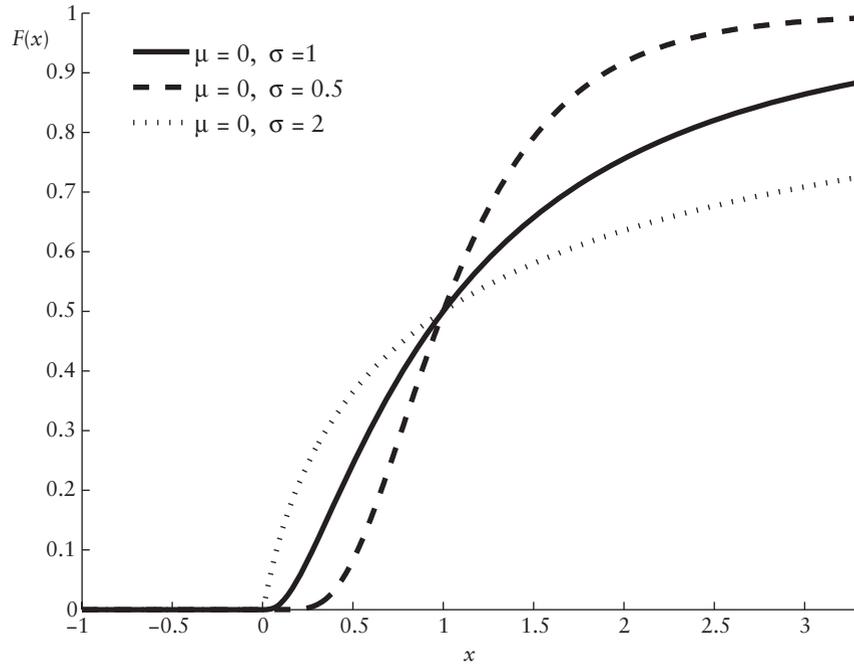

Figure 14 Distribution Function of the Log-Normal Distribution for Various Parameter Values μ and σ^2

random variables X_1, \dots, X_n be log-normally distributed each with parameters μ and σ^2 and uninfluenced by each other, then multiplying all of these and taking the n th root we have that

$$\sqrt[n]{\prod_{i=1}^n X_i} \sim Ln(\mu, \sigma^2)$$

where the product sign is defined as

$$\prod_{i=1}^n X_i \equiv X_1 \times X_2 \times \dots \times X_n$$

As an example, we consider a very simplified stock price model. Let $S = \$100$ be today's stock price of some company. We model tomorrow's price S_1 as driven by the 1-day dynamic X from the previous example of the normal distribution. In particular, the model is

$$S_1 = S_0 \cdot e^X$$

By some slight manipulation of the above equation, we see that the ratio of tomorrow's

price over today's price

$$\frac{S_1}{S_0} = e^X$$

follows a log-normal distribution with parameters μ and σ , that is, $S_1/S_0 \sim LN(\mu, \sigma^2)$. We may now be interested in the probability that tomorrow's price is greater than \$120; that is,

$$\begin{aligned} P(S_1 > 120) &= P(S_0 e^X > 120) \\ &= P(100 \cdot e^X > 120) \end{aligned}$$

This corresponds to

$$\begin{aligned} P\left(\frac{S_1}{S_0} > \frac{120}{S_0}\right) &= P(e^X > 1.20) \\ &= 1 - P(e^X \leq 1.20) \\ &= 1 - F(1.2) \\ &= 1 - 0.8190 = 0.1810 \end{aligned}$$

where in the third equation on the right-hand side, we have applied the log-normal cumulative probability distribution function F . So, in roughly 18% of the scenarios, tomorrow's stock price S_1 will exceed the price of today, $S_0 = \$100$,

by at least 20%. From equation (17), the mean of the ratio is

$$E\left(\frac{S_1}{S_0}\right) = \mu_{S_1/S_0} = e^{0+\frac{0.2}{2}} = 1.1052$$

implying that we have to expect tomorrow's stock price to be roughly 10% greater than today, even though the dynamic X itself has an expected value of 0. Finally, equation (18) yields the variance

$$\text{Var}\left(\frac{S_1}{S_0}\right) = \sigma_{S_1/S_0}^2 = e^{0.2}(e^{0.2} - 1) = 0.2704$$

which is only slightly larger than that of the dynamic X itself.

The statistical concepts learned to this point can be used for pricing certain types of derivative instruments such as the Black-Scholes option pricing model.

KEY POINTS

- The more commonly used distributions with appealing statistical properties that are used in finance are the normal distribution, the chi-square distribution, the Student's t -distribution, the Fisher's F -distribution, the exponential distribution, the gamma, the beta distribution, and the log-normal distribution.
- The normal distribution is probably the most famous probability distribution. Its popularity is credited to the fact that it serves as the distribution of many random sums of random variables. Moreover, it serves as the origin for many other probability distributions with appealing properties.
- The empirical rule is helpful in assessing how the data of most samples are dispersed even if we do not know the underlying distribution. The theoretical counterpart, the Chebychev inequality, provides limits for the dispersion of any probability distribution whose variance we know.
- Logarithmic returns in contrast to percentage returns is the most commonly used method to express changes of asset prices. The reason for the widespread use of returns computed in terms of logarithms lies in the simple mathematical tractability of their form. Moreover, their intuitive appeal results from the fact that they can be understood as the relative price changes obtained from constant trading.
- The default intensity finds extended use in financial models considering stochastic default such as the default of some bond in a bond portfolio. It expresses the probability of defaulting within the next unit of time interval as we let the length of this interval approach zero.
- The interarrival time is the random variable associated with the time between two successive random events. For example, for a bond portfolio manager it is of interest to model the time between some default in the portfolio and the next default. Commonly, the interarrival time is modeled as an exponential random variable.

NOTES

1. There exist generalizations such that the distributions need no longer be identical. However, this is beyond the scope of this entry.
2. For values near 0, the logarithmic return X is virtually equal to the multiplicative return R . Rounding to two decimals, they are both equal to 0.01 here.
3. For some computer software, the probability will be given as 0.5 due to rounding.

Abstract: Continuous probability distributions are commonly the preferred candidates when modeling financial asset returns. The most popular of them is unquestionably the normal distribution because of its appealing properties as well as the fact that it serves as the limit distribution for many sums of random variables such as, for example, aggregated returns. The normal distribution generally renders modeling easy because all moments exist. However, the normal distribution fails to reflect stylized facts commonly encountered in asset returns, namely, the possibility of very extreme movements and skewness. To remedy this shortcoming, probability distributions accounting for such extreme price changes have become increasingly popular. Some of these distributions concentrate exclusively on extreme values and others permit any real number, but in a manner that is capable of reflecting market behavior. Consequently, there is a selection of probability distributions that can realistically reproduce asset price changes. Their common shortcoming is generally that they are mathematically difficult to handle.

In this entry, we present a collection of continuous probability distributions that are used in finance in the context of modeling extreme events. Although there are distributions that are appealing in nature due to their mathematical simplicity, the ones introduced in this entry are sometimes rather complicated, using parameters that are not necessarily intuitive. However, due to the observed behavior of many quanti-

ties in finance, there is a need for more flexible distributions compared to keeping models mathematically simple.

While the Student's t -distribution is able to mimic some behavior inherent in financial data such as so-called *heavy tails* (which means that a lot of the probability mass is attributed to extreme values), it fails to capture other observed behavior such as skewness. Hence,

we decided not to include the Student's t -distribution in this entry.

In this entry, we present the generalized extreme value distribution, the generalized Pareto distribution, the normal inverse Gaussian distribution, and the α -stable distribution together with their parameters of location and spread. The presentation of each distribution is accompanied by some illustration to help render the theory more appealing.

GENERALIZED EXTREME VALUE DISTRIBUTION

Sometimes it is of interest to analyze the probability distribution of extreme values of some random variable rather than the entire distribution. This occurs in risk management (including operational risk, credit risk, and market risk) and risk control in portfolio management. For example, a portfolio manager may be interested in the maximum loss a portfolio might incur with a certain probability. For this purpose, *generalized extreme value (GEV) distributions* are designed. They are characterized by the real-valued parameter ξ . Thus, the abbreviated appellation for this distribution is $GEV(\xi)$.

Technically, one considers a series of identically distributed random variables X_1, X_2, \dots, X_n , which are independent of each other so that each one's value is unaffected by the others' outcomes. Now, the GEV distributions become relevant if we let the length of the series n become ever larger and consider its largest value, that is, the maximum.

The distribution is not applied to the data immediately but, instead, to the so-called *standardized data*. Basically, when standardizing data x , one reduces the data by some constant real parameter a and divides it by some positive parameter b so that one obtains the quantity $(x - a)/b$. (Standardization is a linear transform of the random variable such that its location parameter becomes zero and its scale one.) The parameters are usually chosen such that this standardized quantity has zero mean and unit variance. We have to point out that neither vari-

ance nor mean have to exist for all probability distributions.

Extreme value theory, a branch of statistics that focuses solely on the extremes (tails) of a distribution, distinguishes between three different types of generalized extreme value distributions: Gumbel distribution, Fréchet distribution, and Weibull distribution. In the extreme value theory literature, these distributions are referred to respectively as Type I, Type II, and Type III. (See Embrechts, Klüppelberg, and Mikosch [2003], De Haan and Ferreira [2006], and Kotz and Nadarajah [2002].) The three types are related in that we obtain one type from another by simply varying the value of the parameter ξ . This makes GEV distributions extremely pleasant for handling financial data.

For the *Gumbel distribution*, the general parameter is zero (i.e., $\xi = 0$) and its density function is

$$f(x) = e^{-x} \exp \{-e^{-x}\}$$

A plot of this density is given by the dashed graph in Figure 1 that corresponds to $\xi = 0$. The distribution function of the Gumbel distribution is then

$$F(x) = \exp \{-e^{-x}\}$$

Again, for $\xi = 0$, we have the distribution function displayed by the dashed graph in Figure 2.

The second $GEV(\xi)$ distribution is the *Fréchet distribution*, which is given for $\xi > 0$ and has density

$$f(x) = (1 + \xi x)^{-\xi-1} \cdot \exp\{-x^{-\xi}\}$$

with corresponding distribution function

$$F(x) = \exp \left\{ -(1 + \xi x)^{-1/\xi} \right\}$$

Note that the prerequisite $1 + \xi x > 0$ has to be met. For a parameter value of $\xi = 0.5$, an example of the density and distribution function is given by the dotted graphs in Figures 1 and 3, respectively.

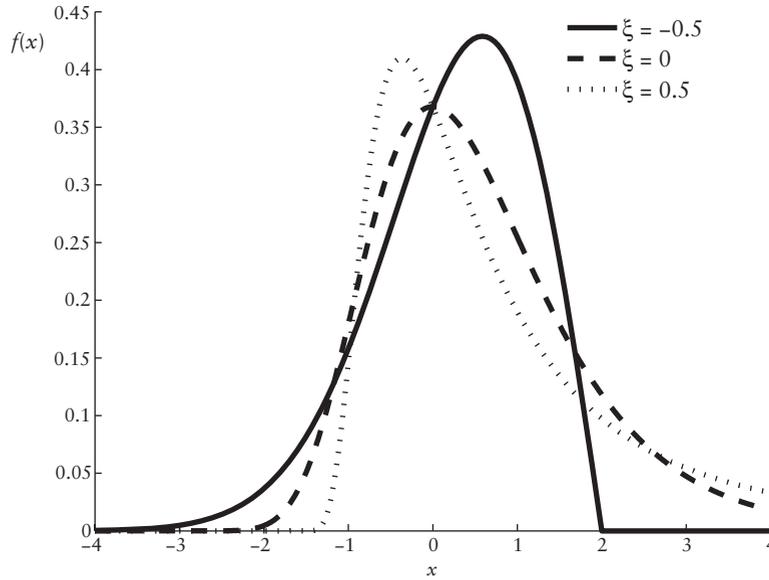

Figure 1 $GEV(\xi)$ Density Function for Various Parameter Values

Finally, the *Weibull distribution* corresponds to $\xi < 0$. It has the density function

$$f(x) = (1 + \xi x)^{-\xi-1} \cdot \exp \{-x^{-\xi}\}$$

A plot of this distribution can be seen in Figure 1, with $\xi = -0.5$ (solid line). Again, $1 + \xi x > 0$ has to be met. It is remarkable that

the density function graph vanishes in a finite right end point, that is, becomes zero. Thus, the support is on $(-\infty, -1/\xi)$. The corresponding distribution function is

$$F(x) = \exp \{-(1 + x)^{-1/\xi}\}$$

a graph of which is depicted in Figure 2 for $\xi = -0.5$ (solid line).

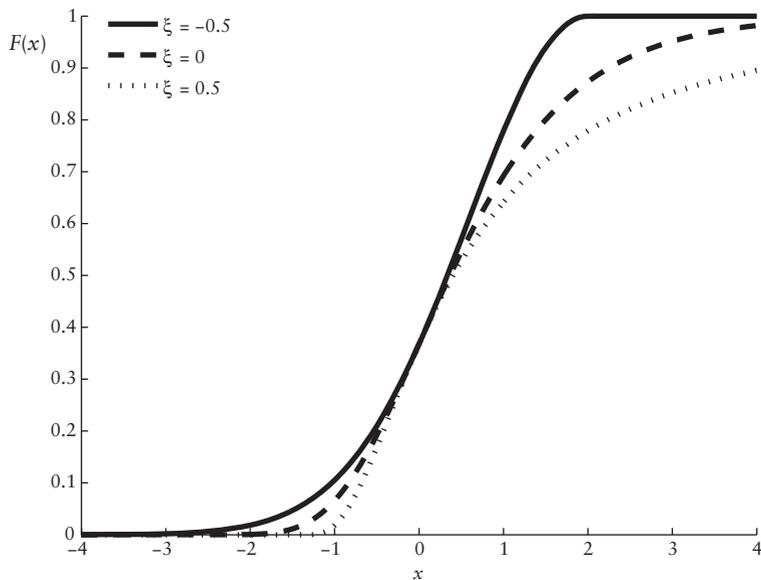

Figure 2 $GEV(\xi)$ Distribution Function for Various Parameter Values

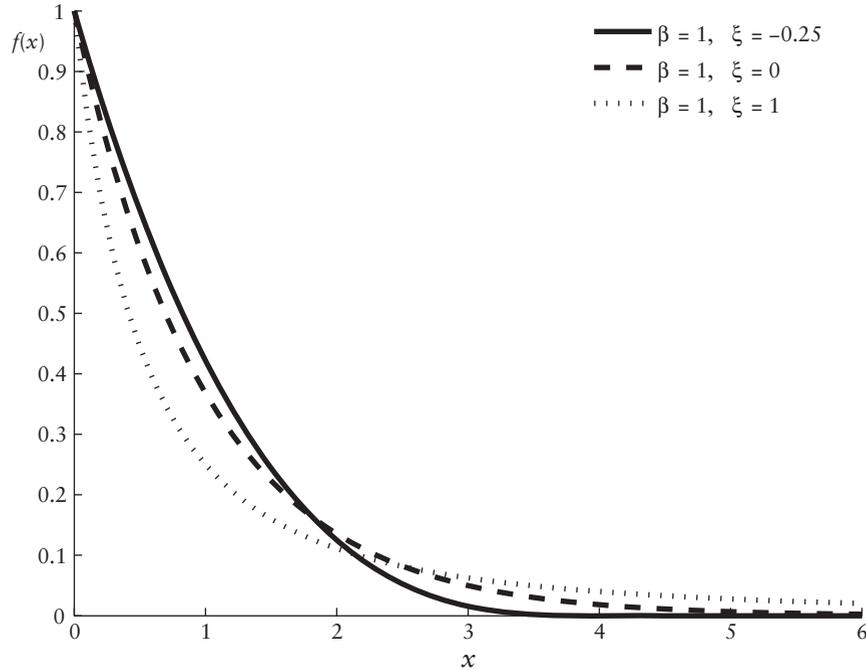

Figure 3 Generalized Pareto Density Function for Various Parameter Values

Notice that the extreme parts of the density function (i.e., the tails) of the Fréchet distribution vanish more slowly than that of the Gumbel distribution. Consequently, a Fréchet type distribution should be applied when dealing with scenarios of large extremes.

GENERALIZED PARETO DISTRIBUTION

A distribution often employed to model large values, such as price changes well beyond the typical change, is the *generalized Pareto distribution* or, as we will often refer to it here, simply *Pareto distribution*. This distribution serves as the distribution of the so called “peaks over thresholds,” which are values exceeding certain benchmarks or loss severity.

For example, consider n random variables X_1, X_2, \dots, X_n that are all identically distributed and independent of each other. Slightly idealized, they might represent the returns of some stock on n different observation days. As the

number of observations n increases, suppose that their maximum observed return follows the distribution law of a GEV distribution with parameter ξ . Furthermore, let u be some sufficiently large threshold return. Suppose that on day i , the return exceeded this threshold. Then, given the exceedance, the amount return X_i surpassed u by, that is, $X_i - u$, is a generalized Pareto distributed random variable.

The following density function characterizes the Pareto distribution

$$f(x) = \begin{cases} \frac{1}{\beta} \left(1 + \xi \frac{x}{\beta}\right)^{-1-1/\xi}, & x \geq 0 \\ 0 & \text{else} \end{cases}$$

with $\beta > 0$ and $1 + (\xi x)/\beta > 0$. Hence, the distribution is right skewed since the support is only on the positive real line. The corresponding distribution function is given by

$$F(x) = \frac{1}{\beta} \left(1 + \xi \frac{x}{\beta}\right)^{-1-1/\xi}, \quad x \geq 0$$

As we can see, the Pareto distribution is characterized by two parameters β and ξ . In brief,

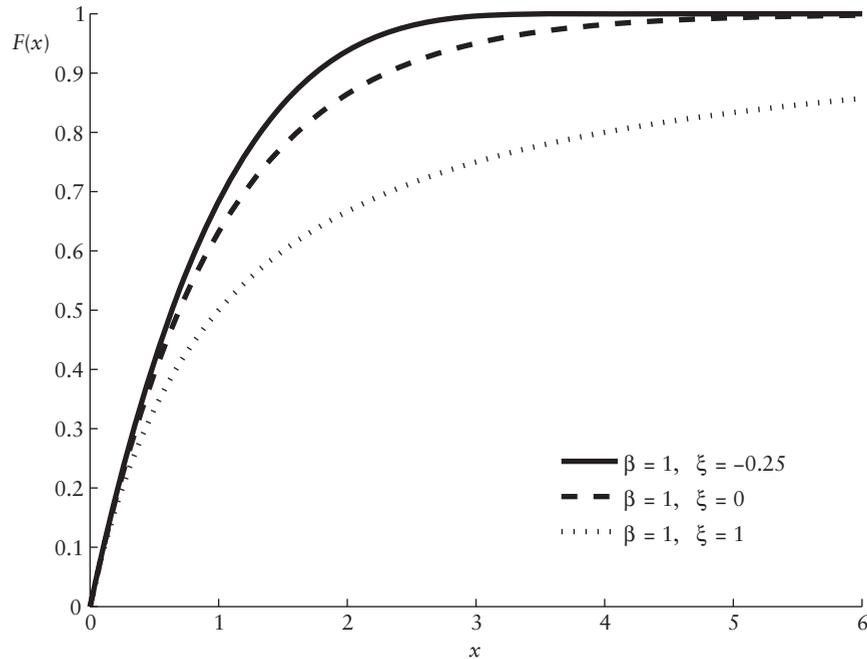

Figure 4 Generalized Pareto Distribution Function for Various Parameter Values

the distribution is denoted by $Pa(\beta, \xi)$. The parameter β serves as a scale parameter while the parameter ξ is responsible for the overall shape as becomes obvious by the density plots in Figure 3. The distribution function is displayed, in Figure 4, for a selection of parameter values.

For $\beta < 1$, the mean is

$$E(X) = \beta/1 - \xi$$

When β becomes very small approaching zero, then the distribution results in the exponential distribution with parameter $\lambda = 1/\beta$.

The Pareto distribution is commonly used to represent the tails of other distributions. For example, while in neighborhoods about the mean, the normal distribution might serve well to model financial returns; for the tails (i.e., the end parts of the density curve), however, one might be better advised to apply the Pareto distribution. The reason is that the normal distribution may not assign sufficient probability to more pronounced price changes measured in log-returns. On the other hand, if one wishes to model behavior that attributes less probability

to extreme values than the normal distribution would suggest, this could be accomplished by the Pareto distribution as well. The reason why the class of the Pareto distributions provides a prime candidate for these tasks is due to the fact that it allows for a great variety of different shapes one can smoothly obtain by altering the parameter values.

NORMAL INVERSE GAUSSIAN DISTRIBUTION

Another candidate for the modeling of financial returns is the *normal inverse Gaussian distribution*. It is considered suitable since it assigns a large amount of probability mass to the tails. This reflects the inherent risks in financial returns that are neglected by the normal distribution since it models asset returns behaving more moderately. But in recent history, we have experienced more extreme shocks than the normal distribution would have suggested with reasonable probability.

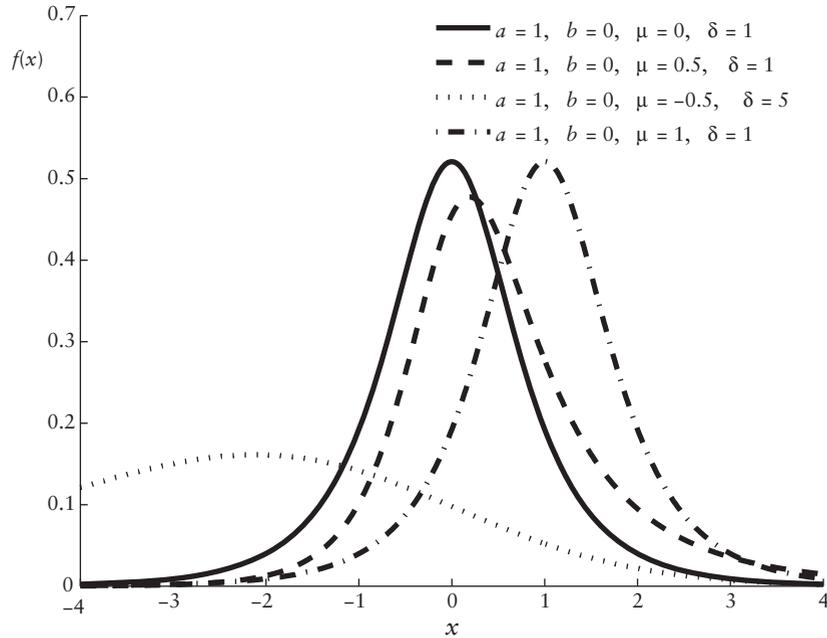

Figure 5 Normal Inverse Gaussian Density Function for Various Parameter Values

The distribution is characterized by four parameters, a , b , μ , and δ . In brief, the distribution is denoted by $NIG(a, b, \mu, \delta)$. For real values x , the density function is given by

$$f(x) = \frac{a \cdot \delta}{\pi} \exp \left\{ \delta \sqrt{a^2 - b^2} + b(x - \mu) \right\} \times \frac{K_1 \left(a \sqrt{\delta^2 + (x - \mu)^2} \right)}{\sqrt{\delta^2 + (x - \mu)^2}}$$

where K_1 is the so-called *Bessel function of the third kind*. In Figure 5, we display the density function for a selection of parameter values.

The distribution function is, as in the normal distribution case, not analytically presentable. It has to be determined with the help of numerical methods. We display the distribution function for a selection of parameter values in Figure 6.

The parameters have the following interpretation. Parameter a determines the overall shape of the density while b controls skewness. The location or position of the density function is governed via parameter μ and δ is responsible for scaling. These parameters have values

according to the following

$$\begin{aligned} a &> 0 \\ 0 &\leq b < a \\ \mu &\in \mathbb{R} \\ \delta &> 0 \end{aligned}$$

The mean of a *NIG* random variable is

$$E(X) = \mu + \frac{\delta \cdot b}{\sqrt{a^2 - b^2}}$$

and the variance is

$$\text{Var}(X) = \delta \frac{a^2}{\left(\sqrt{a^2 - b^2} \right)^3}$$

Normal Distribution versus Normal Inverse Gaussian Distribution

Due to a relationship to the normal distribution that is beyond the scope here, there are some common features between the normal and NIG distributions.

The *scaling property* of the *NIG* distribution guarantees that any *NIG* random variable multiplied by some real constant is again a *NIG* random variable. Formally, for some $k \in \mathbb{R}$ and

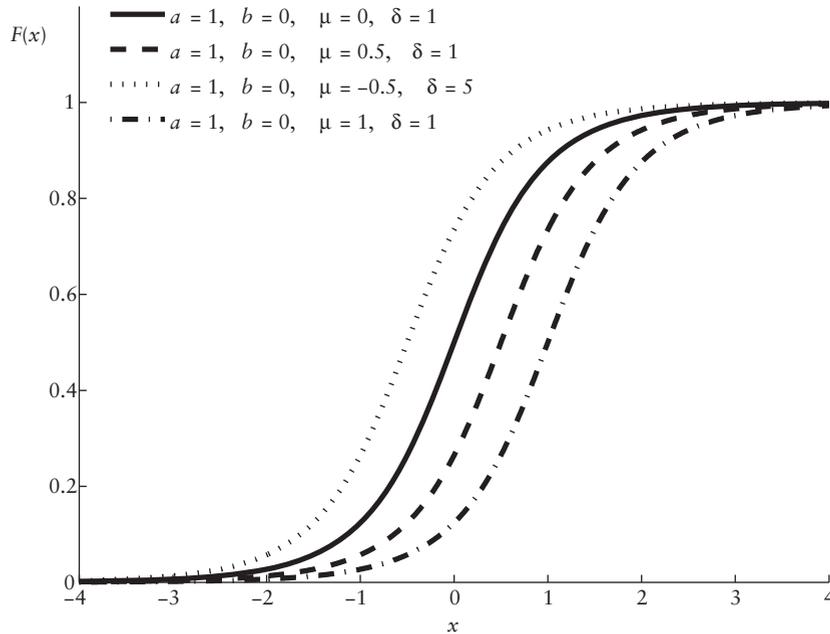

Figure 6 Normal Inverse Gaussian Distribution Function for Various Parameter Values

$X \sim NIG(a, b, \mu, \delta)$, we have that

$$k \cdot X \sim NIG\left(\frac{a}{k}, \frac{b}{k}, k \cdot \mu, k \cdot \delta\right) \quad (1)$$

Among others, the result in equation (1) implies that the factor k shifts the density function by the k -fold of the original position. Moreover, we can reduce skewness in that we inflate X by some factor k .

Also, the NIG distribution is summation stable such that, under certain prerequisites concerning the parameters, independent NIG random variables are again NIG . More precisely, if we have the random variables $X_1 \sim NIG(a, b, \mu_1, \delta_1)$ and $X_2 \sim NIG(a, b, \mu_2, \delta_2)$, the sum is $X_1 + X_2 \sim NIG(a, b, \mu_1 + \mu_2, \delta_1 + \delta_2)$. So, we see that only location and scale are affected by summation.

α -STABLE DISTRIBUTION

The final distribution we introduce is the class of α -stable distributions. (For a further discussion of stable distributions, see Samorodnitsky and Taquq [2000].) Often, these distri-

butions are simply referred to as *stable distributions*. While many models in finance have been modeled historically using the normal distribution based on its pleasant tractability, concerns have been raised that it underestimates the danger of downturns of extreme magnitude inherent in stock markets. The sudden declines of stock prices experienced during several crises since the late 1980s—October 19, 1987 (“Black Monday”), July 1997 (“Asian currency crisis”), 1998–1999 (“Russian ruble crisis”), 2001 (“Dot-com bubble”), and July 2007 and following (“Subprime mortgage crisis”)—are examples that call for distributional alternatives accounting for extreme price shocks more adequately than the normal distribution. This may be even more necessary considering that financial crashes with serious price movements might become even more frequent in time given the major events that transpired throughout the global financial markets in 2008. The immense threat radiating from heavy tails in stock return distributions made industry professionals aware of the urgency to take them seriously and reflect them in their models.

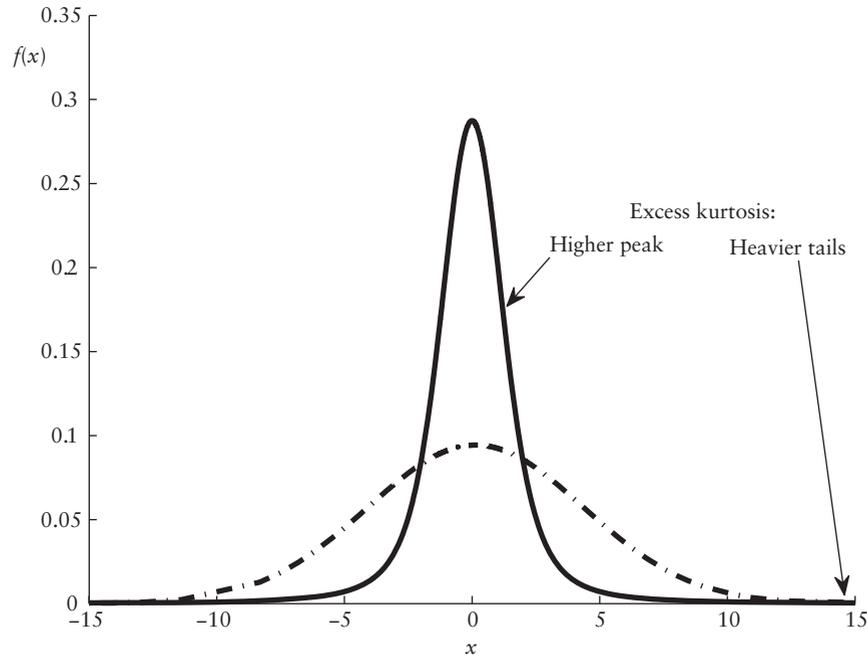

Figure 7 Comparison of the Normal (Dash-Dotted) and α -Stable (Solid) Density Functions

Many distributional alternatives providing more realistic chances to severe price movements are known, such as the Student's t , for example, or the GEV distributions presented earlier in this entry. In the early 1960s, Benoit Mandelbrot suggested as a distribution for commodity price changes the class of stable distributions. The reason is that, through their particular parameterization, they are capable of modeling moderate scenarios as supported by the normal distribution as well as extreme ones beyond the scope of most of the distributions that we have presented in this entry.

The stable distribution is characterized by the four parameters α , β , σ , and μ . In brief, we denote the α -stable distribution by $S(\alpha, \beta, \sigma, \mu)$. Parameter α is the so called *tail index* or *characteristic exponent*. It determines how much probability is assigned around the center and the tails of the distribution. The lower the value α , the more pointed about the center is the density and the heavier are the tails. These two features are referred to as *excess kurtosis* relative to the normal distribution. This can be visualized

graphically as we have done in Figure 7 where we compare the normal density to an α -stable density with a low $\alpha = 1.5$. The parameters for the normal distribution are $\mu = 0.14$ and $\sigma = 4.23$. The parameters for the stable distribution are $\alpha = 1.5$, $\beta = 0$, $\sigma = 1$, and $\mu = 0$. Note that symbols common to both distributions have different meanings.

The density graphs are obtained from fitting the distributions to the same sample data of arbitrarily generated numbers. The parameter α is related to the parameter ξ of the Pareto distribution, resulting in the tails of the density functions of α -stable random variables vanishing at a rate proportional to the Pareto tail.

The tails of the Pareto as well as the α -stable distribution decay at a rate with fixed power α , $x^{-\alpha}$ (i.e., *power law*), which is in contrast to the normal distribution whose tails decay at an exponential rate (i.e., roughly $e^{-x^2/2}$). We illustrate the effect focusing on the probability of exceeding some value x somewhere in the upper tail, say $x = 3$. Moreover, we choose the parameter of stability to be $\alpha = 1.5$. Under the normal law,

the probability of exceedance is roughly $e^{-3^2/2} = 0.011$ while under the power law it is about $3^{-1.5} = 0.1925$. Next, we let the benchmark x become gradually larger. Then the probability of assuming a value at least twice or four times as large (i.e., $2x$ or $4x$) is roughly

$$e^{-\frac{(2 \times 3)^2}{2}} \approx 0$$

or

$$e^{-\frac{(4 \times 3)^2}{2}} \approx 0$$

for the normal distribution. In contrast, under the power law, the same exceedance probabilities would be $(2 \times 3)^{-1.5} = 0.068$ or $(4 \times 3)^{-1.5} \approx 0.024$. This is a much slower rate than under the normal distribution. Note that the value of $x = 3$ plays no role for the power tails while the exceedance probability of the normal distribution decays faster the further out we are in the tails (i.e., the larger is x). The same reasoning applies to the lower tails considering the probability of falling below a benchmark x rather than exceeding it.

The parameter β indicates *skewness* where negative values represent left skewness while positive values indicate right skewness. The *scale* parameter σ has a similar interpretation as the standard deviation. Finally, the parameter μ indicates *location* of the distribution. Its interpretability depends on the parameter α . If the latter is between 1 and 2, then μ is equal to the mean.

Possible values of the parameters are listed below:

$$\begin{aligned} \alpha & (0, 2) \\ \beta & [-1, 1] \\ \sigma & (0, \infty) \\ \mu & \mathbb{R} \end{aligned}$$

Depending on the parameters α and β , the distribution has either support on the entire real line or only the part extending to the right of some location.

In general, the density function is not explicitly presentable. Instead, the distribution of the α -stable random variable is given by its charac-

teristic function. The characteristic function is given by

$$\begin{aligned} \varphi(t) &= \int_{-\infty}^{\infty} e^{itx} f(x) dx \\ &= \begin{cases} \exp \left\{ -\sigma^\alpha |t|^\alpha \left[1 - i\beta \text{sign}(t) \tan \frac{\pi\alpha}{2} \right] + i\mu t \right\}, & \alpha \neq 1 \\ \exp \left\{ -\sigma |t| \left[1 - i\beta \frac{2}{\pi} \text{sign}(t) \ln(t) \right] + i\mu t \right\}, & \alpha = 1 \end{cases} \quad (2) \end{aligned}$$

The density, then, has to be retrieved by an inverse transform to the characteristic function. Numerical procedures are employed for this task to approximate the necessary computations. The characteristic function (2) is presented here more for the sake of completeness rather than necessity. So, one should not be discouraged if it appears overwhelmingly complex.

In Figures 8 and 9, we present the density function for varying parameters β and α , respectively. Note in Figure 9 that for a $\beta = 1$, the density is positive only on a half-line toward the right as α approaches 2.

Only in the case of an α of 0.5, 1, or 2 can the functional form of the density be stated. For our purpose here, only the case $\alpha = 2$ is of interest because for this special case, the stable distribution represents the normal distribution. Then, the parameter β ceases to have any meaning since the normal distribution is not asymmetric.

A feature of the stable distributions is that moments such as the mean, for example, exist only up to the power α . (Recall that a moment exists when the according integral of the absolute values is finite.) So, except for the normal case (where $\alpha = 2$), there exists no finite variance. It becomes even more extreme when α is equal to 1 or less such that not even the mean exists anymore. The nonexistence of the variance is a major drawback when applying stable

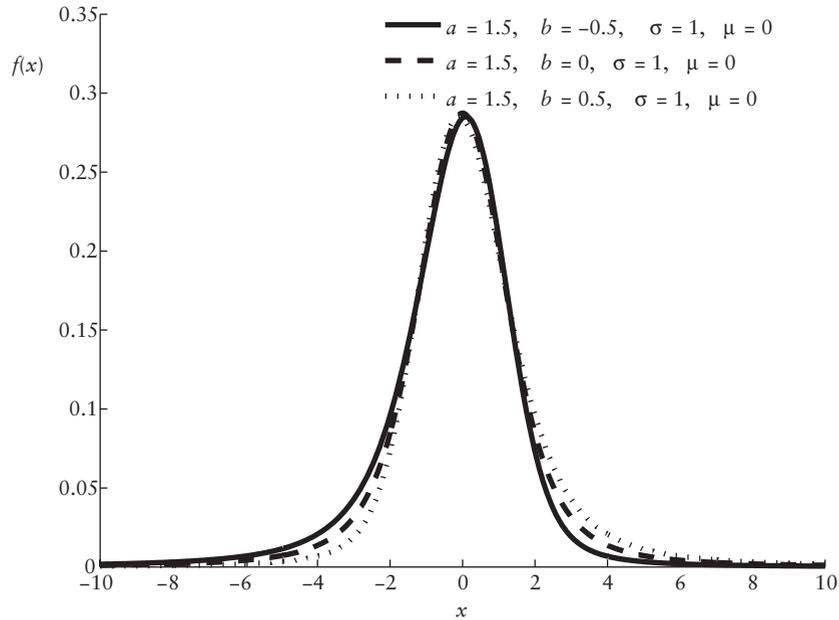

Figure 8 Stable Density Function for Various Values of β

distributions to financial data. This is one reason why the use of this family of distribution in finance is still contended.

This class of distributions owes its name to the *stability property* for the normal distribution

(Property 2): The weighted sum of an arbitrary number of α -stable random variables with the same parameters is, again, α -stable distributed. More formally, let X_1, \dots, X_n be identically distributed and independent of each other. Then,

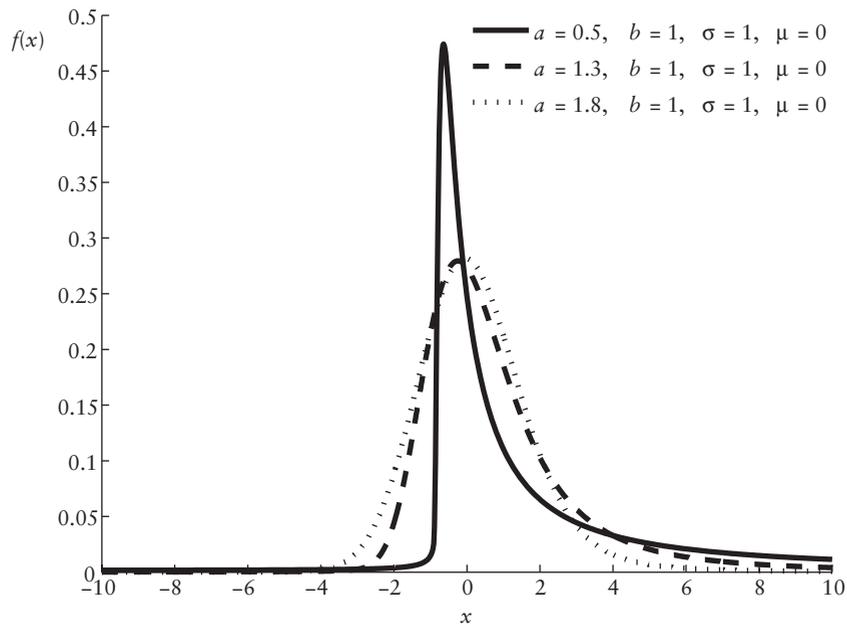

Figure 9 Stable Density Function (totally right-skewed) for Various Values of α

assume that for any $n \in \mathbb{N}$, there exists a positive constant a_n and a real constant b_n such that the normalized sum $Y(n)$

$$Y(n) = a_n(X_1 + X_2 + \cdots + X_n) + b_n \sim S(\alpha, \beta, \sigma, \mu) \quad (3)$$

converges in distribution to a random variable X , then this random variable X must be stable with some parameters α , β , σ , and μ . Again, recall that convergence in distribution means that the distribution function of $Y(n)$ in equation (3) converges to the distribution function on the right-hand side of equation (3).

In the context of financial returns, this means that monthly returns can be treated as the sum of weekly returns and, again, weekly returns themselves can be understood as the sum of daily returns. According to equation (3), they are equally distributed up to rescaling by the parameters a_n and b_n .

From the presentation of the normal distribution, we know that it serves as a limit distribution of a sum of identically distributed random variables that are independent and have finite variance. In particular, the sum converges in distribution to the standard normal distribution once the random variables have been summed and transformed appropriately. The prerequisite, however, was that the variance exists. Now, we can drop the requirement for finite variance and only ask for independence and identical distributions to arrive at the *generalized central limit theorem* expressed by equation (3). The sum of transformed random variables following rather arbitrary laws will have a distribution that follows a stable distribution law as the number n becomes very large. Thus, the class of α -stable distributions provides a greater set of limit distributions than the normal distribution containing the latter as a special case. Theoretically, this justifies the use of α -stable distributions as the choice for modeling asset returns when we consider the returns to be the resulting sum of many independent shocks.

Let us resume the previous example with the random dynamic and the related stock price evolution. Suppose, now, that the 10-day dynamic was S_α distributed. We denote the according random variable by V_{10} . We select a fairly moderate stable parameter of $\alpha = 1.8$. A value in this vicinity is commonly estimated for daily and even weekly stock returns. The skewness and location parameters are both set to zero, that is, $\beta = \mu = 0$. The scale is $\sigma = 1$, so that if the distribution was normal, that is, $\alpha = 2$, the variance would be 2 and, hence, consistent with the previous distributions. Note, however, that for $\alpha = 1.8$, the variance does not exist. Here the probability of the dynamic's exceedance of the lower threshold of 1 is

$$P(V_{10} > 1) = 0.2413 \quad (4)$$

compared to 0.2398 and 0.1870 in the normal and Student's t cases, respectively. Again, the probability in (4) corresponds to the event that in 10 days, the stock price will be greater than \$271. So, it is more likely than in the normal and Student's t model.

For the higher threshold of 3.5, we obtain

$$P(V_{10} > 3.5) = 0.0181$$

compared to 0.0067 and 0.0124 from the normal and Student's t cases, respectively. This event corresponds to a stock price beyond \$3,312, which is an immense increase. Under the normal distribution assumption, this event is virtually unlikely. It would happen in less than 1% of the 10-day periods. However, under the stable as well as the Student's t assumption, this could happen in 1.81% or 1.24% of the scenarios, which is three times or double the probability, respectively. Just for comparison, let us assume $\alpha = 1.6$, which is more common during a rough market climate. The dynamic would now exceed the threshold of 1 with probability

$$P(V_{10} > 1) = 0.2428$$

which fits in with the other distribution. For 3.5, we have

$$P(V_{10} > 3.5) = 0.0315 \quad (5)$$

which is equal to five times the probability under the normal distribution and almost three times the probability under the Student's t distribution assumption. For this threshold, the same probability as in equation (5) could only be achieved with a variance of $\sigma^2 = 4$, which would give the overall distribution a different shape. In the Student's t case, the degree of freedom parameter would have to be less than 3 such that now the variance would not exist any longer.

For the stable parameters chosen, the same results are obtained when the sign of the returns is negative and losses are considered. For example, $P(V_{10} < -3.5) = 0.0315$ corresponds to the probability of obtaining a stock price of \$3 or less. This scenario would only be given 0.67% probability in a normal distribution model. With respect to large portfolios such as those managed by large banks, negative returns deserve much more attention since losses of great magnitude result in widespread damages to industries beyond the financial industry.

As another example, let's look at what happened to the stock price of American International Group (AIG) in September 2008. On one single day, the stock lost 60% of its value. That corresponds to a return of about -0.94 . (Keep in mind that we are analyzing logarithmic returns.) If we choose a normal distribution with $\mu = 0$ and $\sigma^2 = 0.0012$ for the daily returns, a drop in price of this magnitude or less has near zero probability. The distributional parameters were chosen to best mimic the behavior of the AIG returns. By comparison, if we take an α -stable distribution with $\alpha = 1.6$, $\beta = 0$, $\mu = 0$, and $\sigma = 0.001$ where these parameters were selected to fit the AIG returns, we obtain the probability for a decline of at least this size of 0.00003, that is, 0.003%. So even with this distribution, an event of this impact is almost negligible. As a consequence, we have to choose a lower parameter α for the stable distribution. That brings to light the immense risk inherent in the return distributions when they are truly α -stable.

KEY POINTS

- Heavy tails are the general reference term for probability distributions whose probability mass in the tails (i.e., extreme parts of the distribution) is heavier than in the case of a normal distribution. Although there is no unique definition of the feature, there exists a selection of parameters that express whether a distribution is heavy-tailed with respect to the normal distribution. Financial asset returns commonly exhibit heavy tails, which imposes additional risk on asset managers that solely rely on theory based on the normal distribution and other candidates with appealing properties. Hence, it is necessary to account for heavy tails.
- Extreme value theory comprises a collection of distributions dealing with the most extreme values of some set. Either these distributions concentrate on the maxima and minima, respectively, or the most extreme values beyond thresholds. In general, this theory distinguishes among three different kinds of extreme value behavior. Financial risk theory has become intertwined with extreme value theory since it has become common knowledge that it does not suffice to base all analysis on the normal distribution alone.
- Stable distributions form a class of distributions capable of dealing with many stylized facts observed for asset returns. Moreover, the distributions from this class exhibit the property of stability under summation, roughly meaning that sums of random variables following certain probability laws are again distributed as individual random variables. This makes them appealing for the characterization of asset return behavior observed in the real world.
- Skewness is basically a measure of asymmetry of some distribution. While the normal distribution is symmetric about its mean, many other distributions do not share this feature. In fact, when analyzing asset returns, it is often revealed that they are noticeably

skewed to one side; that is, they are asymmetric. Consequently, it is important to consider skewness when dealing with asset returns in order to avoid additional risk arising from its neglect.

- The generalized central limit theorem is the extension of the central limit theorem stating that the appropriately scaled sum of certain random variables is eventually standard normally distributed when their number becomes large. However, the criteria for these random variables for the central limit theorem to hold are sometimes unrealistic. The generalized central limit theorem, in contrast, relaxes some of these criteria to include a larger selection of random variables that would fail to sum up to a standard normally distributed random variable. The lim-

iting distributions of these sums are instead members of the class of α -stable distributions. This theorem provides a justification for the use of stable distributions in mathematical finance.

Abstract: In financial models for asset pricing and asset allocation, asset returns and prices are assumed to follow a normal or Gaussian distribution. However, the properties of the normal distribution are not consistent with the observed behavior found for real-world asset returns. More specifically, the symmetric and rapidly decreasing tail properties of asset return distributions cannot describe the skewed and fat-tailed properties of the empirical distribution of asset returns. The alpha-stable distribution or α -stable distribution has been proposed as an alternative to the normal distribution for modeling asset returns because it allows for skewness and fat tails. Recent research since the turn of the century has introduced alternative distributions such as the tempered stable distributions to better describe asset returns.

In finance, the normal or Gaussian distribution has been the underlying assumption in describing asset returns in major financial theories such as the capital asset pricing theory and option pricing theory. In the early 1960s, Benoit Mandelbrot, a mathematician at

IBM's Thomas J. Watson Research Center, presented empirical evidence regarding returns on commodity prices and interest rate movements that strongly rejected the assumption that asset returns are normally distributed (see Mandelbrot, 1963). The mainstream financial

Dr. Bianchi acknowledges that the views expressed in this entry are his own and do not necessarily reflect those of the Bank of Italy.

models at the time relied on the work of Louis Bachelier, a French mathematician who at the beginning of the 20th century was the first to formulate random walk models for stock prices (see Bachelier, 1900). Bachelier's work assumed that relative price changes followed a normal distribution. Mandelbrot's findings led a leading financial economist, Paul Cootner of MIT, to warn the academic community that Mandelbrot's finding may mean that "past econometric work is meaningless" (see Cootner, 1964).

In Mandelbrot's attack on the normal distribution, he suggested that asset returns are more appropriately described by a non-normal *stable distribution* referred to as a stable Paretian distribution or alpha-stable distribution (α -stable distribution), so named because the tails of this distribution have Pareto power-type decay. The reason for describing this distribution as "non-normal stable" is because the normal distribution is a special case of the stable distribution. Because of the work by Paul Lévy, a French mathematician who introduced and characterized the non-normal stable distribution, this distribution is also referred to as the Lévy stable distribution and the Pareto-Lévy stable distribution.

There are two other facts about asset return distributions that have been supported by empirical evidence. First, distributions have been observed to be skewed or nonsymmetric. That is, unlike in the case of the normal distribution where there is a mirror imaging of the two sides of the probability distribution, typically in a skewed distribution one tail of the distribution is much longer (i.e., has greater probability of extreme values occurring) than the other tail of the probability distribution. Probability distributions with this attribute are referred to as having *fat tails* or *heavy tails*. The second finding is the tendency of large changes in asset prices (either positive or negative) to be followed by large changes, and small changes to be followed by small changes. This attribute of asset return distributions is referred to as *volatility clustering*. In contrast to the normal distribution, the

α -stable distribution allows for skewness and fat tails.

While the α -stable distribution has certain desirable properties that will be discussed in more detail in this entry, it is not suitable in certain modeling applications such as the modeling of option prices. In order to obtain a well-defined model for pricing options, the mean, variance, and exponential moments of the return distribution have to exist. For this reason, the smoothly truncated stable distribution and various types of tempered stable distributions have been proposed for financial modeling. Those distributions are obtained by tempering the tail properties of the α -stable distribution. Because they converge weakly to the α -stable distribution, the α -stable distribution is embedded in the class of the tempered stable distributions.

In this entry, we discuss the α -stable and tempered stable distributions. The more general distribution, named the infinitely divisible distribution, will be discussed as well. The distributions in this entry are defined by their characteristic functions. The density functions are not given by a closed-form formula in general but obtained by a numerical method discussed in Rachev et al. (2011).

α -STABLE DISTRIBUTION

In this section, we discuss a wide class of α -stable distributions. We review the definition and the basic properties of the α -stable distribution. We further present the class of smoothly truncated stable distributions which has been proposed by Menn and Rachev (2009) for dealing with the drawbacks of the α -stable distribution.

Definition of an α -Stable Random Variable

We begin with a definition of an α -stable random variable.¹ Suppose that X_1, X_2, \dots, X_n are independent and identically distributed (IID) random variables, independent copies of X .

Then a random variable X is said to follow an α -stable distribution if there exist a positive constant C_n and a real number D_n such that the following relation holds:

$$X_1 + X_2 + \dots + X_n \stackrel{d}{=} C_n X + D_n$$

The notation $\stackrel{d}{=}$ denotes equality in distribution. The constant $C_n = n^{\frac{1}{\alpha}}$ dictates the stability property, which we will discuss later. When $\alpha = 2$, we have the Gaussian (normal) case. In subsequent discussions of the α -stable distributions in this entry, we restrict ourselves to the non-Gaussian case in which $0 < \alpha < 2$.

For the general case, the density of the α -stable distribution does not have a closed-form solution. The distribution is expressed by its characteristic function:

$$\phi_{\text{stable}}(\mu; \alpha, \beta, \mu) = E[e^{iuX}] \begin{cases} \exp(i\mu u - |\sigma u|^\alpha (1 - i\beta(\text{sign } u) \tan \frac{\pi\alpha}{2})), & \alpha \neq 1 \\ \exp(i\mu u - \sigma |u| (1 - i\beta \frac{2}{\pi}(\text{sign } u) \ln |u|)), & \alpha = 1 \end{cases} \quad (1)$$

where

$$\text{sign } t = \begin{cases} 1, & t > 0 \\ 0, & t = 0 \\ -1, & t < 0 \end{cases}$$

The distribution is characterized by four parameters:

- α : the index of stability or the shape parameter, $\alpha \in (0, 2)$.
- β : the skewness parameter, $\beta \in [-1, +1]$.
- σ : the scale parameter, $\sigma \in (0, +\infty)$.
- μ : the location parameter, $\mu \in (-\infty, +\infty)$.

When a random variable X follows the α -stable distribution characterized by those parameters, then we denote it by $X \sim S_\alpha(\sigma, \beta, \mu)$.

The three special cases where there is a closed-form solution for the densities are (1) the Gaussian case ($\alpha = 2$), (2) the Cauchy case ($\alpha = 1, \beta = 0$), and (3) the Lévy case ($\alpha = 1/2, \beta = \pm 1$) with the following respective densities:

- Gaussian: $f(x) = \frac{1}{2\sigma\sqrt{\pi}} e^{-\frac{(x-\mu)^2}{4\sigma^2}}, -\infty < x < \infty$
- Cauchy: $f(x) = \frac{\sigma}{\pi((x-\mu)^2 + \sigma^2)}, -\infty < x < \infty$
- Lévy: $f(x) = \frac{\sqrt{\sigma}}{\sqrt{2\pi}(x-\mu)^{3/2}} e^{-\frac{\sigma}{2(x-\mu)}}, \mu < x < \infty$

Because of the four parameters, the α -stable distribution is highly flexible and suitable for modeling nonsymmetric, highly kurtotic, and heavy-tailed data. Figures 1 and 2 illustrate the effects of the shape and skewness parameters, respectively, on the shape of the distribution, with other parameters kept constant. As is evident from Figure 1, a lower value for α is attributed to heavier tails and higher kurtosis.

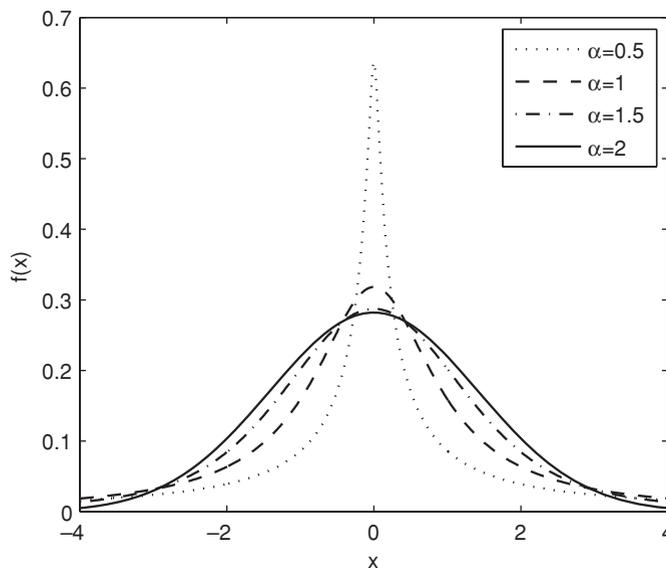

Figure 1 Illustration of α -Stable Densities for Varying α 's, with $\beta = 0, \sigma = 1$, and $\mu = 0$

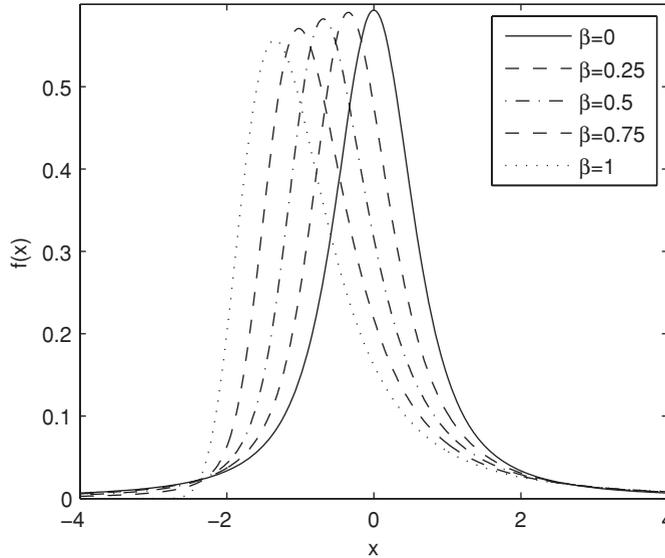

Figure 2 Illustration of α -stable Densities for Varying β 's, with $\alpha = 1.25, \sigma = 0.5,$ and $\mu = 0$

Useful Properties of an α -Stable Random Variable

The four basic properties of the α -stable distribution:

- *Property 1.* The power tail decay property means that the tail of the density function decays like a power function (slower than the exponential decay), which is what allows the distribution to capture extreme events in the tails:

$$P(|X| > x) \propto C \cdot x^{-\alpha}, x \rightarrow \infty$$

for some constant C . More precisely, if $X \sim S_\alpha(\sigma, \beta, \mu)$ with $0 < \alpha < 2$ then

$$\begin{cases} \lim_{\lambda \rightarrow \infty} \lambda^\alpha P(X > \lambda) = C_\alpha \frac{1+\beta}{2} \sigma^\alpha \\ \lim_{\lambda \rightarrow \infty} \lambda^\alpha P(X > -\lambda) = C_\alpha \frac{1-\beta}{2} \sigma^\alpha \end{cases}$$

where

$$C_\alpha = \begin{cases} \frac{1-\alpha}{\Gamma(2-\alpha)\cos(\pi\alpha/2)} & \text{if } \alpha \neq 1 \\ \frac{2}{\pi} & \text{if } \alpha = 1 \end{cases}$$

- *Property 2.* Raw moments satisfy the property:

$$\begin{aligned} E|X|^p &< \infty \text{ for any } 0 < p < \alpha \\ E|X|^p &= \infty \text{ for any } p \geq \alpha \end{aligned}$$

- *Property 3.* Because of Property 2, the mean is finite only for $\alpha > 1$:

$$\begin{aligned} E[X] &= \mu \quad \text{for } \alpha > 1 \\ E[X] &= \infty \quad \text{for } 0 < \alpha \leq 1 \end{aligned}$$

The second and higher moments are infinite, leading to infinite variance together with the skewness and kurtosis coefficients.

- *Property 4.* The stability property is a useful and convenient property and dictates that the distributional form of the variable is preserved under linear transformations. The stability property is governed by the stability parameter α in the constant C_n (which appeared earlier in the definition of an α -stable random variable): $C_n = n^{1/\alpha}$. As was stated earlier, smaller values of α refer to a heavier-tailed distribution. The standard central limit theorem does not apply to the non-Gaussian case: An appropriately standardized large sum of IID random variables converges to an α -stable random variable instead of a normal random variable.

The following examples illustrate the stability property. Suppose that X_1, X_2, \dots, X_n are IID

random variables with $X_i \sim S_\alpha(\sigma_i, \beta_i, \mu_i)$, $i = 1, 2, \dots, n$ and a fixed α . Then:

- The distribution of $Y = \sum_i^n X_i$ is α -stable with the index of stability α and parameters:

$$\beta = \frac{\sum_i^n \beta_i \sigma_i^\alpha}{\sum_i^n \sigma_i^\alpha}, \sigma = \left(\sum_i^n \sigma_i^\alpha \right)^{1/\alpha}, \mu = \sum_i^n \mu_i$$

- The distribution of $Y = X_1 + a$ for some real constant a is α -stable with the index of stability α and parameters:

$$\beta = \beta_1, \sigma = \sigma_1, \mu = \mu_1 + a$$

- The distribution of $Y = aX_1$ for some real constant $a(a \neq 0)$ is α -stable with the index of stability α and parameters:

$$\begin{aligned} \beta &= (\text{sign } a)\beta_1 \\ \sigma &= |a| \sigma_1 \\ \mu &= \begin{cases} a\mu_1 & \text{for } \alpha \neq 1 \\ a\mu_1 - \frac{2}{\pi}a(\ln a)\sigma_1\beta_1 & \text{for } \alpha = 1 \end{cases} \end{aligned}$$

- The distribution of $Y = -X_1$ is α -stable with the index of stability α and parameters:

$$\beta = -\beta_1, \sigma = \sigma_1, \mu = \mu_1$$

Smoothly Truncated Stable Distribution

In some special cases of financial modeling it might occur that the infinite variance of stable distributions make their application impossible. In many cases, the infinite variance of the return might lead to an infinite price for derivative instruments such as options, clearly contradicting reality and intuition. The modeler is confronted with a dilemma. On the one hand, the skewed and heavy-tailed return distribution disqualifies the normal distribution as a suitable candidate; on the other hand, theoretical restrictions in option pricing do not allow the application of the stable distribution due to its infinite moments of order higher than α . For this reason, Menn and Rachev (2009) have sug-

gested the use of appropriately truncated stable distributions.

The exact definition of truncated stable distributions is not that important at this point; that is why we restrict ourselves to a brief description of the idea. The density function of a smoothly truncated stable distribution (STS distribution) is obtained by replacing the heavy tails of the density function g of some stable distribution with parameters $(\alpha, \beta, \sigma, \mu)$ by the thin tails of two appropriately chosen normal distributions h_1 and h_2 :

$$f(x) = \begin{cases} h_1(x), & x < a \\ g(x), & a \leq x \leq b \\ h_2(x), & x > b \end{cases}$$

The parameters of the normal distributions are chosen such that the resulting function is the continuous density function of a probability measure on the real line. If it is possible to choose the cutting points a and b in a way that the resulting distribution possesses zero mean and unit variance, then we have found an easy way to characterize standardized STS distributions. In Figure 3, the influence of the stable parameters on the appropriate cutting points is examined. As α approaches 2 (i.e., when the stable distribution approaches the normal distribution), we observe that the cutting points move to infinity. For small values of α , in contrast, the interval $[a, b]$ shrinks, reflecting the increasing heaviness of the tails of the stable distribution in the center.

Due to the thin tails of the normal density functions, the STS distributions admit finite moments of arbitrary order but nevertheless are able to explain extreme observations. Table 1 provides a comparison of tail probabilities for an arbitrarily chosen STS distribution with zero mean and unit variance and the standard normal distribution. As can be seen from the table, the probability of extreme events is much higher under the assumption of an STS distribution. STS distributions allow for skewness in the returns. Moreover, the tails behave like fat

tails but are light tails in the mathematical sense. Hence, all moments of arbitrary order exist and are finite. For this reason, advocates of the class of STS distribution argue that it is an appropriate class for modeling the return distribution of various financial assets.

TEMPERED STABLE DISTRIBUTIONS

In this section, we discuss six types of *tempered stable distributions*.

Classical Tempered Stable Distribution

Let $\alpha \in (0,1) \cup (1, 2)$, $C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. X is said to follow the *classical tempered stable (CTS) distribution* if the characteristic function of X is given by

$$\begin{aligned} \phi_X(u) &= \phi_{CTS}(u; \alpha, C, \lambda_+, \lambda_-, m) \\ &= \exp(ium - iuC\Gamma(1 - \alpha)(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1}) \\ &\quad + C\Gamma(-\alpha)((\lambda_+ - iu)^\alpha - \lambda_+^\alpha \\ &\quad + (\lambda_- + iu)^\alpha - \lambda_-^\alpha)) \end{aligned} \tag{2}$$

and we denote it by $X \sim CTS(\alpha, C, \lambda_+, \lambda_-, m)$.

Using the n th derivative of $\psi(u) = \log\phi_X(u)$ evaluated around zero, the cumulants $c_n(X) = \frac{1}{i^n} \frac{\partial^n \psi}{\partial u^n}(0)$ of X are obtained by

$$\begin{aligned} c_1(X) &= m \\ c_n(X) &= C\Gamma(n - \alpha)(\lambda_+^{\alpha-n} \\ &\quad + (-1)^n \lambda_-^{\alpha-n}), \text{ for } n = 2, 3, \dots \end{aligned}$$

The role of the parameters is as follows:

- The parameter m determines the location of the distribution.

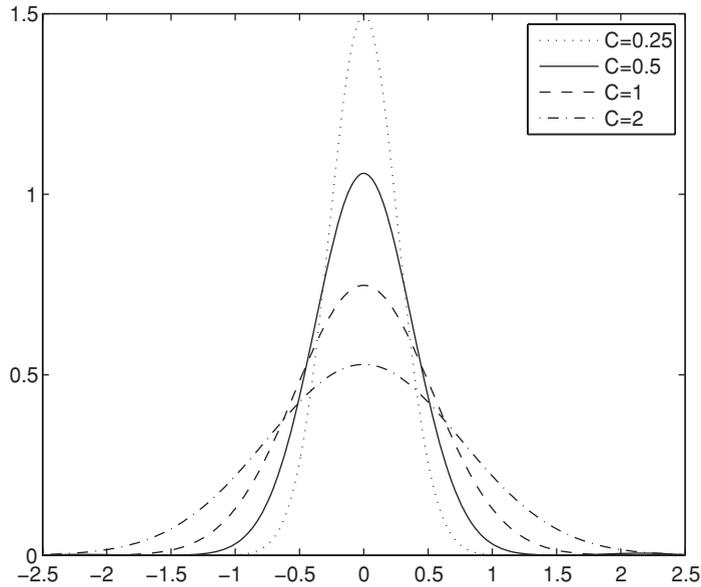

Figure 4 Probability Density of the CTS Distributions' Dependence on C
 Note: $C \in \{0.25, 0.5, 1, 2\}$, $\alpha = 1.4$, $\lambda_+ = 50$, $\lambda_- = 50$, $m = 0$.

- The parameter C is the scale parameter. Figure 4 shows the density function of the CTS distributions' dependence on C .
- The parameters λ_+ and λ_- control the rate of decay on the positive and negative tails,

respectively. If $\lambda_+ > \lambda_-$ ($\lambda_+ < \lambda_-$), then the distribution is skewed to the left (right), and if $\lambda_+ = \lambda_-$, then it is symmetric. Figure 5 illustrates left and right skewed density functions of the CTS distribution, as well as the symmetric case.

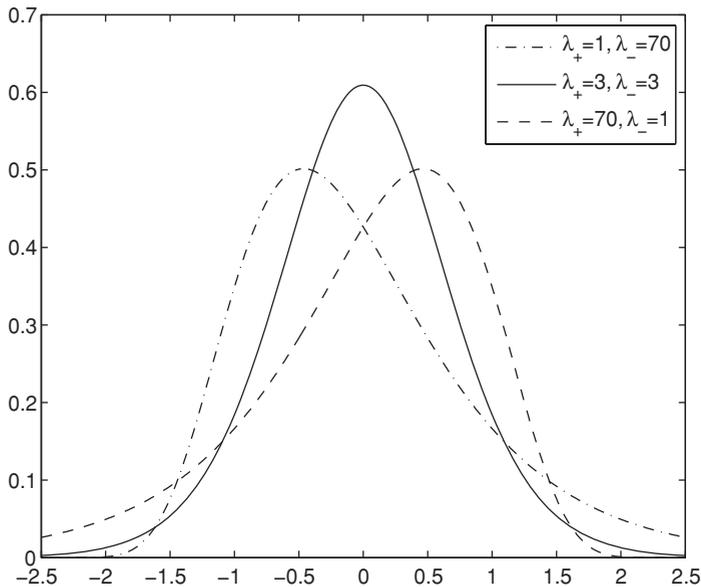

Figure 5 Probability Density of the CTS Distributions: Dependence on λ_+ and λ_-
 Note: $(\lambda_+, \lambda_-) \in \{(1, 70), (3, 3), (70, 1)\}$, $\alpha = 0.8$, $C = 1$, $m = 0$.

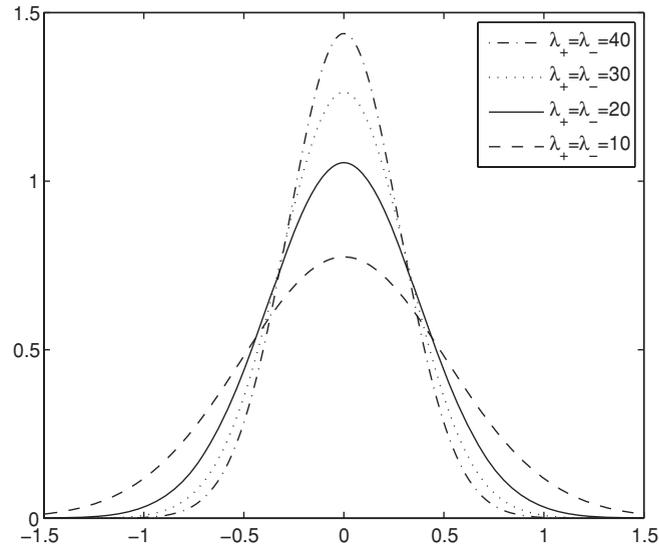

Figure 6 Probability Density of the Symmetric CTS Distributions' Dependence on Parameters λ_+, λ_-
Note: $\lambda_+ = \lambda_- \in \{10, 20, 30, 40\}$, $\alpha = 1.1$, $C = 1$, $m = 0$.

- The parameters λ_+, λ_- , and α are related to tail weights. Figures 6 and 7 illustrate this fact. We will discuss another role of α later.
- If α approaches to 0, the CTS distribution converges to the variance-gamma distribution (discussed later in this entry) in distribution sense.

If we take a special parameter C defined by

$$C = (\Gamma(2 - \alpha)(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}))^{-1} \quad (3)$$

then $X \sim \text{CTS}(\alpha, C, \lambda_+, \lambda_-, 0)$ has zero mean and unit variance. In this case, X is called the standard CTS distribution with parameters $(\alpha, \lambda_+, \lambda_-)$ and denoted by $X \sim \text{stdCTS}(\alpha, \lambda_+, \lambda_-)$.

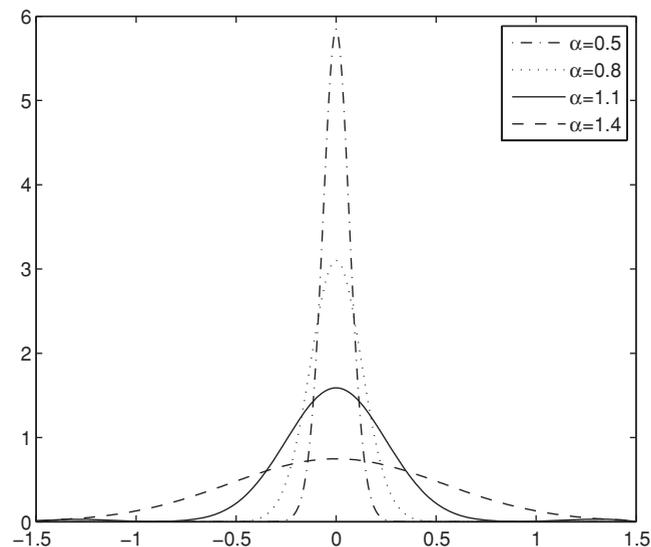

Figure 7 Probability Density of the CTS Distributions: Dependence on α
Note: $\alpha \in \{0.5, 0.8, 1.1, 1.4\}$, $C = 1$, $\lambda_+ = 50$, $\lambda_- = 50$, $m = 0$.

λ_-). Let m be a real number, σ be a positive real number, and $X \sim \text{stdCTS}(\alpha, \lambda_+, \lambda_-)$. Then

$$Y = \sigma X + m \approx \text{CTS} \left(\alpha, \frac{\sigma^\alpha}{\Gamma(2-\alpha)(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})}, \frac{\lambda_+}{\sigma}, \frac{\lambda_-}{\sigma}, m \right)$$

The random variable Y is the CTS distributed, and its mean and variance are m and σ^2 , respectively.

Generalized Classical Tempered Stable Distribution

A more general form of the characteristic function for the CTS distribution is

$$\begin{aligned} \phi_X(u) = & \exp(ium - iu\Gamma(1-\alpha)(C + \lambda_+^{\alpha+1} - C_- \lambda_-^{\alpha-1}) \\ & + C_+ \Gamma(-\alpha_+)((\lambda_+ - iu)^{\alpha_+} - \lambda_+^{\alpha_+}) \\ & + C_- \Gamma(-\alpha_-)((\lambda_- + iu)^{\alpha_-} - \lambda_-^{\alpha_-})) \end{aligned} \quad (4)$$

where $\alpha_+, \alpha_- \in (0, 1) \cup (1, 2)$, $C_+, C_-, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. This distribution has been referred to as the *generalized classical tempered stable (GTS) distribution* and we denote it by $X \sim \text{GTS}(\alpha_+, \alpha_-, C_+, C_-, \lambda_+, \lambda_-, m)$.²

The cumulants of X are $c_1(X) = m$ and

$$\begin{aligned} c_n(X) = & C_+ \Gamma(n - \alpha_+) \lambda_+^{\alpha_+ - n} \\ & + (-1)^n C_- \Gamma(n - \alpha_-) \lambda_-^{\alpha_- - n} \end{aligned}$$

for $n = 2, 3, \dots$. If we substitute

$$C_+ = \frac{p\lambda_+^{2-\alpha_+}}{\Gamma(2-\alpha_+)}, \quad C_- = \frac{(1-p)\lambda_-^{2-\alpha_-}}{\Gamma(2-\alpha_-)} \quad (5)$$

where $p \in (0, 1)$, then $X \sim \text{GTS}(\alpha_+, \alpha_-, C_+, C_-, \lambda_+, \lambda_-, 0)$ has zero mean and unit variance. In this case, X is called the standard GTS distribution with parameters $(\alpha_+, \alpha_-, \lambda_+, \lambda_-, p)$ and denoted by $X \sim \text{stdGTS}(\alpha_+, \alpha_-, \lambda_+, \lambda_-, p)$.

Modified Tempered Stable Distribution

Let $\alpha \in (0, 1) \cup (1, 2)$, $C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. X is said to follow the *modified tempered stable*

(MTS) *distribution* (see Kim et al., 2009) if the characteristic function of X is given by

$$\begin{aligned} \phi_X(u) = & \phi_{\text{MTS}}(u; \alpha, C, \lambda_+, \lambda_-, m) \\ = & \exp(ium + C(G_R(u; \alpha, \lambda_+) + G_R(u; \alpha, \lambda_-)) \\ & + iuC(G_I(u; \alpha, \lambda_+) - G_I(u; \alpha, \lambda_-))) \end{aligned} \quad (6)$$

where for $u \in \mathbb{R}$,

$$G_R(x; \alpha, \lambda) = 2^{-\frac{\alpha+3}{2}} \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) ((\lambda^2 + x^2)^{\frac{\alpha}{2}} - \lambda^\alpha)$$

and

$$\begin{aligned} G_I(x; \alpha, \lambda) = & 2^{-\frac{\alpha+1}{2}} \Gamma\left(\frac{1-\alpha}{2}\right) \lambda^{\alpha-1} \\ & \times \left[{}_2F_1\left(1, \frac{1-\alpha}{2}; \frac{3}{2}; -\frac{x^2}{\lambda^2}\right) - 1 \right] \end{aligned}$$

where ${}_2F_1$ is the hypergeometric function. We denote an MTS distributed random variable X by $X \sim \text{MTS}(\alpha, C, \lambda_+, \lambda_-, m)$.

The role of the parameters of the MTS distribution is same as in the case of the CTS distribution. For example, the parameters λ_+ and λ_- control the rate of decay on the positive and negative tails, respectively, and if $\lambda_+ = \lambda_-$, then it is symmetric. The characteristic function of the symmetric MTS distribution is defined not only for the case $\alpha \in (0, 1) \cup (1, 2)$ but also for the case $\alpha = 1$. The form of the characteristic function for the symmetric case is given by

$$\begin{aligned} \phi_X(u) = & \phi_{\text{MTS}}(u; \alpha, C, \lambda, \lambda, m) \\ = & \exp\left(ium + C2^{-\frac{\alpha+1}{2}} \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \right. \\ & \left. \times ((\lambda^2 + x^2)^{\frac{\alpha}{2}} - \lambda^\alpha)\right) \end{aligned}$$

The mean of X is m , and the cumulants of X are equal to

$$\begin{aligned} c_n(X) = & 2^{n-\frac{\alpha+3}{2}} C \Gamma\left(\frac{n+1}{2}\right) \Gamma\left(\frac{n-\alpha}{2}\right) \\ & \times (\lambda_+^{\alpha-n} + (-1)^n \lambda_-^{\alpha-n}) \end{aligned}$$

for $n = 2, 3, \dots$.

If we substitute

$$C = 2^{\frac{\alpha+1}{2}} \left(\sqrt{\pi} \Gamma\left(1 - \frac{\alpha}{2}\right) (\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}) \right)^{-1} \quad (7)$$

then $X \sim \text{MTS}(\alpha, C, \lambda_+, \lambda_-, 0)$ has zero mean and unit variance. In this case, the random variable X is called the standard MTS distribution and

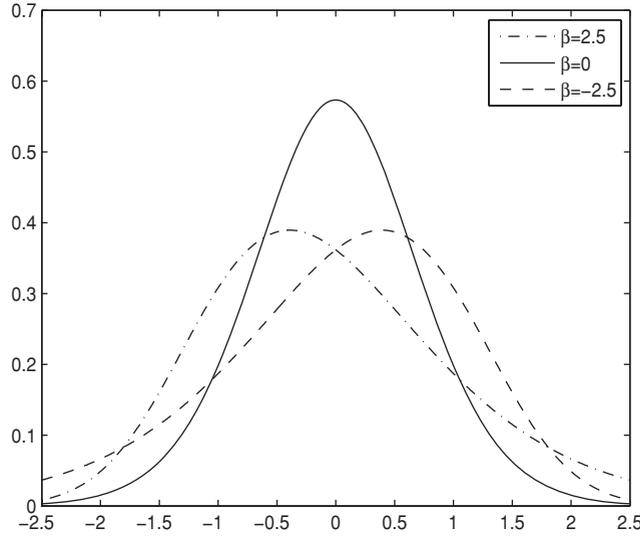

Figure 8 Probability Density of the NTS Distributions' Dependence on β
 Note: $\beta \in \{-2.5, 0, 2.5\}$, $\alpha = 0.8$, $C = 1$, $\lambda = 4$, $m = 0$.

denoted by $X \sim \text{stdMTS}(\alpha, \lambda_+, \lambda_-)$. Let m be a real number, σ be a positive real number, and $X \sim \text{stdMTS}(\alpha, \lambda_+, \lambda_-)$. Then

$$Y = \sigma X + m \sim \text{MTS}(\alpha, \sigma^\alpha C, \lambda_+/\sigma, \lambda_-/\sigma, m)$$

where C is equal to (7). The random variable Y is MTS distributed, and its mean and variance are m and σ^2 , respectively.

Normal Tempered Stable Distribution

Let $\alpha \in (0, 2)$, $C, \lambda > 0$, $|\beta| < \lambda$, and $m \in \mathbb{R}$. X is said to follow the *normal tempered stable (NTS) distribution*.³ If the characteristic function of X is given by

$$\begin{aligned} \phi_X(u) &= \phi_{NTS}(u; \alpha, C, \lambda, \beta, m) \\ &= \exp(ium - iu2^{-\frac{\alpha-1}{2}} \sqrt{\pi} C \Gamma\left(1 - \frac{\alpha}{2}\right) \\ &\quad \times \beta(\lambda^2 - \beta^2)^{\frac{\alpha}{2}-1} + 2^{-\frac{\alpha+1}{2}} C \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \\ &\quad \times \left(\left(\lambda^2 - (\beta + iu)^2\right)^{\frac{\alpha}{2}} - (\lambda^2 - \beta^2)^{\frac{\alpha}{2}}\right) \end{aligned} \quad (8)$$

We denote an NTS distributed random variable X by $X \sim \text{NTS}(\alpha, C, \lambda, \beta, m)$.

The mean of X is m . The general expressions for cumulants of X are omitted since they are

rather complicated. Instead of the general form, we present three cumulants

$$\begin{aligned} c_2(X) &= \bar{C}(\lambda^2 - \beta^2)^{\frac{\alpha}{2}-2} \alpha(\alpha\beta^2 - \lambda^2 - \beta^2) \\ c_3(X) &= -\bar{C} \alpha \beta (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-3} (\alpha^2 \beta^2 - 3\alpha\lambda^2 - 3\alpha\beta^2 + 6\lambda^2 + 2\beta^2) \\ c_4(X) &= \bar{C} \alpha (\alpha - 2) (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-4} \\ &\quad \times (\alpha^2 \beta^4 - 6\alpha\lambda^2 \beta^2 - 4\alpha\beta^4 + 3\beta^4 + 18\lambda^2 \beta^2 + 3\lambda^4) \end{aligned}$$

where $\bar{C} = 2^{-\frac{\alpha+1}{2}} C \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right)$

The roles of parameters α, C , and λ are same as in the case of the symmetric MTS distribution. The parameter β is related to the distribution's skewness. If $\beta < 0$ ($\beta > 0$), then the distribution is skewed to the left (right). Moreover, if $\beta = 0$, then it is symmetric. This fact is illustrated in Figure 8.

If we substitute

$$\begin{aligned} C &= 2^{\frac{\alpha+1}{2}} \\ &\quad \times \left(\sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \alpha (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-2} (\alpha\beta^2 - \lambda^2 - \beta^2)\right)^{-1} \end{aligned} \quad (9)$$

then $X \sim \text{NTS}(\alpha, C, \lambda, \beta, 0)$ has zero mean and unit variance. In this case, X is called the standard NTS distribution and denoted by $X \sim \text{stdNTS}(\alpha, \lambda, \beta)$. Let m be a real number, σ be a

positive real number, and $X \sim \text{stdNTS}(\alpha, \lambda, \beta)$. Then

$$Y = \sigma X + m \sim \text{NTS}(\alpha, \sigma^\alpha C, \lambda/\sigma, \beta/\sigma, m)$$

where C is equal to (9). The random variable Y is NTS distributed, and its mean and variance are m and σ^2 , respectively.

If we substitute $\alpha = 1$ and $C = \frac{c}{\pi}$ into the definition of the NTS distribution, we obtain the normal inverse Gaussian (NIG) distribution.⁴ That is, if random variable $X \sim \text{NTS}(1, c/\pi, \lambda, \beta, m)$, then X becomes an NIG distributed random variable. In this case, we denote $X \sim \text{NIG}(c, \lambda, \beta, m)$.

By substituting $\alpha = 1$ and $C = \frac{c}{\pi}$ into (8), we obtain the characteristic function of the NIG distributed X as

$$\begin{aligned} \phi_X(u) &= \phi_{\text{NIG}}(u; c, \lambda, \beta, m) \\ &= \exp\left(ium - \frac{iuc\beta}{\sqrt{\lambda^2 - \beta^2}} - c \right. \\ &\quad \left. \times \left(\sqrt{\lambda^2 - (\beta + iu)^2} - \sqrt{\lambda^2 - \beta^2}\right)\right) \end{aligned} \quad (10)$$

If we substitute

$$c = \frac{(\lambda^2 - \beta^2)^{\frac{3}{2}}}{\lambda^2} \quad (11)$$

then $X \sim \text{NIG}(c, \lambda, \beta, 0)$ has zero mean and unit variance. In this case, X is called the standard NIG distribution and denoted by $X \sim \text{stdNIG}(\lambda, \beta)$.

Kim-Rachev Tempered Stable Distribution

Let $\alpha \in (0, 1) \cup (1, 2)$, $k_+, k_-, r_+, r_- > 0$, $p_+, p_- \in \{p > -\alpha \mid p \neq -1, p \neq 0\}$, and $m \in \mathbb{R}$. X is said to follow the *Kim-Rachev tempered stable* (KRTS) distribution (see Kim et al., 2008b) if the characteristic function of X is given by

$$\begin{aligned} \phi_X(u) &= \phi_{\text{KRTS}}(u; \alpha, k_+, k_-, r_+, r_-, p_+, p_-, m) \\ &= \exp\left(ium - iu\Gamma(1 - \alpha) \left(\frac{k_+ r_+}{p_+ + 1} - \frac{k_- r_-}{p_- + 1}\right) \right. \\ &\quad \left. + k_+ H(iu; \alpha, r_+, p_+) + k_- H(-iu; \alpha, r_-, p_-)\right) \end{aligned} \quad (12)$$

where

$$H(x; \alpha, r, p) = \frac{\Gamma(-\alpha)}{p} ({}_2F_1(p, -\alpha; 1 + p; rx) - 1)$$

We denote a KRTS distributed random variable X by $X \sim \text{KRTS}(\alpha, k_+, k_-, r_+, r_-, p_+, p_-, m)$.

The KRTS distribution is an extension of the CTS distribution. Indeed, the distribution $\text{KRTS}(\alpha, k_+, k_-, r_+, r_-, p_+, p_-, m)$ converges weakly to the CTS distribution as $p_\pm \rightarrow \infty$ provided that $C_\pm = c(\alpha + p_\pm)r_\pm^{-\alpha}$ where $c > 0$ (see Kim et al., 2008a). Figure 9 shows that the KRTS distribution converges to the CTS distribution when parameter $p = p_+ = p_-$ increases to infinity.

The cumulants of the KRTS distributed random variable X are $c_1(X) = m$ and

$$\begin{aligned} c_n(X) &= \Gamma(n - \alpha) \left(\frac{k_+ r_+^n}{p_+ + n} + (-1)^n \frac{k_- r_-^n}{p_- + n} \right), \\ &\quad \text{for } n = 2, 3, \dots \end{aligned}$$

If we substitute

$$\begin{aligned} k_+ &= C \frac{\alpha + p_+}{r_+^\alpha} \\ k_- &= C \frac{\alpha + p_-}{r_-^\alpha} \end{aligned}$$

where

$$C = \frac{1}{\Gamma(2 - \alpha)} \left(\frac{\alpha + p_+}{2 + p_+} r_+^{2-\alpha} + \frac{\alpha + p_-}{2 + p_-} r_-^{2-\alpha} \right)^{-1} \quad (13)$$

then $X \sim \text{KRTS}(\alpha, k_+, k_-, r_+, r_-, p_+, p_-, 0)$ has zero mean and unit variance. In this case, X is said to be standard KRTS distributed and denoted by $X \sim \text{stdKRTS}(\alpha, r_+, r_-, p_+, p_-)$. Let m be a real number, σ be a positive real number, and $X \sim \text{stdKRTS}(\alpha, r_+, r_-, p_+, p_-)$. Then

$$\begin{aligned} Y &= \sigma X + m \\ &\sim \text{KRTS}(\alpha, C(\alpha + p_+)(\sigma r_+)^{-\alpha}, C(\alpha + p_-) \\ &\quad (\sigma r_-)^{-\alpha}, \sigma r_+, \sigma r_-, p_+, p_-, m) \end{aligned}$$

where C is equal to (13). The random variable Y is KRTS distributed, and its mean and variance are m and σ^2 , respectively.

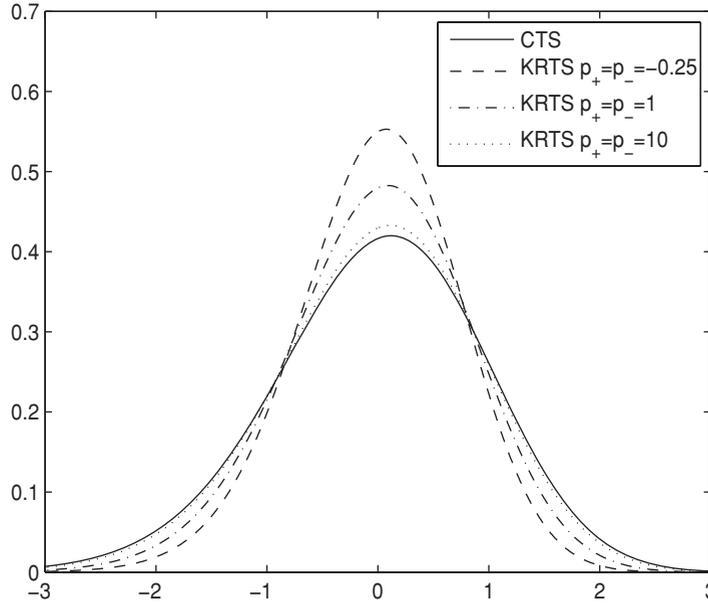

Figure 9 Probability Density of the CTS Distribution with Parameters $C = 1, \lambda_+ = 10, \lambda_- = 2, \alpha = 1.25$, and the KRTS Distributions with $k_{\pm} = C(\alpha + p)_{\pm}^{\alpha}, r_+ = 1/\lambda_+, r_- = 1/\lambda_-$, where $p = p_+ = p_- \in \{-0.25, 1, 10\}$

Rapidly Decreasing Tempered Stable Distribution

Let $\alpha \in (0, 1) \cup (1, 2), C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. A random variable X is said to follow the *rapidly decreasing tempered stable* (RDTS) distribution (see Bianchi et al., 2010 and Kim et al., 2010) if the characteristic function of X is given by

$$\phi_X(u) = \phi_{RDTS}(u; \alpha, C, \lambda_+, \lambda_-, m) \exp(ium + C(G(iu; \alpha, \lambda_+) + G(-iu; \alpha, \lambda_-))) \tag{14}$$

where

$$G(x; \alpha, \lambda) = 2^{-\frac{\alpha}{2}-1} \lambda^{\alpha} \Gamma\left(-\frac{\alpha}{2}\right) \left(M\left(-\frac{\alpha}{2}, \frac{1}{2}; \frac{x^2}{2\lambda^2}\right) - 1\right) + 2^{-\frac{\alpha}{2}-\frac{1}{2}} \lambda^{\alpha-1} x \Gamma\left(\frac{1-\alpha}{2}\right) \times \left(M\left(\frac{1-\alpha}{2}, \frac{3}{2}; \frac{x^2}{2\lambda^2}\right) - 1\right)$$

and M is the confluent hypergeometric function. Further details of the confluent hypergeometric function are presented at the end of this entry. In this case, we denote $X \sim RDTS(\alpha, C, \lambda_+, \lambda_-, m)$. The role of the parameters are the same as for the case of the CTS distribution.

The mean of X is m , and the cumulants of X are

$$c_n(X) = 2^{\frac{n-\alpha-2}{2}} C \Gamma\left(\frac{n-\alpha}{2}\right) \times (\lambda_+^{\alpha-n} + (-1)^n \lambda_-^{\alpha-n}), \text{ for } n = 2, 3, \dots$$

If we substitute

$$C = 2^{\frac{\alpha}{2}} \left(\Gamma\left(1 - \frac{\alpha}{2}\right) (\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})\right)^{-1} \tag{15}$$

then $X \sim RDTS(\alpha, C, \lambda_+, \lambda_-, 0)$ has zero mean and unit variance, and X is called the standard RDTS distribution and denoted by $X \sim \text{stdRDTS}(\alpha, \lambda_+, \lambda_-)$. Let m be a real number, σ be a positive real number, and $X \sim \text{stdCTS}(\alpha, \lambda_+, \lambda_-)$. Then

$$\sigma X + m \sim RDTS(\alpha, \sigma^{\alpha} C, \lambda_+/\sigma, \lambda_-/\sigma, m)$$

where C is equal to (15). The random variable Y is RDTS distributed, and its mean and variance are m and σ^2 , respectively.

INFINITELY DIVISIBLE DISTRIBUTIONS

A random variable Y is referred to as *infinitely divisible* if for each positive integer n , there are IID random variables Y_1, Y_2, \dots, Y_n such that $Y \stackrel{d}{=} \sum_{k=1}^n Y_k$ that is, the distribution of Y is the same as the distribution of $\sum_{k=1}^n Y_k$

For example, the normal distribution is infinitely divisible. Using the characteristic function for the normal distribution, we can easily check the property. Suppose $Y \sim N(\mu, \sigma^2)$. For any positive integer n , consider a sequence of IID random variables Y_1, Y_2, \dots, Y_n such that $Y_k \sim N(\mu/n, \sigma^2/n)$. Since Y_k 's are independent we have

$$E \left[\exp \left(iu \sum_{k=1}^n Y_k \right) \right] = \prod_{k=1}^n E [iuY_k]$$

The characteristic function of Y_k is given by

$$E [iuY_k] = \exp \left(\frac{iu\mu}{n} - \frac{\sigma^2 u^2}{2n} \right)$$

Hence, the characteristic function of $\sum_{k=1}^n Y_k$ is

$$E \left[\exp \left(iu \sum_{k=1}^n Y_k \right) \right] = \exp \left(iu\mu - \frac{\sigma^2 u^2}{2} \right)$$

which is the same as the characteristic function of Y . Therefore, $Y \stackrel{d}{=} \sum_{k=1}^n Y_k$.

Using similar arguments, we can show that the Poisson, gamma, variance-gamma (VG), inverse Gaussian (IG), α -stable, CTS, GTS, MTS, NTS(NIG), RDTS, and KRTS distributions are infinitely divisible. The relations of Y and $Y_k, k = 1, \dots, n$ for those distributions are presented in Table 2. We can show that the sum of infinitely divisible random variables is again infinitely divisible.

In the literature, the characteristic function of the one-dimensional infinitely divisible distribution is generalized by the Lévy-Khinchine formula:

$$\exp \left(i\gamma u - \frac{1}{2}\alpha^2 u^2 + \int_{-\infty}^{\infty} (e^{iux} - 1 - iux1_{|x|\leq 1})v(dx) \right) \tag{16}$$

Table 2 Infinitely Divisible Distributions

	$Y \stackrel{d}{=} \sum_{k=1}^n Y_k$	Y_k
Poisson	$Poiss(\lambda)$	$Poiss(\frac{\lambda}{n})$
Gamma	$Gamma(c, \lambda)$	$Gamma(\frac{c}{n}, \lambda)$
Variance gamma	$VG(C, \lambda_+, \lambda_-)$	$VG(\frac{C}{n}, \lambda_+, \lambda_-)$
Inverse Gaussian	$IG(c, \lambda)$	$IG(\frac{c}{n}, \lambda)$
Normal	$N(\mu, \sigma^2)$	$N(\frac{\mu}{n}, \frac{\sigma^2}{n})$
α -stable	$S_\alpha(\sigma, \beta, \mu)$	$S_\alpha(\frac{\sigma}{n}, \beta, \frac{\mu}{n})$
CTS	$CTS(\alpha, C, \lambda_+, \lambda_-, m)$	$CTS(\alpha, \frac{C}{n}, \lambda_+, \lambda_-, \frac{m}{n})$
GTS	$GTS(\alpha_+, \alpha_-, C_+, C_-, \lambda_+, \lambda_-, m)$	$GTS(\alpha_+ \alpha_-, \frac{C_+}{N}, \frac{C_-}{N}, \lambda_+, \lambda_-, \frac{m}{n})$
MTS	$MTS(\alpha, C, \lambda_+, \lambda_-, m)$	$MTS(\alpha, \frac{C}{n}, \lambda_+, \lambda_-, \frac{m}{n})$
NTS	$NTS(\alpha, C, \lambda, \beta, m)$	$NTS(\alpha, \frac{C}{n}, \lambda, \beta, \frac{m}{n})$
KRTS	$KRTS(\alpha_+, k_+, k_-, r_+, r_-, p_+, p_-, m)$	$KRTS(\alpha, \frac{k_+}{n}, \frac{k_-}{n}, r_+, r_-, p_+, p_-, \frac{m}{n})$
RDTS	$RDTS(\alpha, C, \lambda_+, \lambda_-, m)$	$RDTS(\alpha, \frac{C}{n}, \lambda_+, \lambda_-, \frac{m}{n})$

Table 3 Lévy Measures

Distributions	Lévy Measure
Poisson	$\nu_{\text{Poisson}}(dx) = \lambda \delta_x(dx)^5$
Gamma	$\nu_{\text{gamma}}(dx) = \frac{ce^{-\lambda x}}{x} 1_{x>0} dx$
Variance gamma	$\nu_{\text{VG}}(dx) = \left(\frac{C_+ e^{-\lambda_+ x}}{x} 1_{x>0} + \frac{C_- e^{-\lambda_- x }}{x} 1_{x<0} \right) dx$
Inverse Gaussian	$\nu_{\text{IG}}(dx) = \frac{ce^{-\frac{\lambda^2}{2} x}}{\sqrt{2\pi x^3}} 1_{x>0} dx$

In the formula, the measure ν is referred to as the Lévy measure. The measure is a Borel measure satisfying the conditions that $\nu(0) = 0$ and $\int_{\mathbb{R}} (1 \wedge |x^2|) \nu(dx) < \infty$. The parameters γ and σ are real numbers. The variable γ is referred to as the center or drift and determines the location. This triplet (σ^2, ν, γ) is uniquely defined for each infinitely divisible distribution and called a Lévy triplet.

If $\nu(dx) = 0$, then the characteristic function equals the characteristic function of the normal distribution. That is, the infinitely divisible distribution with $\nu(dx) = 0$ becomes the normal distribution with mean γ and variance σ^2 .

If $\sigma = 0$, then the distribution is referred to as a purely non-Gaussian distribution. The characteristic functions of purely non-Gaussian distributions are computed by

$$\exp \left(i\gamma u + \int_{-\infty}^{\infty} (e^{iux} - 1 - iux 1_{|x| \leq 1}) \nu(dx) \right)$$

Hence, except for the location determined by γ , all the properties of the distribution are characterized by the Lévy measure $\nu(dx)$. The Poisson, gamma, VG, IG, α -stable, CTS, GTS, MTS, NTS, RDTS, and KRTS distributions are purely non-Gaussian distributions. The Lévy measure of the Poisson, gamma, VG, and IG distributions are given in Table 3.

The Lévy measure of the α -stable distribution is given by

$$\nu_{\text{stable}}(dx) = \left(\frac{C_+}{x^{1+\alpha}} 1_{x>0} + \frac{C_-}{|x|^{1+\alpha}} 1_{x<0} \right) dx \quad (17)$$

Using the Lévy Khinchine formula we can obtain the characteristic function in (1).⁵

The Lévy measure of the CTS, MTS, NTS, KRTS, and RDTS distributions can be obtained by multiplying the tempering function by the Lévy measure of α -stable distribution. For example, if we take $q(x) = e^{-\lambda_+ x} 1_{x>0} + e^{-\lambda_- |x|} 1_{x<0}$ as the tempering function, then we obtain the Lévy measure of the CTS distribution as

$$\begin{aligned} \nu(dx) &= q(x) \nu_{\text{stable}}(dx) \\ &= \left(\frac{C + e^{-\lambda_+ x}}{x^{1+\alpha}} 1_{x>0} + \frac{C_- e^{-\lambda_- |x|}}{|x|^{1+\alpha}} 1_{x<0} \right) dx \end{aligned}$$

Tempering functions of the other distributions are presented in Table 4. For this reason, they are referred to as the *tempered stable distributions*. The GTS distribution is also a purely non-Gaussian distribution, but not a tempered stable distribution in this sense. Indeed, its Lévy measure is given by

$$\nu(dx) = \left(\frac{C + e^{-\lambda_+ x}}{x^{1+\alpha_+}} 1_{x>0} + \frac{C_- e^{-\lambda_- |x|}}{|x|^{1+\alpha_-}} 1_{x<0} \right) dx$$

However, we will refer to the GTS distribution as a tempered stable distribution for convenience. Using the Lévy measures and the Lévy-Khinchine formula, we can obtain the characteristic functions (1), (2), (4), (6), (8), (12), and (14).

Generalizations of the tempering function and the tempered stable distribution have been studied in the literature.⁶

Table 4 Tempering Functions

	Tempering Function $q(x)$
CTS	$e^{-\lambda_+x}1_{x>0} + e^{-\lambda_- x }1_{x<0}$
MTS	$(\lambda_+x)^{\frac{\alpha+1}{2}}K_{\frac{\alpha+1}{2}}(\lambda_+x)1_{x>0} + (\lambda_- x)^{\frac{\alpha+1}{2}}K_{\frac{\alpha+1}{2}}(\lambda_- x)1_{x<0}$
NTS	$e^{\beta x}(\lambda x)^{\frac{\alpha+1}{2}}K_{\frac{\alpha+1}{2}}(\lambda x)$
KRTS	$r_+^{-p_+} \int_0^{r_+} e^{-x/s} s^{\alpha+p_+-1} ds 1_{x>0} + r_-^{-p_-} \int_0^{r_-} e^{- x /s} s^{\alpha+p_- -1} ds 1_{x<0}$
RDTs	$e^{-\frac{\lambda_+x^2}{2}}1_{x>0} + e^{-\frac{\lambda_- x ^2}{2}}1_{x<0}$

Exponential Moments

The exponential moment of a random variable X is defined by $E[e^{uX}]$ for some real number u . Existence of the exponential moment is important for modeling an asset price process in option pricing theory.

The exponential moment of the normal distribution is given by

$$E[e^{uX}] = \exp\left(\mu u + \frac{\sigma^2 u^2}{2}\right)$$

where $X \sim N(\mu, \sigma)$.

Using the Lévy measure we can check the existence of the exponential moment for an infinitely divisible random variable. The following theorem (see Sato, 1999) provides a useful tool to verify the existence of an exponential moment of an infinitely divisible distribution.

Theorem Let X be an infinitely divisible random variable with the Lévy triplet (σ^2, ν, γ) and let $u \in \mathbb{R}$. Then $E[e^{uX}] < \infty$ if and only if

$$\int_{|x|>1} e^{ux} \nu(dx) < \infty \tag{18}$$

In this case,

$$E[e^{uX}] = \phi_X(-iu)$$

where ϕ is the characteristic function of X and $i = \sqrt{-1}$.

The existence of exponential moments in the tempered stable distributions is as following:

- For the α -stable random variable X , the exponential moment of X generally does not exist.

However, if $X \sim S_\alpha(\sigma, 1, 0)$, then $E[e^{uX}] < \infty$ for $u < 0$. In this case,

$$E[e^{uX}] = \begin{cases} \exp\left(-\frac{\sigma^\alpha}{\cos\frac{\pi\alpha}{2}}\mu\alpha\right), & \alpha \neq 1 \\ \exp\left(\frac{2\sigma}{\pi}u \ln u\right), & \alpha = 1 \end{cases}$$

- For the CTS, GTS, and MTS distributions, the condition (18) is satisfied if and only if $-\lambda_- \leq u \leq \lambda_+$. Hence, $E[e^{uX}] < \infty$ for $u \in [-\lambda_-, \lambda_+]$.
- For the KRTS distribution, $E[e^{uX}] < \infty$ for $u \in [-1/r_-, 1/r_+]$.
- For the NTS and the NIG distributions, $E[e^{uX}] < \infty$ for $u \in [-\lambda - \beta, \lambda - \beta]$.
- For the RDTs distribution, (18) is satisfied for the entire real number u . Hence, $E[e^{uX}] < \infty$ for all $u \in \mathbb{R}$.

If $E[e^{uX}] < \infty$, then we can define the log-Laplace transform for the random variable X . The log-Laplace transform is given by

$$L(u) = \log E[e^{uX}] = \log \phi(-iu)$$

if (18) is satisfied.

For example, let $X \sim \text{stdCTS}(\alpha, \lambda_+, \lambda_-)$. The log-Laplace transform L_{CTS} of X is defined on $u \in [-\lambda_-, \lambda_+]$, and is given by

$$\begin{aligned} L_{\text{CTS}}(u; a, \lambda_+, \lambda_-) &= \log \phi_{\text{CTS}}(-iu; \alpha, C, \lambda_+, \lambda_-, 0) \\ &= \frac{(\lambda_+ - u)^\alpha - \lambda_+^\alpha + (\lambda_- + u)^\alpha - \lambda_-^\alpha}{\alpha(\alpha - 1)(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})} \\ &\quad - \frac{u(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1})}{(1 - \alpha)(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})} \end{aligned}$$

where C is satisfied (3). Using the same method, we can obtain the log-Laplace transform of the other standard tempered stable distributions as follows:

- Standard GTS distribution:

$$L_{GTS}(u; \alpha_+, \alpha_-, \lambda_+, \lambda_-) = \log \phi_{GTS}(-iu; \alpha_+, \alpha_-, C_+, C_-, \lambda_+, \lambda_-, 0)$$

on $u \in [-\lambda_-, \lambda_+]$ where C_+ and C_- satisfy (5).

- Standard MTS distribution:

$$L_{MTS}(u; \alpha, \lambda_+, \lambda_-) = \log \phi_{MTS}(-iu; \alpha, C, \lambda_+, \lambda_-, 0)$$

on $u \in [-\lambda_-, \lambda_+]$ where C satisfies (7).

- Standard NTS distribution:

$$L_{NTS}(u; \alpha, \lambda, \beta) = \log \phi_{NTS}(-iu; \alpha, C, \lambda, \beta, 0)$$

on $u \in [-\lambda - \beta, \lambda - \beta]$ where C satisfies (9).

- Standard NIG distribution:

$$L_{NIG}(u; \lambda, \beta) = \log \phi_{NIG}(-iu; C, \lambda, \beta, 0)$$

on $u \in [-\lambda - \beta, \lambda - \beta]$ where C satisfies (11).

- Standard KRTS distribution:

$$L_{KRTS}(u; \alpha, r_+, r_-, p_+, p_-) = \log \phi_{KRTS}(-iu; \alpha, k_+, k_-, r_+, r_-, p_+, p_-, 0)$$

on $u \in [-\lambda_-, \lambda_+]$ where k_+ and k_- satisfy (13).

- Standard RDTS distribution:

$$L_{RDTS}(u; \alpha, \lambda_+, \lambda_-) = \log \phi_{RDTS}(-iu; \alpha, C, \lambda_+, \lambda_-, 0)$$

on $u \in \mathbb{R}$ where C satisfies (15).

HYPERGEOMETRIC FUNCTION AND CONFLUENT HYPERGEOMETRIC FUNCTION

In this entry, we referred to the hypergeometric function and the confluent hypergeometric function. Here we describe these two special functions. (For more details, see Andrews,

1998.) We begin by introducing the following notation

$$(a)_0 = 1, \quad (a)_n = a(a+1)\cdots(a+n-1) \\ n = 1, 2, 3, \dots, a \in \mathbb{R} \tag{19}$$

and we refer to the notation as the Pochhammer symbol. By properties of the gamma function, the Pochhammer symbol can also be defined by

$$(a)_n = \frac{\Gamma(a+n)}{\Gamma(a)}, \quad n = 0, 1, 2, 3, \dots$$

From (19), we obtain

$$(2n+1)! = 2^{2n}n! \left(\frac{3}{2}\right)_n \tag{20}$$

The Hypergeometric Function

The function

$${}_2F_1(a, b; c; x) = \sum_{n=0}^{\infty} \frac{(a)_n(b)_n}{(c)_n} \frac{x^n}{n!}, \quad |x| < 1 \tag{21}$$

is called the hypergeometric function. If $c \neq 0, -1, -2, \dots$, the function $F(a, b; c; x)$ is a solution to the linear second-order differential equation

$$x(1-x)y'' + (c - (a+b+1)x)y' - aby = 0 \tag{22}$$

referred to as the hypergeometric equation. Moreover, if $c \neq 0, \pm 1, \pm 2, \dots$,

$$y = C_1 {}_2F_1(a, b; c; x) + C_2 x^{1-c} {}_2F_1(1+a-c, 1+b-c; 2-c; x)$$

for any constants C_1 and C_2 , is a general solution to equation (22). For $k = 1, 2, 3, \dots$, k th derivatives are obtained from the following equation:

$$\frac{d^k}{dx^k} {}_2F_1(a, b; c; x) = \frac{(a)_k(b)_k}{(c)_k} {}_2F_1(a+k, b+k; c+k; x) \tag{23}$$

The Confluent Hypergeometric Function

The function

$$M(a; c; x) = \sum_{n=0}^{\infty} \frac{(a)_n x^n}{(c)_n n!}, \quad -\infty < x < \infty \quad (24)$$

is called the confluent hypergeometric function and is obtained by the limit of the hypergeometric function as follows:

$$M(a; c; x) = \lim_{b \rightarrow \infty} F(a, b; c; x/b)$$

The function $M(a; c; x)$ is a solution of the linear second-order differential equation

$$xy'' + (c - x)y' - ay = 0 \quad (25)$$

referred to as the confluent hypergeometric equation. Moreover, if $c \neq 0, \pm 1, \pm 2, \dots$,

$$y = C_1 M(a; c; x) + C_2 x^{1-c} F(1 + a - c; 2 - c; x)$$

for any constants C_1 and C_2 , is a general solution of equation (25). For $k = 1, 2, 3 \dots$, k th derivatives are obtained by the following equation:

$$\frac{d^k}{dx^k} M(a; c; x) = \frac{(a)_k}{(c)_k} M(a + k; c + k; x) \quad (26)$$

KEY POINTS

- The distribution assumed in financial models for asset returns is the normal or Gaussian distribution. Real-world asset returns, however, have been observed to be skewed and non-symmetric, two features that are inconsistent with the normal distribution.
- Although the non-Gaussian alpha-stable distribution is superior to the normal distribution because it allows for skewness and fat tails, it is not suitable in certain modeling applications such as in modeling option prices. This is because the mean, variance, and exponential moments of the return distribution have to exist. The smoothly truncated sta-

ble distribution, obtained by tempering the tail properties of the alpha-stable distribution, have been proposed for modeling in such instances.

- There are six tempered stable distributions: classical tempered stable distribution, generalized classical tempered stable distribution, modified tempered stable distribution, normal tempered stable distribution, Kim-Rachev tempered stable distribution, and rapidly decreasing tempered stable distribution. All six tempered stable distributions and the alpha-stable distribution are defined by their characteristic functions.
- The infinitely divisible distribution is characterized by the Lévy-Khinchine formula and contains the alpha-stable and the tempered stable distributions as special cases.

NOTES

1. Extensive analysis of α -stable distributions and their properties can be found in Samorodnitsky and Taqqu (1994), Rachev and Mittnik (2000), and Stoyanov and Racheva-Iotova (2004a, 2004b).
2. The KoBoL distribution (see Boyarchenko and Levendorskii, 2000) is obtained by substituting $\alpha = \alpha_+ = \alpha_-$, the truncated Lévy flight is obtained by substituting $\lambda = \lambda_+ = \lambda_-$ and $\alpha = \alpha_+ = \alpha_-$, while the CGMY distribution (see Carr et al., 2002) is obtained by substituting $C = C_+ = C_-$, $G = \lambda_-$, $M = X_+$ and $Y = \alpha_+ = \alpha_-$.
3. The NTS distribution was originally obtained using a time-changed Brownian motion with a tempered stable subordinator by Barndorff-Nielsen and Levendorskii (2001). Later, Kim, Rachev, Chung, and Bianchi (2008c) define the NTS distribution by the exponential tilting for the symmetric MTS distribution.
4. The NIG distribution has been used for financial modeling by Barndorff-Nielsen (1998, 1997) and Rydberg (1997).

5. More details about the calculation can be found in Samorodnitsky and Taqqu (1994) and Sato (1999).
6. The tempered stable distribution has been generalized by Rosiński (2007) and Bianchi et al. (2010). Rosiński (2007) defined the tempering function as the completely monotone function. The complete monotonicity of the tempering function $q(x)$ means that $(-1)^n \frac{d^n}{dx^n} q(x) > 0$ for all $n = 0, 1, 2, \dots$ and $x \in \mathbb{R}$ with $x \neq 0$. The CTS and the KRTS distributions are included in Rosiński's generalization. In Bianchi et al. (2010), the tempering function is defined by the positive definite radial function. The RDTs and the MTS distributions are subclasses of the class of the TID distributions.

Fat Tails, Scaling, and Stable Laws

SERGIO M. FOCARDI, PhD
Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

Abstract: Fat-tailed laws have been found in many economic variables. Fully approximating a finite economic system with fat-tailed laws depends on an accurate statistical analysis of the phenomena, but also on a number of the theoretical implications of subexponentiality and scaling. Modeling financial variables with stable laws implies the assumption of infinite variance, which seems to contradict empirical observations. Nevertheless, scaling laws might still be an appropriate modeling paradigm given the complex interaction of distributional shape and correlations in price processes. They might help in understanding not only the sheer size of economic fluctuations but also the complexity of economic cycles. There are applications where scaling laws play a fundamental role, in particular in risk management and financial optimization. Ignoring the possibility of large deviations would render financial risk management ineffective and dangerous.

Most models of stochastic processes and time series assume that distributions have finite mean and finite variance. In this entry we describe fat-tailed distributions with infinite variance. Fat-tailed distributions have been found in many financial economic variables ranging from forecasting returns on financial assets to modeling recovery distributions in bankruptcies. They have also been found in numerous insurance applications such as catastrophic insurance claims and in value-at-risk measures employed by risk managers.

In this entry, we review the related concepts of *fat-tailed*, *power-law*, and *Levy-stable distributions*, *scaling*, and *self-similarity*, as well as explore the mechanisms that generate these distributions.

We discuss the key intuition relative to the applicability of fat-tailed or scaling processes to finance: In a fat-tailed or scaling world (as opposed to an ergodic world), the past does not offer an exhaustive set of possible configurations. Adopting, as an approximation, a scaling description of financial phenomena implies the belief that only a small space of possible configurations has been explored; vast regions remain unexplored.

We begin with the mathematics of fat-tailed processes, followed by a discussion of classical *extreme value theory* for independent and identically distributed sequences. We then explore the consequences of eliminating the assumption of independence and discuss different concepts of

scaling and self similarity. We will not provide a review of the literature on the evidence of fat tails in financial markets. For a review, see Rachev, Menn, and Fabozzi (2005).

SCALING, STABLE LAWS, AND FAT TAILS

Let's begin with a review of the different but related concepts and properties of fat tails, power laws, and stable laws. These concepts appear frequently in the financial and economic literature, applied to both random variables and stochastic processes.

Fat Tails

Consider a random variable X . By definition, X is a real-valued function from the set Ω of the possible outcomes to the set R of real numbers, such that the set $(X \leq x)$ is an event. If $P(X \leq x)$ is the probability of the event $(X \leq x)$, the function $F(x) = P(X \leq x)$ is a well-defined function for every real number x . The function $F(x)$ is called the cumulative distribution function, or simply the distribution function, of the random variable X . Note that X denotes a function $\Omega \rightarrow R$, x is a real variable, and $F(x)$ is an ordinary real-valued function that assumes values in the interval $[0,1]$. If the function $F(x)$ admits a derivative

$$f(x) = \frac{dF(x)}{dx}$$

The function $f(x)$ is called the probability density of the random variable X . The function $\bar{F}(x) = 1 - F(x)$ is the tail of the distribution $F(x)$. The function $\bar{F}(x)$ is called the survival function.

Fat tails are somewhat arbitrarily defined. Intuitively, a fat-tailed distribution is a distribution that has more weight in the tails than some reference distribution. The exponential decay of the tail is generally assumed as the borderline separating fat-tailed from light-tailed distributions. In the literature, distributions with

a power-law decay of the tails are referred to as *heavy-tailed distributions*. It is sometimes assumed that the reference distribution is Gaussian (i.e., normal), but this is unsatisfactory; it implies, for instance, that exponential distributions are fat-tailed because Gaussian tails decay as the square of an exponential and thus faster than an exponential.

These characterizations of fat-tailedness (or heavy-tailedness) are not convenient from a mathematical and statistical point of view. It would be preferable to define fat-tailedness in terms of a function of some essential property that can be associated to it. Several proposals have been advanced. Widely used definitions focus on the moments of the distribution. Definitions of fat-tailedness based on a single moment focus either on the second moment, the variance, or the kurtosis, defined as the fourth moment divided by the square of the variance. In fact, a distribution is often considered fat-tailed if its variance is infinite or if it is leptokurtic (i.e., its kurtosis is greater than 3). However, as remarked by Bryson (1982), definitions of this type are too crude and should be replaced by more complete descriptions of tail behavior.

Others consider a distribution fat-tailed if all its exponential moments are infinite, $E[e^{sX}] = \infty$ for every $s \geq 0$. This condition implies that the moment-generating function does not exist. Some suggest weakening this condition, defining fat-tailed distributions as those distributions that do not have a finite exponential moment of first order. Exponential moments are particularly important in finance and economics when the logarithm of variables, for instance logprices, are the primary quantity to be modeled.¹

Fat-tailedness has a consequence of practical importance: The probability of *extremal events* (i.e., the probability that the random variable assumes large values) is much higher than in the case of normal distributions. A fat-tailed distribution assigns higher probabilities to extremal events than would a normal distribution.

For instance, a six-sigma event (i.e., a realized value of a random variable whose difference from the mean is six times the size of the standard deviation) has a near zero probability in a Gaussian distribution but might have a non-negligible probability in fat-tailed distributions.

The notion of fat-tailedness can be made quantitative as different distributions have different degrees of fat-tailedness. The degree of fat-tailedness dictates the weight of the tails and thus the probability of extremal events. Extreme value theory attempts to estimate the entire tail region, and therefore the degree of fat-tailedness, from a finite sample. A number of indicators for evaluating the size of extremal events have been proposed; among these is the extremal claim index proposed in Embrechts, Kluppelberg, and Mikosch (1999), which plays an important role in risk management.

The Class \mathcal{L} of Fat-Tailed Distributions

Many important classes of fat-tailed distributions have been defined; each is characterized by special statistical properties that are important in given application domains. We will introduce a number of such classes in order of inclusion, starting from the class with the broadest membership: the class \mathcal{L} , which is defined as follows. Suppose that F is a distribution function defined in the domain $(0, \infty)$ with $F < 1$ in the entire domain (i.e., F is the distribution function of a positive random variable with a tail that never decays to zero). It is said that $F \in \mathcal{L}$ if, for any $y > 0$, the following property holds:

$$\lim_{x \rightarrow \infty} \frac{\bar{F}(x - y)}{\bar{F}(x)} = 1, \quad \forall y > 0$$

We can rewrite the above property in an equivalent (and perhaps more intuitive from the probabilistic point of view) way. Under the same assumptions as above, it is said that, given a positive random variable X , its distribution function $F \in \mathcal{L}$ if the following property holds

for any $y > 0$:

$$\begin{aligned} & \lim_{x \rightarrow \infty} P(X > x + y | X > x) \\ &= \lim_{x \rightarrow \infty} \frac{\bar{F}(x + y)}{\bar{F}(x)} = 1, \quad \forall y > 0 \end{aligned}$$

Intuitively, this second property means that if it is known that a random variable exceeds a given value x , then it will exceed any bigger value with certainty as the value x tends to infinity. Some authors define a distribution as being heavy-tailed if it satisfies this property.²

It can be demonstrated that if a distribution $F(x) \in \mathcal{L}$, then it has the following properties:

- Infinite exponential moments of every order: $E[e^{sX}] = \infty$ for every $s \geq 0$
- $\lim_{x \rightarrow \infty} \bar{F}(x)e^{\lambda x} = \infty, \quad \forall \lambda > 0$

As distributions in class \mathcal{L} have infinite exponential moments of every order, they satisfy one of the previous definitions of fat-tailedness. However, they might have finite or infinite mean and variance.

The class \mathcal{L} is in fact quite broad. It includes, in particular, the two classes of subexponential distributions and distributions with regularly varying tails that are discussed in the following sections.

Subexponential Distributions

A class of fat-tailed distributions, widely used in insurance and telecommunications, is the class S of *subexponential distributions*. Introduced by Chistyakov (1964), subexponential distributions can be characterized by two equivalent properties: (1) the convolution closure property of the tails and (2) the property of the sums.³

The *convolution closure property* of the tails prescribes that the shape of the tail is preserved after the summation of identical and independent copies of a variable. This property asserts that, for $x \rightarrow \infty$, the tail of a sum of independent and identical variables has the same shape as the tail of the variable itself. As the distribution of a sum of n independent variables is the n -convolution of their distributions, the

convolution closure property can be written as

$$\lim_{x \rightarrow \infty} \frac{\bar{F}^{n^*}(x)}{\bar{F}(x)} = n$$

Note that Gaussian distributions do not have this property although the sum of independent Gaussian distributions is again a Gaussian distribution. Subexponential distributions can be characterized by another important (and perhaps more intuitive) property, which is equivalent to the convolution closure property: In a sum of n variables, the largest value will be of the same order of magnitude as the sum itself. For any n , define

$$S_n(x) = \sum_{i=1}^n X_i$$

as a sum of independent and identical copies of a variable X and call M_n their maxima. In the limit of large x , the probability that the tail of the sum exceeds x equals the probability that the largest summand exceeds x :

$$\lim_{x \rightarrow \infty} \frac{P(S_n > x)}{P(M_n > x)} = 1$$

The class S of subexponential distributions is a proper subset of the class \mathfrak{L} . Every subexponential distribution belongs to the class \mathfrak{L} while it can be demonstrated (but this is not trivial) that there are distributions that belong to the class \mathfrak{L} but not to the class S . Distributions that have both properties are called subexponential as it can be demonstrated that, as all distributions in \mathfrak{L} , they satisfy the property:

$$\lim_{x \rightarrow \infty} \bar{F}(x)e^{\lambda x} = \infty, \quad \forall \lambda > 0$$

Note, however, that the class of distributions that satisfies the latter property is broader than the class of subexponential distributions; this is because the former includes, for instance, the class \mathfrak{L} .⁴

Subexponential distributions do not have finite exponential moments of any order, that is, $E[e^{sX}] = \infty$ for every $s \geq 0$. They may or may not have a finite mean and/or a finite variance. Consider, in fact, that the class of subexpo-

ponential distributions includes both Pareto and Weibull distributions. The former have infinite variance but might have finite or infinite mean depending on the index; the latter have finite moments of every order (see below).

The key indicators of subexponentiality are (1) the equivalence in the distribution of the tail between a variable and a sum of independent copies of the same variable and (2) the fact that a sum is dominated by its largest term. The importance of the largest terms in a sum can be made more quantitative using measures such as the large claims index introduced in Embrechts, Kluppelberg, and Mikosch (1999) that quantifies the ratio between the largest p terms in a sum and the entire sum.

The class of subexponential distributions is quite large. It includes not only Pareto and stable distributions but also log-gamma, lognormal, Benkander, Burr, and Weibull distributions. Pareto distributions and stable distributions are a particularly important subclass of subexponential distributions; these will be described in some detail below.

Power-Law Distributions

Power-law distributions are a particularly important subset of subexponential distributions. Their tails follow approximately an inverse power law, decaying as $x^{-\alpha}$. The exponent α is called the tail index of the distribution. To express formally the notion of approximate power-law decay, we need to introduce the class $\mathfrak{R}(\alpha)$, equivalently written as \mathfrak{R}_α of regularly varying functions.

A positive function f is said to be regularly varying with index α or $f \in \mathfrak{R}(\alpha)$ if the following condition holds:

$$\lim_{x \rightarrow \infty} \frac{f(tx)}{f(x)} = t^\alpha$$

A function $f \in \mathfrak{R}(\alpha)$ is called slowly varying. It can be demonstrated that a regularly varying function $f(x)$ of index α admits the representation $f(x) = x^\alpha l(x)$ where $l(x)$ is a slowly varying function.

A distribution F is said to have a regularly varying tail if the following property holds:

$$\bar{F} = x^{-\alpha}l(x)$$

where l is a slowly varying function. An example of a distribution with a regularly varying tail is Pareto's law. The latter can be written in various ways, including the following:

$$\bar{F}(x) = P(X > x) = \frac{c}{c + x^\alpha} \text{ for } x \geq 0$$

Power-law distributions are thus distributions with regularly varying tails. It can be demonstrated that they satisfy the convolution closure property of the tail. The distribution of the sum of n independent variables of tail index α is a power-law distribution of the same index α . Note that this property holds in the limit for $x \rightarrow \infty$. Distributions with regularly varying tails are therefore a proper subset of subexponential distributions.

Being subexponential, power laws have all the general properties of fat-tailed distributions and some additional ones. One particularly important property of distributions with regularly varying tails, valid for every tail index, is the rank-size order property. Suppose that samples from a power law of tail index α are ordered by size, and call S_r the size of the r th sample. One then finds that the law

$$S_r = ar^{-\frac{1}{\alpha}}$$

is approximately verified. The well-known Zipf's law is an example of this rank-size ordering. Zipf's law states that the size of an observation is inversely proportional to its rank. For example, the frequency of words in an English text is inversely proportional to their rank. The same is approximately valid for the size of U.S. cities.

Many properties of power-law distributions are distinctly different in the three following ranges of α : $0 < \alpha \leq 1$, $1 < \alpha \leq 2$, $\alpha > 2$. The threshold $\alpha = 2$ for the tail index is important as it marks the separation between the applicability of the standard central limit theorem (CLT); the threshold $\alpha = 1$ is important as it separates

variables with a finite mean from those with infinite mean. Let's take a closer look at the *law of large numbers* and the CLT.

The Law of Large Numbers and the Central Limit Theorem

There are four basic versions of the law of large numbers (LLN), two weak laws of large numbers (WLLN), and two strong laws of large numbers (SLLN).

The two versions of the WLLN are formulated as follows.

1. Suppose that the variables X_i are IID with finite mean $E[X_i] = E[X] = \mu$. Under this condition it can be demonstrated that the empirical average tends to the mean in probability:

$$\bar{X}_n = \frac{\sum_{i=1}^n X_i}{n} \xrightarrow[n \rightarrow \infty]{P} E[X] = \mu$$

2. If the variables are only independently distributed (ID) but have finite means and variances (μ_i, σ_i) , then the following relationship holds:

$$\bar{X}_n = \frac{\sum_{i=1}^n X_i}{n} \xrightarrow[n \rightarrow \infty]{P} \frac{\sum_{i=1}^n \bar{X}_i}{n} = \frac{\sum_{i=1}^n \mu_i}{n}$$

In other words, the empirical average of a sequence of finite-mean finite-variance variables tends to the average of the means.

The two versions of the SLLN are formulated as follows.

1. The empirical average of a sequence of IID variables X_i tends almost surely to a constant a if and only if the expected value of the variables is finite. In addition, the constant a is equal to μ . Therefore, if and only if $|E[X_i]| = |E[X]| = |\mu| < \infty$ the following relationship holds:

$$\bar{X}_n = \frac{\sum_{i=1}^n X_i}{n} \xrightarrow[n \rightarrow \infty]{A.S.} E[X] = \mu$$

where convergence is in the sense of almost sure convergence.

2. If the variables X_i are only independently distributed (ID) but have finite means and variances (μ_i, σ_i) and

$$\lim_{n \rightarrow \infty} \frac{1}{n^2} \sum_{i=1}^n \sigma_i^2 < \infty$$

then the following relationship holds:

$$\bar{X}_n = \frac{\sum_{i=1}^n X_i}{n} \xrightarrow[n \rightarrow \infty]{A.S.} \frac{\sum_{i=1}^n \bar{X}_i}{n} = \frac{\sum_{i=1}^n \mu_i}{n}$$

Suppose the variables are IID. If the scaling factor n is replaced with \sqrt{n} , then the limit relation no longer holds as the normalized sum

$$\frac{\sum_{i=1}^n X_i}{\sqrt{n}}$$

diverges. However, if the variables have finite second-order moments, the classical version of the CLT can be demonstrated. In fact, under the assumption that both first- and second-order moments are finite, it can be shown that

$$\frac{S_n - n\mu}{\sigma\sqrt{n}} \xrightarrow{D} \Phi$$

$$S_n = \sum_{i=1}^n X_i$$

where μ, σ are respectively the expected value and standard deviation of X , and Φ the standard normal distribution.

If the tail index $\alpha > 1$, variables have finite expected value and the SLNN holds. If the tail index $\alpha > 2$, variables have finite variance and the CLT in the previous form holds. If the tail index $\alpha \leq 2$, then variables have infinite variance: The CLT in the previous form does not hold. In fact, variables with $\alpha \leq 2$ belong to the domain of attraction of a stable law of index α . This means that a sequence of properly normalized and centered sums tends to a stable distribution with infinite variance. In this case, the CLT takes the form

$$\frac{S_n - n\mu}{n^{\frac{1}{\alpha}}} \xrightarrow{D} G_\alpha, \text{ if } 1 < \alpha \leq 2$$

$$\frac{S_n}{n^{\frac{1}{\alpha}}} \xrightarrow{D} G_\alpha, \text{ if } 0 < \alpha \leq 1$$

where G are stable distributions as defined below. Note that the case $\alpha = 2$ is somewhat special: variables with this tail index have infinite variance but fall nevertheless in the domain of attraction of a normal variable, that is, G_2 . Below the threshold 1, distributions have neither finite variance nor finite mean. There is a sharp change in the normalization behavior at this tail-index threshold.

Stable Distributions

Stable distributions are not, in their generality, a subset of fat-tailed distributions as they include the normal distribution. There are different, equivalent ways to define stable distributions. Let's begin with a key property: the equality in distribution between a random variable and the (normalized) independent sum of any number of identical replicas of the same variable. This is a different property than the closure property of the tail insofar as (1) it involves not only the tail but the entire distribution and (2) equality in distribution means that distributions have the same functional form but, possibly, with different parameters. Normal distributions have this property: The sum of two or more normally distributed variables is again a normally distributed variable. But this property holds for a more general class of distributions called stable distributions or Levy-stable distributions.⁵ Normal distributions are thus a special type of stable distributions.

The above can be formalized as follows: Stable distributions can be defined as those distributions for which the following identity in distribution holds for any number $n \geq 2$:

$$\sum_{i=1}^n X_i \stackrel{D}{=} C_n X + D_n$$

where X_i are identical independent copies of X and the C_n, D_n are constants. Alternatively, the same property can be expressed stating that stable distributions are distributions for which the following identity in distribution holds:

$$AX_1 + BX_2 \stackrel{D}{=} CX + D$$

Stable distributions are also characterized by another property that might be used in defining them: a stable distribution has a domain of attraction (i.e., it is the limit in distribution of a normalized and centered sum of identical and independent variables). Stable distributions coincide with all variables that have a domain of attraction.

Except in the special cases of Gaussian ($\alpha = 2$), symmetric Cauchy ($\alpha = 1, \beta = 0$), and stable inverse Gaussian ($\alpha = \frac{1}{2}, \beta = 0$) distributions, stable distributions cannot be written as simple formulas; formulas have been discovered but are not simple. However, stable distributions can be characterized in a simple way through their characteristic function, the Fourier transform of the distribution function. In fact, this function can be written as

$$\Phi_X(t) = \exp\{i\gamma t - c|t|^\alpha[1 - i\beta\text{sign}(t)z(t, \alpha)]\}$$

where $t \in R, \gamma \in R, c > 0, \alpha \in (0, 2), \beta \in [-1, 1]$, and

$$z(t, \alpha) = \tan \frac{\pi\alpha}{2} \text{ if } \alpha \neq 1$$

$$z(t, \alpha) = -2 \log |t| \text{ if } \alpha = 1$$

It can be shown that only distributions with this characteristic function are stable distributions (i.e., they are the only distributions closed under summation). A stable law is characterized by four parameters: α, β, c , and γ . Normal distributions correspond to the parameters: $\alpha = 2, \beta = 0, \gamma = 0$.

Even if stable distributions cannot be written as simple formulas, the asymptotic shape of their tails can be written in a simple way. In fact, with the exception of Gaussian distributions, the tails of stable laws obey an inverse power law with exponent α (between 0 and 2). Normal distributions are stable but are an exception as their tails decay exponentially.

For stable distributions, the CLT holds in the same form as for inverse power-law distributions. In addition, the functions in the domain of attraction of a stable law of index $\alpha < 2$ are characterized by the same tail index. This means that a distribution G belongs to the domain of

attraction of a stable law of parameter $\alpha < 2$ if and only if its tail decays as α . In particular, Pareto's law belongs to the domain of attraction of stable laws of the same tail index.

EXTREME VALUE THEORY FOR IID PROCESSES

In this section we introduce a number of important probabilistic concepts that form the conceptual basis of extreme value theory (EVT). The objective of EVT is to estimate the entire tail of a distribution from a finite sample by fitting to an appropriate distribution those values of the sample that fall in the tail. Two concepts play a crucial role in EVT: (1) the behavior of the upper order statistics (i.e., the largest k values in a sample) and, in particular, of the sample maxima; and (2) the behavior of the points where samples exceed a given threshold. We will explore the limit distributions of maxima and the distribution of the points of exceedances of a high threshold. Based on these concepts a number of estimators of the tail index in sequences of independent and identically distributed (IID) variables are presented.

Maxima

In the previous sections we explored the behavior of sums. The key result of the theory of sums is that the behavior of sums simplifies in the limit of properly scaled and centered infinite sums regardless of the shape of individual summands. If sums converge, their limit distributions can only be stable distributions. In addition, the normalized sums of finite-mean, finite-variance variables always converge to a normal variable.

A parallel theory can be developed for maxima, informally defined as the largest value in a sample. The limit distribution of maxima, if it exists, belongs to one of three possible distributions: *Frechet*, *Weibull*, or *Gumbel*. This result forms the basis of classical EVT. Each limit distribution of maxima has its own maximum domain of attraction. In addition, limit laws are

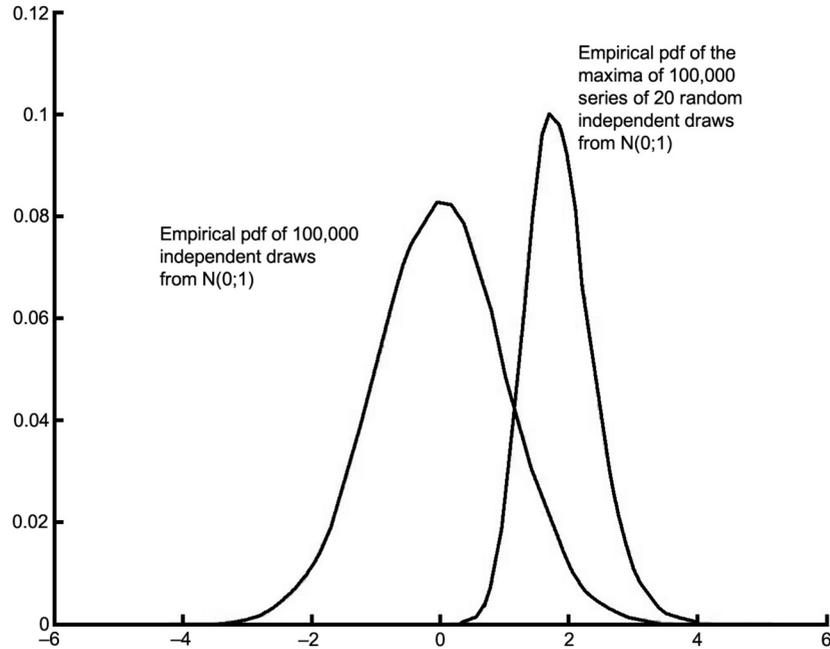

Figure 1 The Distribution of the Maxima of a Normal Variable

max-stable (i.e., they are closed with respect to maxima). However, the behavior of maxima is less robust than the behavior of sums. Maxima do not converge to limit distributions for important classes of distributions, such as Poisson or geometric distributions.

Consider a sequence of independent variables X_i with common, nondegenerate distribution F and the maxima of samples extracted from this sequence:

$$M_1 = X_1, M_n = \max(X_1, \dots, X_n)$$

The maxima M_n form a new sequence of random variables, which are not, however, independent.

As the variables of the sequence X_i are assumed to be independent, the distribution F_n of the maxima M_n can be immediately written down:

$$F(x)_n = P(X_1 \leq x \vee \dots \vee X_n \leq x) = F^n(x)$$

where \vee is the logical symbol for *and*.

If the distribution F , which is a nondecreasing function, reaches 1 at a finite point x_F —that is,

if $x_F = \sup\{x: F(x) < 1\} < \infty$, then

$$\lim_{n \rightarrow \infty} P(M_n < x) = \lim_{n \rightarrow \infty} F_n(x) = 0, \text{ for } x < x_F$$

If x_F is finite,

$$P(M_n < x) = F_n(x) = 1, \text{ for } x > x_F$$

The point x_F is called the right endpoint of the distribution F .

Figure 1 illustrates the behavior of maxima in the case of a normal distribution. Given a normal distribution with mean zero and variance one, 100,000 samples of 20 elements each are selected. For each sample, the maximum is chosen. The distribution of the maxima and the empirical distribution of independent draws from the same normal are illustrated in the figure.

A deeper understanding of the behavior of maxima can be obtained considering sequences of normalized and centered maxima. Consider the following sequence: $c_n^{-1}(M_n - d_n)$ where $c_n > 0$, $d_n \in \mathbb{R}$ are constants.

A fundamental result on the behavior of maxima is the Fisher-Tippett theorem, which can be stated as follows. Consider a sequence of IID

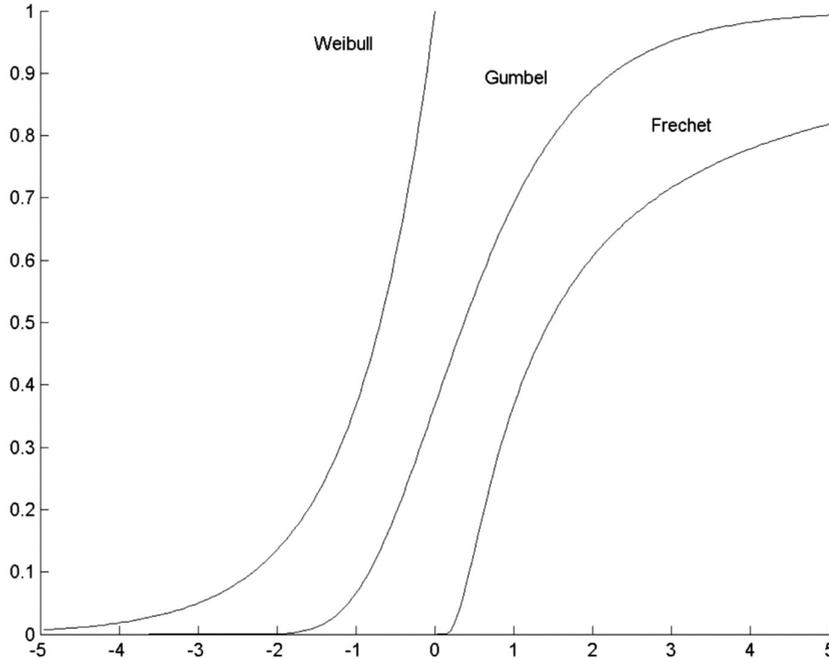

Figure 2 The Distribution of Fréchet, Gumbel, and Weibull

variables X_i and the relative sequence of maxima M_n . If there exist two sequences of constants $c_n > 0, d_n \in R$ and a nondegenerate distribution function H such that

$$c_n^{-1}(M_n - d_n) \xrightarrow{D} H$$

then H is one of the following distributions:

Fréchet: $\Phi_\alpha(x) = \begin{cases} 0 & x \leq 0 \\ \exp(-x^{-\alpha}) & x > 0 \end{cases} \quad \alpha > 0$

Weibull: $\Psi_\alpha(x) = \begin{cases} \exp[-(-x)^{-\alpha}] & x < 0 \\ 1 & x \geq 0 \end{cases} \quad \alpha > 0$

Gumbel: $\Lambda(x) = \exp\{-e^{-x}\}, x \in R$

The limit distribution H is unique, in the sense that different sequences of normalizing constants determine the same distribution.

The three above distributions—Fréchet, Weibull, and Gumbel—are called *standard extreme value distributions*. They are continuous functions for every real x . Random variables distributed according to one of the extreme value distributions are called *extremal random variables*.

As an example, consider a standard exponential variable X . As $F(x) = P(X \leq x) = 1 - e^{-x}, x \geq 0$ the distribution of the maxima is $P(M_n \leq x) = F^n(x) = (1 - e^{-x})^n, x \geq 0$. If we choose $d_n = \ln n$, we can write: $P(M_n - d_n \leq x) = P(M_n \leq \ln n + x) = (1 - n^{-1}e^{-x})^n, x \geq 0$. For any given $x, (1 - n^{-1}e^{-x})^n \rightarrow \exp(-e^{-x})$, which shows that the maxima of standard exponential variables centered with $d_n = \ln n$ tend to a Gumbel distribution. Figure 2 illustrates the three distributions: Fréchet, Gumbel, and Weibull.

We can now ask if there are conditions on the distribution F that ensure the existence of centering and scaling constants and the convergence to an extreme value distribution. To this end, let's first introduce the concept of the maximum domain of attraction (MDA) of an extreme value distribution H or $MDA(H)$.

A random variable X is said to belong to the $MDA(H)$ of the extreme value distribution H if there exist constants $c_n > 0, d_n \in R$ such that

$$c_n^{-1}(M_n - d_n) \xrightarrow{D} H$$

Two distribution functions F, G are said to be tail equivalent if they have the same right endpoints and the following condition holds:

$$\lim_{x \rightarrow \infty} \frac{\bar{F}(x)}{\bar{G}(x)} = c, 0 < c < \infty$$

Tail equivalence is an important concept for characterizing MDAs. In fact, it can be demonstrated that every $MDA(H)$ is closed with respect to tail equivalence (i.e., if two distribution functions F and G are tail equivalent $F \in MDA(H)$ if and only if $G \in MDA(H)$). Tail equivalence allows for a powerful characterization of the three MDAs.

Let's first define the quantile function. Given a distribution function F , the quantile function of F , written $F^{\leftarrow}(x)$, is defined as follows:

$$F^{\leftarrow}(x) = \inf\{s \in R : F(s) \geq x\}, 0 < x < 1$$

The MDA of the Frechet Distribution

The Frechet distribution is written as $\Phi_{\alpha}(x) = \exp(-x^{-\alpha})$. Let's start by observing that the tail of the Frechet distribution decays as an inverse power law. In fact, we can write $1 - \Phi_{\alpha}(x) = 1 - \exp(-x^{-\alpha}) \approx x^{-\alpha}$ for $x \rightarrow \infty$.

It can be demonstrated that a distribution function F belongs to the MDA of a Frechet distribution $\Phi_{\alpha}(x)$, $\alpha > 0$ if and only if there is a slowly varying function L such that $\bar{F}(x) = x^{-\alpha}L(x)$. In this case, the constants assume the values

$$c_n = (1/F^{\leftarrow})(n), d_n = 0$$

We can rewrite this condition more compactly as follows:

$$F \in MDA(\Phi_{\alpha}) \Leftrightarrow \bar{F} \in R_{-\alpha}$$

From the above definitions it can be demonstrated that the following five distributions belong to the MDA of the Frechet distribution: (1) Pareto; (2) Cauchy; (3) Burr; (4) stable laws with exponent $\alpha < 2$; or (5) log-gamma distribution.

The MDA of the Weibull Distribution

The Weibull distribution is written as follows:

$$\Psi_{\alpha} = \exp[-(-x^{-\alpha})]$$

The Weibull and the Frechet distributions are closely related to each other. In fact, it is clear from the definition that the following relationship holds:

$$\Psi_{\alpha}(x) = \Phi_{\alpha}(-x^{-1}), x > 0$$

One can therefore expect that the MDA of the two distributions are closely related. In fact, it can be demonstrated that a distribution function F belongs to the MDA of a Weibull distribution $\alpha > 0$ if and only if

$$x_F < \infty$$

and

$$\bar{F}(x_F - x^{-1}) = x^{-\alpha}L(x)$$

where L is a slowly varying function.

If

$$F \in MDA(\Psi_{\alpha})$$

then

$$c_n^{-1}(M_n - x_F) \xrightarrow{D} \Psi_{\alpha}$$

The MDA of the Weibull distribution includes important distributions such as the distribution uniform in $(0,1)$, power laws truncated to the right, and beta distributions.

The MDA of the Gumbel Distribution

The Gumbel distribution is written as $\Lambda(x) = \exp[-\exp(-x)]$. Observe that the Gumbel distribution has exponential tails. This fact can be easily ascertained through Taylor expansion. There is no simple characterization of the MDA of the Gumbel distribution.

The MDA of a Gumbel distribution encompasses a large class of distributions that includes the exponential distribution, the normal distribution, and the lognormal distribution. Though the Gumbel distribution has exponential tails, its MDA includes subexponential

distributions such as the Berkander distribution, as explained in Goldie and Resnick (1988).

Max-Stable Distributions

Stable distributions remain unchanged after summation; *max-stable distributions* remain unchanged after taking maxima. A nondegenerate random variable X and the relative distribution is called max-stable if there are constants $c_n > 0$, $d_n \in R$ such that the following conditions are satisfied

$$\max(X_1, \dots, X_n) \stackrel{D}{=} c_n X + d_n$$

where X, X_1, \dots, X_n are IID variables.

It can be demonstrated that the class of max-stable distributions coincides with the class of possible limit laws for normalized and centered maxima. In view of the previous discussions, the max-stable laws are the three possible limit laws: Frechet, Weibull, and Gumbel.

Generalized Extreme Value Distributions

The three extreme value distributions, Frechet, Weibull, and Gumbel, can be represented as a one-parameter family of distributions through the standard generalized extreme value distribution (GEV) of Jenkinson and Von Mises. Define the distribution function H_ξ as follows:

$$H_\xi = \begin{cases} \exp[-(1 + \xi x)^{-1/\xi}] & \text{for } \xi \neq 0 \\ \exp(-\exp(-x)) & \text{for } \xi = 0 \end{cases}$$

where $1 + \xi x > 0$. One can see from the definition that $\xi = \alpha^{-1} > 0$ corresponds to the Frechet distribution, $\xi = 0$ corresponds to the Gumbel distribution, and $\xi = -\alpha^{-1} < 0$ corresponds to the Weibull distribution. We can now introduce the related location-scale dependent family $H_{\xi;\mu,\psi}$ by replacing the argument x with $(x - \mu)/\psi$.

Order Statistics

The behavior of *order statistics* is a useful tool for characterizing fat-tailed distributions. For instance, the famous Zipf's law is an example of the behavior of order statistics. Consider a sample X_1, \dots, X_n made of n independent draws from the same distribution F . Let's arrange the sample in decreasing order:

$$X_{n,n} \leq \dots \leq X_{1,n}$$

The random variable $X_{k,n}$ is called the k th upper order statistic. It can be demonstrated that the distribution of the k th upper order statistic is

$$F_{k,n} = P(X_{k,n} < x) = \sum_{r=0}^{k-1} \bar{F}^r(x) F^{n-r}(x)$$

In addition, if F is continuous, it has a density with respect to F such that

$$f_{k,n} = \int_{-\infty}^x f_{k,n}(z) dF(z)$$

where

$$f_{k,n} = \frac{n!}{(k-1)!(n-k)!} \bar{F}^{k-1}(x) F^{n-k}(x)$$

The differences between two consecutive variables in a sample $X_{k,n} - X_{k+1,n}$ are random variables called spacings. In the case of variables with finite right endpoint x_F the zero-th spacing is defined as: $X_{0,n} - X_{1,n} = x_F - X_{1,n}$. The distribution of spacings depends on the distribution F . For instance, it can be demonstrated that the spacings of an exponential random variable are independent, exponential random variables with mean $1/n$ for an n -sample. Spacings are a key concept for the definition of the Hill estimator, as explained later in this section.

Another key concept, which is related to spacings, is that of quantile transformation. Let X_1, \dots, X_n be IID variables with distribution function F and let U_1, \dots, U_n be IID variables uniformly distributed on the interval $(0,1)$. Recall that, given a distribution function F , the

quantile function of F , written $F^{\leftarrow}(x)$, is defined as follows:

$$F^{\leftarrow}(x) = \inf\{s \in R : F(s) \geq x\}, \quad 0 < x < 1$$

It can be demonstrated that the following results hold:

- $F^{\leftarrow}(U_1) \stackrel{D}{=} X_1$
- $(X_{1,n}, \dots, X_{n,n}) \stackrel{D}{=} [F^{\leftarrow}(U_{1,n}), \dots, F^{\leftarrow}(U_{n,n})]$
- The random variable $F(X_1)$ has a uniform distribution on $(0,1)$ if and only if F is a continuous function.

To appreciate the importance of the quantile transformation, let's introduce first the notion of *empirical distribution function* and second the Glivenko-Cantelli theorem. The empirical distribution function F_n of a sample X_1, \dots, X_n is defined as follows:

$$F_n(x) = \frac{1}{n} \sum_{i=1}^n I(X_i \leq x)$$

where I is the indicator function. In other words, for each x , the empirical distribution function counts the number of samples that are less than or equal to x .

The Glivenko-Cantelli theorem provides the theoretical underpinning of nonparametric statistics. It states that, if the samples X_1, \dots, X_n are independent draws from the distribution F , the empirical distribution function F_n tends to F for large n in the sense that

$$\Delta_n = \sup_{x \in R} |F_n(x) - F(x)| \xrightarrow{a.s.} 0, \quad \text{for } n \rightarrow \infty$$

The quantile transformation tells us that in cases where F is a Pareto distribution, if we approximate n random draws from a uniformly distributed variable as the sequence $1, 2, \dots, n$, then the corresponding values of the sample X_1, \dots, X_n will be

$$\frac{1}{1}, \frac{1}{2}, \dots, \frac{1}{n}$$

which is a statement of Zipf's law.

From the quantile transformation, the limit law of the ratio between two successive order statistics can also be inferred. Suppose that

an (infinite) population is distributed according to a distribution $F \in \mathfrak{N}(\alpha)$ with regularly varying tails. Suppose that n samples are randomly and independently drawn from this distribution and ordered in function of size: $X_{n,n} \geq X_{n-1,n} \geq \dots \geq X_{1,n}$. It can be demonstrated that the following property holds:

$$\frac{X_{k,n}}{X_{k+1,n}} = 1, \quad \frac{k}{n} \rightarrow 0$$

Point Process of Exceedances or Peaks over Threshold

We have now reviewed the behavior of sums, maxima, and upper order statistics of continuous random variables. Yet another approach to EVT is based on point processes; herein we will use point processes only to define the point process of exceedances.

Point processes can be defined in many different ways. To illustrate the mathematics of point processes, let's first introduce the homogeneous Poisson process. A *homogeneous Poisson process* is defined as a process $N(t)$ that starts at zero, i.e., $N(0) = 0$, and has independent stationary increments. In addition, the random variable $N(t)$ is distributed as a Poisson variable with parameter λt . $N(t)$ is therefore a time-dependent discrete variable that can assume nonnegative integer values. Figure 3 illustrates the distribution of a Poisson variable.

A homogeneous Poisson process can also be defined as a random sequence of points on the real line. Consider all discrete sequences of points on the real line separated by random intervals. Intervals are independent random variables with exponential distribution. This is the usual definition of a Poisson process. Call $N(t)$ the number of points that fall in the interval $[0, t]$. It can be demonstrated that $N(t)$ is a homogeneous Poisson process according to the previous definition.

This latter definition can be generalized to define point processes. Intuitively, a generic point process is a random collection of discrete points

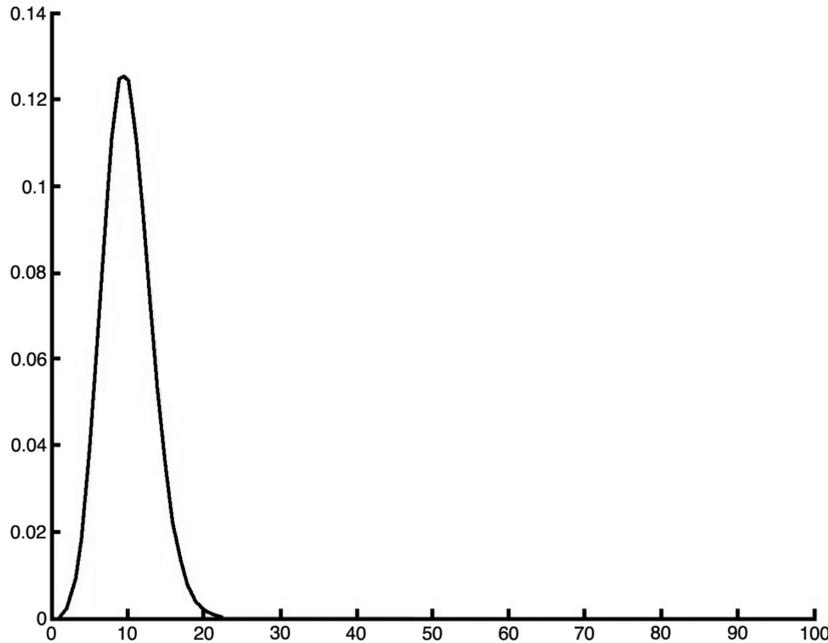

Figure 3 Distribution of a Poisson Variable

in some space. From a mathematical point of view, it is convenient to describe a point process through the distribution of the number of points that fall in an arbitrary set.⁶ In the case of homogeneous Poisson processes, we consider the number of points that fall in a given interval; for a generic point process, it is convenient to consider a wider class of sets.

Consider a subspace E of a finite dimensional Euclidean space of dimension n . Consider also the σ -algebra \mathfrak{B} of the Borel sets generated by open sets in E . The space E is called the state space. For each point x in E and for each set $A \in \mathfrak{B}$, define the *Dirac measure* ε_x as

$$\varepsilon_x = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A \end{cases}$$

For any given sequence $x_i, i \geq 1$ of points in E , define the following set function:

$$m(A) = \sum_{i=1}^{\infty} \varepsilon_{x_i}(A) = \text{card}\{i : X_i \in A\}, A \in \mathfrak{B}$$

It can be verified that $m(A)$ is a measure \mathfrak{B} , called a counting measure. If a counting mea-

sure is finite on each compact set, then it is called a point measure. In other words, any given countable sequence in E generates a counting measure on \mathfrak{B} .

A point process is obtained associating to each family of sets $A_i \in \mathfrak{B}$ the joint probability distributions:

$$\Pr\{m(A_i) = n_i; i = 1, 2, \dots, k; k = 1, 2, \dots\}$$

To make this definition mathematically rigorous, a point process can be defined as a measurable map from some probability space to the set of all point measures equipped with an appropriate σ -algebra. Besides the mathematical details, it should be clear that point processes are defined by the probability distribution of the number of points that fall in each set A of some σ -algebra. The key ingredients of point processes are (1) counting measures that associate to each set A the number of points of each discrete sequence that falls in A with the additivity restrictions of measures and (2) probability distributions defined over the space of counting measures.

Equipped with the general concept of point processes, we can now define the *point process of exceedances*. Consider a threshold formed by any real number u and a sequence of random variables $X_i, i = 1, 2, \dots$. The point process of exceedances with state space $E = (0,1)$ counts the number of instances where the random variables X_i exceed the threshold u :

$$N_n(A) = \sum_{i=1}^{\infty} \varepsilon_{i/n}(A) = \text{card}\{i \leq n \text{ and } X_i > u\}$$

Note that in this case the state space specifies the size of the sample.

Estimation

In the previous sections we presented some key topics related to the probability structure of the tails of distributions, be they light- or fat-tailed. Let's now turn to the problem of estimation, which is the key practical task. The problem of estimation for EVT is essentially the problem of estimating the tail of a distribution from a finite sample. The key statistical idea of EVT from the point of view of estimation is to use only those sample data that belong to the tail and not the entire sample. This notion has to be made precise by finding criteria that allow one to separate the tail from the bulk of the distribution. Therefore, the estimation problem of EVT distribution can be broken down into three separate subproblems:

- Identify the beginning of the tail.
- Identify the shape of the tail, in particular discriminate if it is a power-law tail.
- Estimate the tail parameters, in particular the tail index in the case of a power-law tail.

It turns out that these three problems cannot be easily separated. In fact, there is no reliable constructive theory for solving all these problems automatically. In particular, the choice of the statistical model (i.e., the distribution that best describes data) is a classical problem of formulating and validating a scientific hypothesis in a probabilistic context. However, there

are many tools and tests to help the modeler in this endeavor.

The first fundamental tool is the graphical representation of data, in particular the *quantile plot* or *QQ-plot* defined as the following set:

$$\left\{ X_{k,n}, F \leftarrow \left(\frac{n-k+1}{n+1} \right) : k = 1, 2, \dots, n \right\}$$

The quantile transformation and the Glivenko-Cantelli theorem allow concluding that this plot must be approximately linear. Should F be a Pareto distribution, the linearity of the QQ-plot is another statement of Zipf's law. The quantile plot allows a quick verification of a statistical hypotheses by checking the approximate linearity of the plot. It also allows the modeler to form a preliminary opinion on where the tail begins and whether the model fails at the far end of the tail.

Though invaluable as an exploratory tool, graphics rely on human judgment and intuition. Rigorous tests are needed. A starting point is parameter estimation for the generalized extreme value (GEV) distribution that we write as

$$H_{\xi;\mu,\Psi}(x) = \exp \left\{ - \left(1 + \xi \frac{x - \mu}{\Psi} \right)^{-1/\xi} \right\},$$

$$1 + \xi \frac{x - \mu}{\Psi} > 0$$

with the convention that the case $\xi = 0$ corresponds to the Gumbel distribution:

$$H_{0;\mu,\Psi}(x) = \exp \left\{ -e^{-\frac{x-\mu}{\Psi}} \right\}, \quad x \in R$$

We saw above that these distributions are the limit distributions, if they exist, of the normalized maxima of IID sequences. Suppose that the data to be estimated are independent draws from some EGV. This is a rather strong assumption that we will progressively relax. This assumption might be justified in domains where long series of data are available so that the sample data are the maxima of blocks of consecutive data. Though this assumption is probably too strong in the domain of finance, it is useful to elaborate its consequences.

Standard methodologies exist for parameter estimation in this case. In particular, the usual maximum likelihood (ML) methodology can be used for fitting the best GEV to data. Note that if the above distributions fit maxima we have to divide data into blocks and consider the maxima of each block. To apply ML, we have to compute the likelihood function on the data and choose the parameters that maximize it. This can be done with numerical integration methods.

An estimation method alternative to ML is the method of moments, which consists in equating empirical moments with theoretical moments. An ample literature on various versions of the method of moments exists.⁷

Let's now release the assumption that the sequence of empirical data are independent draws from an exact GEV and replace this with the weaker assumption that empirical data are independent draws from $F \in \text{MDA}(H_\xi)$. If we assume that the limit distribution is a Frechet distribution, then data must be independent draws from some distribution F whose tail has the form:

$$\bar{F} = x^{-\alpha}L(x)$$

where L is a slowly varying function as described earlier in this entry. For this reason, estimation under this weaker assumption is semiparametric in nature. We will now introduce a number of estimators of the shape parameter ξ .

The Pickand Estimator

The *Pickand estimator* $\hat{\xi}_{k,n}^{(P)}$ for an n -sample of independent draws from a distribution $F \in \text{MDA}(H_\xi)$ is defined as

$$\hat{\xi}_{k,n}^{(P)} = \frac{1}{\ln 2} \ln \frac{X_{k,n} - X_{2k,n}}{X_{2k,n} - X_{4k,n}}$$

where the $X_{k,n}$ are upper order statistics.

It can be demonstrated that the Pickand estimator has the following properties:

- Weak consistency:

$$\hat{\xi}_{k,n}^{(P)} \xrightarrow{P} \xi, n \rightarrow \infty, k \rightarrow \infty, \frac{k}{n} \rightarrow 0$$

- Strong consistency:

$$\hat{\xi}_{k,n}^{(P)} \xrightarrow{a.s.} \xi, n \rightarrow \infty, \frac{k}{\ln(\ln n)} \rightarrow \infty, \frac{k}{n} \rightarrow 0$$

- Asymptotic normality under technical conditions.

The Pickand estimator is an estimator of the parameter ξ that does not require any assumption on the type of limit distribution. Let's now examine the Hill estimator, which requires the prior knowledge that sample data are independent draws from a Frechet distribution. Later in this entry we will see that the assumption of independence can be weakened.

The Hill Estimator

Suppose that X_1, \dots, X_n are independent draws from a distribution $F \in \text{MDA}(\Phi_\alpha)$, $\alpha > 0$ so that $\bar{F} = x^{-\alpha}L(x)$ where L is a slowly varying function. The *Hill estimator* can be obtained as an MLE based on the k upper order statistics. The Hill estimator takes the following form:

$$\hat{\alpha}^{(H)} = \hat{\alpha}_{k,n}^{(H)} = \left(\frac{1}{k} \sum_{j=1}^k \ln X_{j,n} - \ln X_{k,n} \right)^{-1}$$

The Hill estimator has the same weak and strong consistency property as well as asymptotic normality as the Pickand estimator. The Hill estimator is by far the most popular estimator of the tail index. It has the advantage of being robust to some dependency in the data but can perform very poorly in case of deviations from strict Pareto behavior. In addition, it is subject to a bias-variance trade-off in the following sense: The variance of the Hill estimator depends on the ratio k/n : It decreases for increasing k . However, using a large fraction of the data will introduce bias in the estimator.

As stated above, a critical tenet of EVT is the idea of fitting the tail rather than the entire distribution. A number of articles on the automatic

determination of the optimal subset of samples to be included in the tail have appeared. One approach to the automatic determination of the tail sample using the variance-bias trade-off was proposed by Drees and Kaufmann (2000), while Dacorogna et al. (1995), and Danielsson and de Vries (1977) proposed methods based on a bootstrap approach.

The *moment ratio estimator* is a generalization of the Hill estimator. Consider the following estimator of the second order moments of the k upper order statistic:

$$\hat{M}_{k,n} = \frac{1}{k} \left(\sum_{j=1}^k \ln X_{j,n} - \ln X_{k+1,n} \right)^2$$

The moment ratio estimator is defined as follows:

$$\hat{\alpha}_{k,n}^{(m)} = \frac{1}{2} \left(\frac{\hat{M}_{k,n}}{\hat{\alpha}_{k,n}^{(H)}} \right)$$

Wagner and Marsh (2000) did extensive simulation analysis of various estimators. Their finding is that the moment ratio estimator outperforms the Hill estimator in sequences with a dependence structure (this is discussed further in the next section).

The Hill estimator was extended by Dekkers and de Haan (1989) to cover the entire range of shape parameters ξ . A number of other estimators have been proposed. In particular, under the assumption that financial data follow a stable process, estimation procedures based on regression analysis have been suggested. In fact, the assumption of stable behavior, or at least of exact Pareto tail, naturally leads to fitting a linear model in a logarithmic scale. There is an ample literature on this topic with a number of useful discussions, though empirical studies based on Monte Carlo simulations are still limited.⁸

The estimation methods reviewed above are based on the behavior of maxima and upper order statistics; another methodology uses the points of exceedances of high thresholds. Estimation methodologies based on the points of

exceedances require an appropriate model for the point process of exceedances that was defined in general terms previously in this entry.

ELIMINATING THE ASSUMPTION OF IID SEQUENCES

In the previous sections we reviewed a number of mathematical tools that are used to describe fat-tailed processes under the key assumption of IID sequences. In this section we discuss the implications of eliminating this assumption. However, in finance theory the assumption of stationary sequences of independent variables is only a first approximation; it has been challenged in several instances. Consider individual price time series. The autocorrelation function of returns decays exponentially and goes to near zero at very short-time horizons while the autocorrelation function of volatility decays only hyperbolically and remains different from zero for long periods. In addition, if we consider portfolios made of many securities, price processes exhibit patterns of cross correlations at different time-lags and, possibly, cointegrating relationships. These findings offer additional reasons to consider the assumption of serial independence as only a first approximation.

If we now consider the question of stationarity, empirical findings are more delicate. The nonstationarity that can be removed by differencing is easy to handle and does not present a problem. The critical issue is whether financial time series can be modeled with a single data generation process (DGP) that remains the same for the entire period under consideration or if the model must be modified. Consider, for instance, the question of structural breaks. At a basic level, structural breaks entail nonstationarity as the model parameters change with time and thus the finite-dimension distributions change with time. However, at a higher level one might try to model structural

changes, for instance through state-space models or *Markov switching models*. In this way, stationarity is recovered but at the price of a more complex, serially autocorrelated model.

EVT for multivariate models with complex patterns of serial correlations loses its generality and becomes model-dependent. One has to evaluate each model in terms of its behavior as regards extremes. In this section we will explore a number of models that have been proposed for modeling financial time series: ARCH and GARCH models and, more in general, state-space models. First, however, a number of methodological considerations are in order.

In the context of IID sequences, EVT tries to answer the question of how to estimate a distribution with heavy tails given only a limited amount of data. The model is the simplest (i.e., a sequence of IID variables) and the question is how to extrapolate from finite samples to the entire tail. In the context of IID distributions, conditional and unconditional distributions coincide. However, if we release the IID assumption, we have to specify the model and to estimate the entire model—not just the tail of one variable. Conditional and unconditional distributions no longer coincide. For instance, there are families of models that are conditionally normal and unconditionally fat-tailed.

Here difficulties begin as model estimation might be complex. In addition, estimation of some specific tail might not be the primary concern in model estimation. In the context of variables with a dependence structure, EVT can be thought of as a methodology to estimate the tails of the unconditional distribution, leaving aside the question of full model estimation.

An important methodological question is whether fat-tailedness is generated by the transformation of a sequence of zero-mean, finite variance IID variables (i.e., white noise) or whether innovations themselves have fat tails (i.e., so-called colored noise). For instance, as we

will see, GARCH models entail fat-tailed return distributions as the result of the transformation of white noise. On the other hand, one might want to estimate an autoregressive moving average (ARMA) model under the assumption of innovations with infinite variance.

Understanding how power laws and, more in general, fat tails are generated from normal variables has been a primary concern of econometrics and econophysics. Given the universality of power laws in economics, it is clearly important to understand how they are generated. These questions go well beyond the statistical analysis of heavy-tailed processes and involve questions of economic theories. Essentially, one wants to understand how the decisions of a large number of economic agents do not average out but produce cascading and amplification phenomena.

The law of large numbers tells that if individual processes are independent and have finite variance, then phenomena average out in aggregate and tend to an average limit. However, if individual processes have fat tails, phenomena do not average out even in the infinite limit. The weight of individual tails prevails and drives the aggregate process. Philip W. Anderson, the corecipient of the 1997 Nobel Prize in Physics, remarked:

Much of the real world is controlled as much by the "tails" of distributions as by means or averages: by the exceptional, not the mean; by the catastrophe, not the steady drip; by the very rich, not the "middle class." We need to free ourselves from "average" thinking. (Anderson, 1997)

When and if fat-tailed drivers exist, they control the ensemble to which they belong. But what generates these powerful drivers? Models that generate fat tails from standard normal innovations attempt to answer this question. Different types of models have been proposed. One such category of models is purely geometric and exploits mathematical theories such as percolation and random graph. Others exploit phenomena of dynamic nonlinear self-reinforcing cascades of events.

Percolation models are based on the well known mathematical fact that in regular spatial structures of nodes connected by links, a uniform density of links produces connected subsets of nodes whose size is distributed according to power laws. Percolation models are time-transversal models: They model aggregation at any given time. They might be used to explain how fat-tailed IID sequences are generated.

Dynamic financial econometric models exploit cascading phenomena due to nonlinearities, in particular multiplicative noise. In a deterministic setting, it is well known that nonlinear chaotic models generate sequences that, when analyzed statistically, exhibit fat-tailed distributions. The same happens when noise is subject to nonlinear transformation. In the next sections, we explore simple ARMA models, ARCH-GARCH models, subordinated models, and state-space models, all examples of dynamic financial econometric models.

Before doing this, however, let's go back to the question of estimation. As observed above, if variables are not IID but can be considered generated by a DGP, the question of estimation is no longer the estimation of a variable but that of estimating a model or a theory. The estimation of the eventual tail index is part of a larger effort. However, empirical data are a sequence of samples characterized by an unconditional distribution. One might want to understand if estimation procedures used for IID sequences can be applied in this more general setting. For instance, one might want to understand if tail-index estimators such as the Hill estimator can be used in the case of serially correlated sequences generated by a generic DGP.

From a practical standpoint, this question is quite important as one wants to estimate the tails even if one does not know exactly what model generated the sequence. Clearly, there is no general answer to this problem. However, the behavior of a number of estimators under different DGPs has been explored through simulation as explained in the following section.

Heavy-Tailed ARMA Processes

Let's first consider the infinite moving average representation of a univariate stationary series:

$$x_t = \sum_{i=0}^{\infty} h_i \varepsilon_{t-i} + m$$

under the assumption that innovations are IID α -stable laws of tail index α . By the properties of stable distributions it can be demonstrated that the finite-dimensional distributions of the process x are α -stable. However, restrictions on the coefficients need to be imposed. It can be demonstrated that a sufficient condition to ensure that the process x exists and is stationary is the following:

$$\sum_{i=0}^{\infty} |h_i|^\alpha < \infty$$

A general univariate ARMA(p,q) model is written as follows:

$$X_t = \sum_{i=1}^p \alpha_i X_{t-i} + \sum_{j=1}^q \alpha_j Z_{t-j}$$

where the Z are IID variables.

Using the lag operator— L —notation, L^i represents the variable at i lags, the ARMA(p,q) model is written as follows:

$$X_t = \sum_{i=1}^p L^i X_t + \sum_{j=1}^q L^j Z_t$$

The theory of ARMA processes can be carried over at least partially to cover the case of fat-tailed innovations. In particular, an ARMA(p,q) process with IID α -stable innovations admits a stationary, infinite moving average representation under the same conditions as in the classical finite-variance case. The coefficients of the moving average satisfy the condition

$$\sum_{i=0}^{\infty} |h_i|^\alpha < \infty$$

In the case of fat-tailed innovations, covariances and autocovariances lose their meaning. It can also be demonstrated, however, that the

empirical autocorrelation function is meaningful and is asymptotically normal. It can be demonstrated that maximum likelihood estimates can be extended to the infinite variance case, though through a number of ad hoc processes.

ARCH/GARCH Processes

The simplest ARCH model can be written as follows. Suppose that X is the random variable to be modeled, Z is a sequence of independent standard normal variables, and σ is a hidden variable. The ARCH(1) model is written as

$$\begin{aligned} X_t &= \sigma_t Z_t \\ \sigma_t^2 &= \beta + \delta X_{t-1}^2 \end{aligned}$$

This basic model was extended by Bollerslev (1989), who proposed the GARCH(p,q) model written as

$$\begin{aligned} X_t &= \sigma_t Z_t \\ \sigma_t^2 &= \beta + \sum_{i=1}^p \gamma_i \sigma_{t-i}^2 + \sum_{i=1}^q \delta_i X_{t-i}^2 \end{aligned}$$

The IID variables Z can be standard normal variables or other symmetrical, eventually fat-tailed, variables.

Let's first observe that model parameters must be constrained in order to guarantee the stationarity of the model. Stationarity conditions depend on each model. No general simple expression for the stationarity conditions is available.

Due to the multiplicative nature of noise, GARCH models are able to generate fat-tailed distributions even if innovations have finite variance. This fact was established by Kesten (1973). The tail index can be theoretically computed at least in the case GARCH(1,1). Suppose a GARCH(1,1) stationary process with Gaussian innovation is given. It can be demonstrated that

$$P(X > x) \approx \frac{c}{2} x^{-2\kappa}$$

where κ is the solution of an integral equation. In the generic p, q case, the return process is still fat-tailed but no practical way to compute the index from model parameter is known.

Subordinated Processes

Subordinated processes allow the time scale to vary. Subordinated models are, in a sense, the counterpart of stochastic volatility models insofar as they model the change in volatility by contracting and expanding the time scale. The first model was proposed by Clark (1973). Subordinated models have been extensively studied by Ghysels, Gouriou, and Josiak (1995).

Subordinated models can be applied quite naturally in the context of trading. Individual trades are randomly spaced. In modern electronic exchanges, the time and size of trades are individually recorded, thus allowing for accurate estimates of the distributional properties of inter-trades intervals. Consideration of random spacings between trades naturally leads to the consideration of subordinated models. Subordinated models generate unconditional fat-tailed distributions.

Markov Switching Models

The GARCH family of models is not the only family of serially correlated models able to produce fat tails starting from normally distributed innovations. State-space models and Markov-switching models present the same feature. The basic ideas of state-space models and Markov switching models is to split the model into two parts: (1) a regressive model that regresses the model variable over a hidden variable and (2) an autoregressive model that describes the hidden variables.

In its simplest linear form, a state-space model is written as follows:

$$\begin{aligned} X_t &= \alpha Z_t + \varepsilon_t \\ Z_t &= \beta Z_{t-1} + \delta_t \end{aligned}$$

where ε_t, δ_t are normally distributed independent white noises. State-space models can also be written in a multiplicative form:

$$\begin{aligned} X_t &= \alpha Z_{t-1} + \varepsilon_t \\ \alpha_t &= \beta \alpha_{t-1} + \delta_t \end{aligned}$$

If the second equation is a Markov chain, the model is called a Markov-switching model. A well-known example of Markov-switching models is the Hamilton model in which a two-state Markov chain drives the switch between two different regressions.

Purely linear state-space models exhibit fat tails only if innovations are fat-tailed. However, multiplicative state-space models and Markov-switching models can exhibit fat tails even if innovations are normally distributed. There is a growing literature on Markov-switching and multiplicative state-space models and a relatively large number of different models, univariate as well as multivariate, have been proposed. Stochastic volatility models are the continuous-time version of multiplicative state-space models.

Estimation

Let's now go back to the question of model estimation in a non-IID framework. Suppose that we want to estimate the tail index of the unconditional distribution of a set of empirical observations in the general setting of non-IID variables. Note that if variables are fat-tailed, we cannot say that they are serially autocorrelated as moments of second order generally do not exist. Therefore we have to make some hypothesis on the DGP.

There is no general theory of estimation under arbitrary DGP. Both theoretical and simulation work are limited to specific DGPs. ARMA models have been extensively studied. EVT holds for ARMA models under general nonclustering conditions.⁹

Often only simulation results are available. A fairly ample set of results are available for

GARCH(1,1) models. For these models Resnick and Starica (1998) showed that the Hill estimator is a consistent estimator of the tail index. Wagner and Marsh compared the performance of the Hill estimator and of the moment ratio estimator for three model classes: IID α -stable returns, IID symmetric Student, and GARCH(1,1) with Student-t innovation. They found that, in an adoptive framework, the moment ratio estimator generally yields results superior to the Hill estimator.

Scaling and Self-Similarity

The concept of scaling is now quite frequently evoked in economics and finance. Let's begin by making a distinction between scaling and self-similarity and some of the properties associated with inverse power laws within or outside the Levy-stable scaling regime. These concepts have different, and not equivalent, definitions.

The concepts of scaling and self-similarity apply to distributions, processes, or structures. Self-similarity was introduced as a property that applies to geometrical self-similar objects (i.e., fractal structures). In this context, self-similarity means that a structure can be put into a one-to-one correspondence with a part of itself. Note that no finite structure can have this property; self-similarity is the mark of infinite structures. Self-similarity entails scaling: If a fractal structure is expanded by a given factor, its measure expands by a power of the same factor.¹⁰ The notion of scaling is often expressed as absence of scale, meaning that a scaling object looks the same at any scale, large or small: It is impossible to ascertain the size of a portion of a scaling object by looking at its shape. The classical illustration is a Norwegian coastline with its fjords and fjords within fjords that look the same regardless of the scale.

However, scaling can be defined without making reference to fractals. In its simplest form, the notion of scaling entails a variable x and an observable A , which is a function of $A = A(x)$. If the observable obeys a scaling

relationship, there is a constant factor between x and A in the sense that $A(\lambda x) = \lambda^s A(x)$, where s is the scaling exponent that does not depend on x . The only function $A(x)$ that satisfies this relationship is a power law. In the three-dimensional Euclidean space, volume scales as the third power of linear length and surface as the second power, while fractals scale according to their fractal dimension.

The same ideas can be applied in a random context, but require careful reasoning. A power-law distribution has a scaling property as multiplying the variable by a factor multiplies probabilities by a constant factor, regardless of the level of the variable. This means that the ratio between the probability of the events $X > x$ and $X > ax$ depends only on a power of a , not on x . As an inverse power law is not defined at zero, scaling in this sense is a property of the tails. The probabilistic interpretation of this property is the following: The probability that an observation exceeds ax conditional on the knowledge that the observation exceeds x does not depend on x but only on a .

There are, however, other meanings attached to scaling and these might be a source of confusion. In the context of physical phenomena, scaling is often intended as identity of distribution after aggregation. The same idea is also behind the theory of groups of renormalization and the notion of self-similarity applied to structures such as coastlines. In the latter case, the intuitive meaning of self-similarity is that if one aggregates portions of the coastline, approximating their shape with a straight line, and then rescales, the resulting picture is qualitatively similar to the original. The same idea applies to percolation structures: By aggregating “sites” (i.e., points in a percolation lattice) into supersites and carefully redefining links, one obtains the same distribution of connected clusters.

Applying the idea of aggregation in a random context, self-similarity seems to mean that, after rescaling, the distribution of the sum of independent copies of a random variable maintains

the same shape of the distribution of the variable itself. Note that this property holds only for the tails of subexponential distributions—and it holds strictly only for stable laws that have tails in the (0,2) range but whose shape is not a power law except, approximately, in the tails. It also holds for Gaussian distributions that do not have power-law tails.

Scaling acquires yet another meaning when applied to stochastic processes that are functions of time. The most common among the different meanings is the following: A stochastic process is said to have a scaling property if there is no natural scale for looking at its paths and distributions. Intuitively, this means that it is not possible to gauge the scale of a sample by looking at its distribution; there is absence of scale. An example from finance comes from price patterns. If a price pattern is generated by a process with the scaling property, the plots of average daily and monthly prices will appear to be perfectly similar in distribution; looking at the plot, it’s impossible to tell if it refers to daily or monthly prices.

Self-similarity is another way of expressing the same concept. A process is self-similar if a portion of the process is similar to the entire process. As we are considering a random environment, self-similarity applies to distributions, not to the actual realization of a process. Let’s now make these concepts more precise.

A stochastic process $X(t)$ is said to be self-similar (ss) of index H (H-ss) if all its finite-dimensional distributions obey the scaling relationship:

$$(X_{kt_1}, X_{kt_2}, \dots, X_{kt_m}) \stackrel{D}{=} k^{-H}(X_{t_1}, X_{t_2}, \dots, X_{t_m}) \forall k > 0$$

$$0 < H < 1, t_1, t_2, \dots, t_m > 0$$

The above expression means that the scaling of time by the factor k scales the variables X by the factor k^H . It gives precise meaning to the notion of self-similarity applied to stochastic processes.

There is a wide variety of self-similar processes that cannot be characterized in a simple way as scaling laws: The scaling property of

stochastic processes might depend upon the shape of distributions as well as the shape of correlations. Let's restrict our attention to processes that are self-similar with stationary increments (sssi) and with index H (H -sssi). These processes can be either Gaussian or non-Gaussian. Note that a Gaussian process is a process whose finite-dimensional distributions are all Gaussian.

Gaussian H -sssi processes might have independent increments or exhibit long-range correlations. The only Gaussian H -sssi process with independent increment is the Brownian motion, but there are an infinite number of fractional Brownian motions, which are Gaussian H -sssi processes with long-range correlations. Thus there are an infinite variety of Gaussian self-similar processes. Among the many non-Gaussian H -sssi processes with independent increments are the stable Levy processes, which are random walks whose increments follow a stable distribution.¹¹

There is another definition of self-similarity for stochastic processes that makes use of the concept of aggregation; it is closer, at least in spirit, to the theory of renormalization groups. Consider a stationary infinite sequence of independent and identically distributed variables X_i , $i \geq 1$. Create consecutive nonoverlapping blocks of m variables and define the corresponding aggregated sequence of level m averaging over each block as follows:

$$X_k^{(m)} = \frac{1}{m} \sum_{i=(k-1)m+1}^{km} X_i$$

A sequence is called exactly self-similar if, for any integer m the following relationship holds:

$$X \stackrel{D}{=} m^{1-H} X^{(m)}$$

A stationary sequence is called asymptotically self-similar if the above relationship holds only for $m \rightarrow \infty$.

When we apply the notion of scaling to stochastic processes—the natural setting for economics and finance—we have to abandon

the simple characterization of scaling as inverse power laws. Though the scaling property is in itself characterized through simple power laws, the scaling processes are complex and rich mathematical structures entailing a variety of distributions and correlation functions. In particular, the long-range correlation structure of the process plays a role as important as the distribution of its variables.

KEY POINTS

- Fat-tailed laws have been found in many economic variables.
- Fully approximating a finite economic system with fat-tailed laws depends on an accurate statistical analysis of the phenomena, but also on a number of the theoretical implications of subexponentiality and scaling.
- Modeling financial variables with stable laws implies the assumption of infinite variance, which seems to contradict empirical observations.
- Scaling laws might still be an appropriate modeling paradigm given the complex interaction of distributional shape and correlations in price processes.
- Scaling laws might help in understanding not only the sheer size of economic fluctuations but also the complexity of economic cycles.

Abstract: Understanding dependences or functional links between variables is a key theme in financial modeling. In general terms, functional dependences are represented by dynamic models. Many important models are linear models whose coefficients are correlations coefficients. In many instances in financial modeling, it is important to arrive at a quantitative measure of the strength of dependencies. The correlation coefficient provides such a measure. In many instances, however, the correlation coefficient might be misleading. In particular, there are cases of nonlinear dependencies that result in a zero correlation coefficient. From the point of view of financial modeling, this situation is particularly dangerous as it leads to substantially underestimated risk. Different measures of dependence have been proposed, in particular copula functions.

Correlation is a widespread concept in financial modeling and stands for a measure of dependence between random variables. However, this term is very often incorrectly used to mean any notion of dependence. Actually *correlation* is one particular measure of *dependence* among many. In the world of multivariate normal distribution and, more generally, in the world of spherical and elliptical distributions, it is the accepted measure. This follows from a property of the multivariate normal distribution. In this entry, we discuss the limitations of correlation as a measure of the dependence between two random variables and introduce an alter-

native measure to overcome these limitations, *copulas*.¹

DRAWBACKS OF CORRELATION

In the general case, there are at least three major drawbacks of the correlation measure. Consider the case of two real-valued random variables X and Y . First, the variances of X and Y must be finite or the correlation is not defined. This assumption causes problems when working with heavy-tailed data because under certain circumstances the variances are infinite

and, for that reason, the correlation between them is not defined.

Second, independence of two random variables implies correlation equal to zero; however, generally speaking the opposite is not correct—zero correlation does not imply independence.² Only in the case of elliptical distribution are uncorrelatedness and independence interchangeable notions. This statement is not valid if only the marginal distributions are elliptical and the joint distribution is nonelliptical.

Lastly, a more technical point. The correlation is not invariant under nonlinear strictly increasing transformations, a serious disadvantage. In general $\text{corr}(T(X), T(Y)) \neq \text{corr}(X, Y)$. One example that explains this technical requirement is the following: Assume that X and Y represent the continuous return (log-return) of two financial assets over the period $[0, t]$, where t denotes some point of time in the future. If you know the correlation of these two random variables, this does not imply that you know the dependence structure between the asset prices itself because the asset prices (P and Q for asset X and Y , respectively) are obtained by $P_t = P_0 \cdot \exp(X)$ and $Q_t = Q_0 \cdot \exp(Y)$. The asset prices are strictly increasing functions of the return but the correlation structure is not maintained by this transformation. This observation implies that the return could be uncorrelated whereas the prices are strongly correlated and vice versa.

OVERCOMING THE DRAWBACKS OF CORRELATION: COPULAS

A more prevalent approach, which overcomes this disadvantage, is to model dependency using copulas. As noted by Patton (2004, p. 3): “The word *copula* comes from Latin for a ‘link’ or ‘bond’, and was coined by Sklar (1959), who first proved the theorem that a collection of marginal distributions can be ‘coupled’ together via a copula to form a multivariate distribution.” The idea is as follows. The

description of the joint distribution of a random vector is divided into two parts:

1. The specification of the marginal distributions.
2. The specification of the dependence structure by means of a special function, called *copula*.

The use of copulas offers the following advantages:

- The nature of dependency that can be modeled is more general. In comparison, only linear dependence can be explained by the correlation.
- Dependence of extreme events might be modeled.
- Copulas are indifferent to continuously increasing transformations (not only linear as it is true for correlations).

Because of these advantages, in recent years there has been increased application of copulas in asset and option pricing, portfolio selection, and risk management.

MATHEMATICAL DEFINITION OF COPULAS

From a mathematical viewpoint, a copula function C is nothing more than a probability distribution function on the d -dimensional hypercube $I_d = [0, 1] \times [0, 1] \times \dots \times [0, 1]$:

$$C : I_d \rightarrow [0, 1] \\ (x_1, \dots, x_d) \rightarrow C(x_1, \dots, x_d)$$

It has been shown³ that any multivariate probability distribution function F_Y of some random vector $Y = (Y_1, \dots, Y_d)$ can be represented with the help of a copula function C in the following form:

$$F_Y(y_1, \dots, y_d) = P(Y_1 \leq y_1, \dots, Y_d \leq y_d) \\ = C(P(Y_1 \leq y_1), \dots, P(Y_d \leq y_d)) \\ = C(F_{Y_1}(y_1), \dots, F_{Y_d}(y_d))$$

where the F_{Y_i} , $i = 1, \dots, d$ denote the marginal distribution functions of the random variables Y_i , $i = 1, \dots, d$.

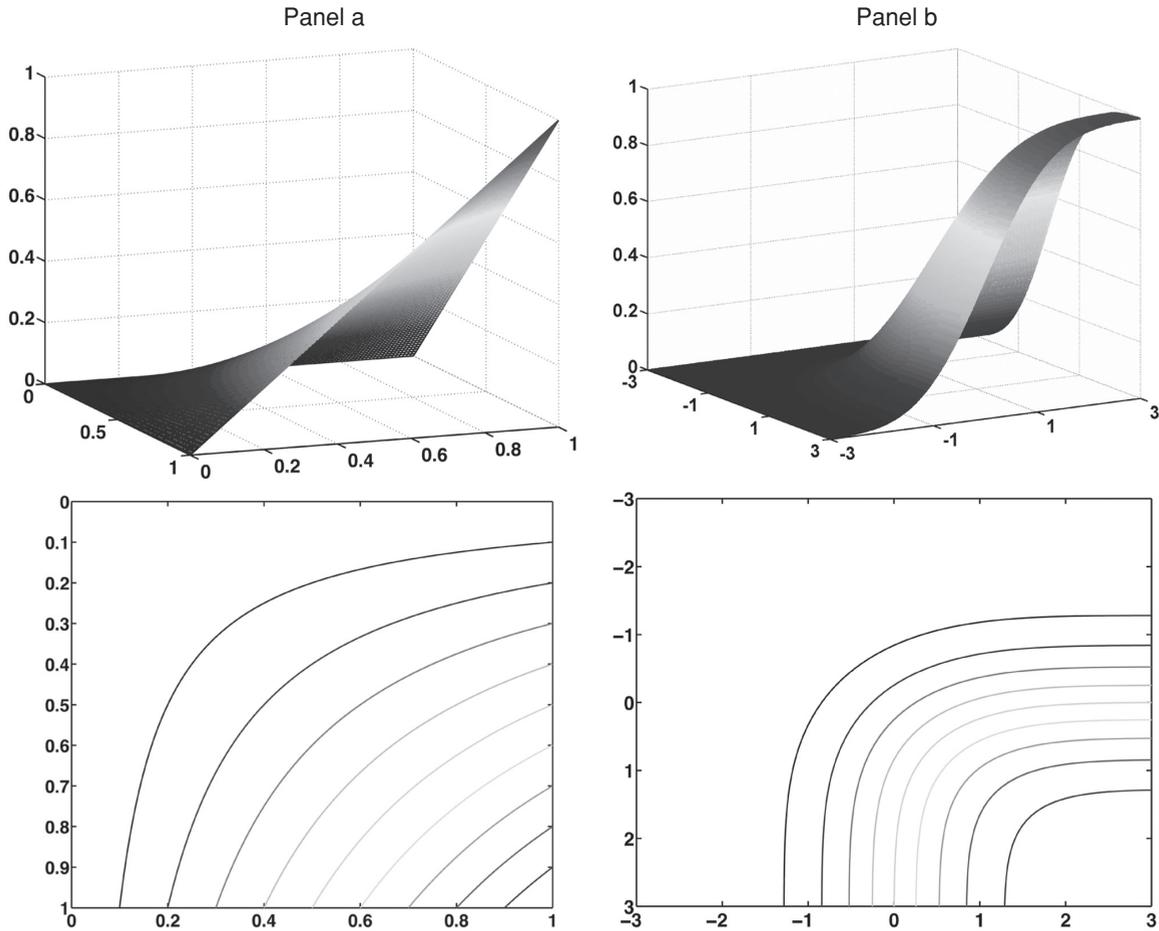

Figure 1 Visualization of the Copula for Bivariate Independence*
 Panel a: Uniform Marginal Distributions. Panel b: Standard Normal Marginal Distributions.
 *The graphs show the joint distribution function of a bivariate random vector for two different marginal distributions. Each panel consists of a surface and a corresponding contour plot.

The copula function makes the bridge between the univariate distribution of the individual random variables and their joint probability distribution. This justifies the fact that the copula function creates uniquely the dependence, whereas the probability distribution of the involved random variables is provided by their marginal distribution.

As an example we consider the following three bivariate copula functions:

- $C(x, y) = x \cdot y$
- $C(x, y) = \min(x, y)$

$$C(x, y) = \int_{-\infty}^{\Phi^{-1}(x)} \int_{-\infty}^{\Phi^{-1}(y)} \frac{1}{2\pi(1-\rho^2)^{1/2}} \exp\left(\frac{s^2 - 2\rho st + t^2}{2(1-\rho^2)}\right) ds dt$$

The first represents the independent case as the joint probability distribution equals the product of their marginals. The second example represents a case of extreme dependence whereas the third example represents the general Gaussian copula function for the bivariate case.

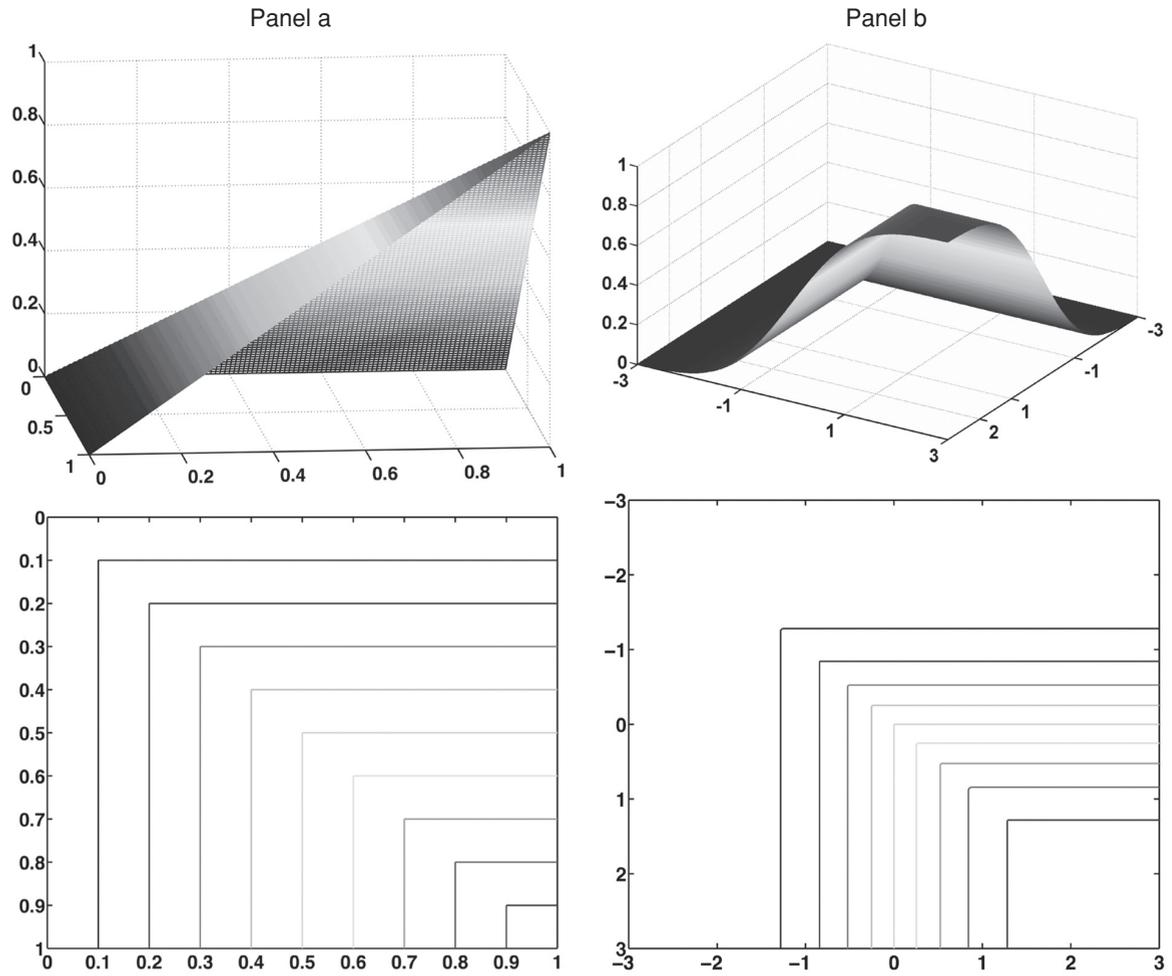

Figure 2 Visualization of the Bivariate Minimum Copula*

Panel a: Uniform Marginal Distributions. Panel b: Standard Normal Marginal Distributions.

*The graphs show the joint distribution function of a bivariate random vector for two different marginal distributions. Each panel consists of a surface and a corresponding contour plot.

We illustrate the effect of the different copulas by applying them to two different marginal distributions, namely (1) the uniform distribution on the interval $[0,1]$ and (2) the standard normal distribution. The results are presented in Figures 1, 2, and 3.

KEY POINTS

- In financial modeling, it is critical to understand dependencies or functional links be-

tween variables and have a quantitative measure of the strength of dependencies.

- The most commonly used measure of dependency in finance is the correlation coefficient. This measure might be misleading. In particular, there are cases of nonlinear dependencies that result in a zero correlation coefficient.
- The existence of finite variances is required for a correlation to be computed. Some return distributions, however, have fat tails, and the variances are infinite.

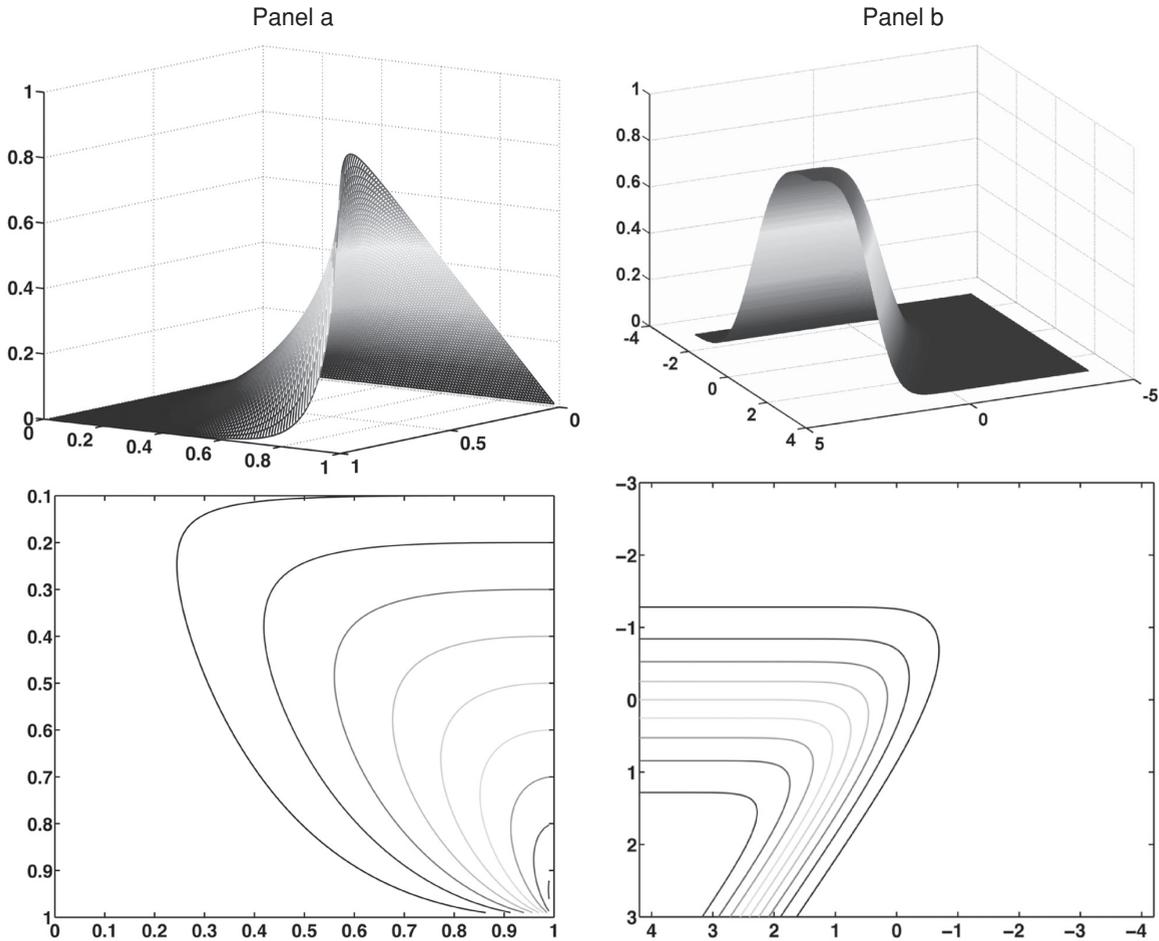

Figure 3 Visualization of the Gaussian Copula with Correlation $\rho = 0.8^*$
 Panel a: Uniform Marginal Distributions. Panel b: Standard Normal Marginal Distributions.
 *The graph shows the joint distribution function of a bivariate random vector for two different marginal distributions. Each panel consists of a surface and a corresponding contour plot.

- The correlation is not invariant under non-linear strictly increasing transformations, making the use of this measure a serious disadvantage.
- The copula overcomes the drawbacks of the correlation as a measure of dependency by allowing for a more general measure than linear dependence, allowing for the modeling of dependence for extreme events, and being indifferent to continuously increasing transformations.
- The copula function bridges the univariate distribution of the individual random vari-

ables and their joint probability distribution, thereby justifying the fact that the copula function creates the dependence uniquely, whereas the probability distribution of the involved random variables is provided by their marginal distribution.

NOTES

1. For a discussion of applications in finance and insurance, see Embrechts, McNeil, and Straumann (1999) and Patton (2003a, 2003b, 2004).

2. A simple example is the following: Let X be a standard normal distribution and $Y = X^2$. Because the third moment of the standard normal distribution is zero, the correlation between X and Y is zero despite the fact that Y is a function of X , which means that they are dependent.
3. The importance of copulas in the modeling of the distribution of multivariate random variables is provided by Sklar's theorem. The derivation was provided in Sklar (1959).

Applications of Order Statistics to Risk Management Problems

RADU TUNARU, PhD

Professor of Quantitative Finance, Business School, University of Kent

Abstract: Value-at-risk (VaR) calculation based on parametric models is in essence an estimation problem. The point estimates should be interpreted accompanied by their confidence intervals. Risk management for complex portfolios may consider simultaneously two or more VaR confidence levels. The quantiles used for VaR estimation at different orders such as 1% and 5% are not independent and therefore should be analyzed jointly. Consequently, it would be useful to establish confidence regions for bivariate VaR estimates that will provide the risk managers with a valuable tool for verifying the accuracy of their estimation process, as requested by external audit. A trade-off between the complexity of probability distribution underlying the model and the degree of robustness achieved is recommended.

While there are many models used for calculations of risk management measures such as *value-at-risk* (VaR) and *expected tail loss* (ETL), there are not many tools available to a risk manager to verify whether the models chosen are very good in practice. In this entry, we highlight some practical aspects of VaR and ETL calculus that are underpinned by theoretical results on *order statistics*. More precisely, we show how to compute VaR and ETL based on quantile sample statistics and how to derive the probability distribution of this estimator. The most important development in this entry is that we illustrate how to control the backtesting of two risk measures, given by different specifications of confidence levels such as 99% and 95%. Usually there is a difference between the confidence level that a bank may use internally and the

confidence level required by a regulator. Then the risk manager should make sure that the *risk models* used perform well for both confidence levels.

PERFORMANCE OF VaR ESTIMATION

VaR is widely used in the financial industry as a measure for market risk in normal conditions. This concept has a strong influence on bank capital, some of the major implications of this estimation process being described in Jackson et al. (1997). The European Capital Adequacy Directive allows internal risk management models. Marshall and Siegel (1997) found

great errors in the estimation methods used in the industry. Berkowitz and O'Brien (2002) investigated the accuracy of value-at-risk models used by a sample of large commercial banks and their analysis revealed discrepancies in the performance of their models. Brooks and Persaud (2002) analyzed common methodologies for calculating VaR and concluded that simpler models provide better performance than very complex models. In the light of severe market disruptions and appeal for more stringent measures, the issue of how reliable is the model used for market risk is of paramount importance.

The estimation of VaR is a statistical exercise and the risk manager, trader, or quant analyst has to consider the reliability of the estimates proposed, especially when large amounts of money are involved. Although there is a plethora of models for VaR pointwise estimation, reviewed for example in Duffie and Pan (1997) and Jorion (1996, 1997), the literature on the confidence associated with these estimators is sparse. Jorion (1996) was among the first researchers to consider the uncertainty associated with VaR models leading to model risk. Kupiec (1995) suggested that it may be very hard to determine statistically the accuracy of VaR estimates. After his seminal paper, Pritsker (1997) and Dowd (2001) showed how to employ order statistics for assessing the VaR accuracy. Dowd (2000) described how to build confidence intervals for VaR estimates using simulations methods but his technique was illustrated only for some special cases linked to the Gaussian distribution.

Calibrating the models is not always easy and for auditing and backtesting purposes the pre-specified level of confidence can play an important role. The nonlinearity in results when calculating VaR at various levels of confidence means that, based on the same model, conclusions obtained in backtesting at one level cannot be extrapolated to other levels. In other words, we can have a model with very good forecasting power at 5% and quite bad results at 1%, or vice versa.

VaR AND DIFFERENT LEVELS OF CONFIDENCE

The starting point of VaR modeling is a time series Y_1, Y_2, \dots, Y_n of profit and loss observations (P/L); the time series consists of past returns or simulated returns. If the critical level (of confidence) for VaR is specified as α (e.g., 10%, 5%, 1%), for a given sample the VaR is determined from the empirical quantile at $\alpha\%$, which we shall denote by z_α . This means that, if $F(y) = \int_{-\infty}^y f(u)du$ is the cumulative density function of returns, then $F(z_\alpha) = \alpha$ and the probability area to the right of z_α is equal to $1 - \alpha$. One of the main assumptions made with many models for calculating VaR is that the returns Y_1, Y_2, \dots, Y_n are independent and identically distributed (IID). This is extremely important in supporting the idea that VaR (for future returns) can be forecasted based on past data. If the IID assumption is not true, then the empirical quantile cannot be simply calculated from a formula.

Let η be the number of times the realized losses exceed the VaR threshold. The risk manager expects *ex ante* that $E(\eta) = n\alpha$. However, *ex post* it is likely that $\eta \neq n\alpha$. For backtesting, the daily loss series implies a sequence of success or failure, depending whether the loss is greater than VaR threshold or not. The probability of failure is α and therefore, with n datapoints, the probability density function of η is given by the binomial distribution with parameters n and α

$$p(\eta = x) = \binom{n}{x} \alpha^x (1 - \alpha)^{n-x} \quad (1)$$

for $x \in \{0, 1, 2, \dots\}$. If the sample size n is large enough, the central limit theorem implies that $\frac{\eta - n\alpha}{\sqrt{n\alpha(1-\alpha)}}$ follows a standard Gaussian distribution. An asymptotic confidence interval for the number of losses that will be seen η can then be easily calculated. For example, a 95% asymptotic confidence interval for η is

$$\begin{aligned} -1.96\sqrt{n\alpha(1-\alpha)} + n\alpha &< \eta \\ &< 1.96\sqrt{n\alpha(1-\alpha)} + n\alpha \end{aligned} \quad (2)$$

From the probabilistic point of view the P/L values constitute a random sample $\{Y_1, Y_2, \dots, Y_n\}$ with cumulative distribution function

$$F(y_1, y_2, \dots, y_n; \theta) = \prod_{i=1}^n F_k(y_k; \phi_k) = \prod_{i=1}^n F(y; \phi)$$

where the last equality follows from the IID assumptions. For the empirical calculations of VaR the reordered sample $(Y_{[1]}, Y_{[2]}, \dots, Y_{[n]})$, with $Y_{[1]} \leq Y_{[2]} \leq \dots \leq Y_{[n]}$ is of interest because the VaR at level α is equal to the negative of the ν -th lowest value, where $\nu = 100\alpha + 1$. The statistic $Y_{[1]}$ is called the first order statistic, $Y_{[2]}$ is called the second order statistic, and so on. $Y_{[n]}$ is called the n -th order statistic, and they are all sample quantiles. The theory of order statistics allows making calculations on sample quantiles. This translates for empirical work based on the sample above into calculating the negative of the ν -th lowest value, where $\nu = n\alpha + 1$, or $Y_{[\nu]}$.

The portfolio losses can be analyzed through the empirical cumulative distribution function

$$\tilde{F}(y) = \begin{cases} 0 & \text{if } y < Y_{[1]} \\ \frac{i}{n} & \text{if } Y_{[i]} \leq y < Y_{[i+1]} \\ 1 & \text{if } y \geq Y_{[\nu]} \end{cases} \quad (3)$$

The inverse of this empirical cdf can be used as an estimator of VaR at α level. The VaR estimator is the order statistic $Y_{[j]}$ such that $\frac{i-1}{v} < \alpha \leq \frac{i}{v}$, which is slightly different from the upper empirical cumulative distribution function value calculated as the $Y_{[j]}$ such that $\frac{i-1}{v} \leq \alpha < \frac{i}{v}$. Mausser (2001) pointed out that with 100 IID P/L values, the VaR at 5% level would be estimated by the former estimator as $Y_{[5]}$ and by the latter as $Y_{[6]}$.

One major criticism in using VaR to quantify potential losses is the inability to gauge the size of extreme losses. To overcome this problem another risk measure called expected tail loss (ETL) has been introduced. The ETL is defined as the mean losses that exceed the VaR threshold. Hence, within the same framework proposed to calculate VaR, one can determine ETL by simply estimating the mean of the sam-

ple censored by the VaR estimate. If $Y_{[j]}$ is the order statistic estimator representing VaR, ETL can be estimated as the average of $(Y_{[1]}, Y_{[2]}, \dots, Y_{[j-1]})$. It is important to realize that while ETL may be more informative for gauging the potential losses than VaR, from an estimation point of view ETL will always depend on VaR.

The calculation of VaR and expected tail loss (ETL) with the order statistics methodology can be easily implemented in Matlab. Table 1 contains the VaR and ETL as estimated via the order statistics method for simulated samples using the Gaussian distribution and the t distribution for the series of P/L, at various confidence levels and sample sizes. In addition, the confidence intervals determined as the 0.025% and 0.975% percentiles of the distribution of each risk measure are also included. For a given sample size, the confidence intervals for both VaR and ETL are widening with the increase in the level of confidence, as shown in Figures 1 and 2. Similar results are obtained for larger sample sizes and other distributions. For a prespecified level of confidence, the confidence intervals tend to go narrower with the increase in the sample size.

JOINT PROBABILITY DISTRIBUTIONS FOR ORDER STATISTICS

If $F_{[i]}(u) = P(Y_{[i]} \leq u)$ is the cumulative distribution function of the i -th order statistic, then it is not difficult to see that $F_{[1]}(y) = 1 - [1 - F(y; \phi)]^n$ and $F_{[n]}(y) = F(y; \phi)^n$. Exploiting the fact that we use the quantile as a VaR estimator, Dowd (2001) suggested applying the following known result from order statistics for backtesting purposes

$$P(\text{exactly } j \text{ values from } Y_1, Y_2, \dots, Y_n \text{ are } \leq y) = \binom{n}{j} F(y; \phi)^j [1 - F(y; \phi)]^{n-j} \quad (4)$$

to derive the cumulative distribution function of this estimator

$$F_{[j]}(y) = P(Y_{[j]} \leq y) = \sum_{i=j}^n \binom{n}{i} F(y; \phi)^i [1 - F(y; \phi)]^{n-i} \quad (5)$$

Note: The number of degrees of freedom for *t* is chosen as the sample size minus 2.

In the following we shall denote $F(y; \phi)$ by $F(y)$, for simplicity. David (1981) pointed to the following useful result giving an analytical formula for the distribution function of the order statistic of order *j*.

$$F_{[j]}(y) = \mathcal{B}_{F(y)}(j, n - j + 1) \tag{6}$$

where $\mathcal{B}_U(a, b) = \frac{\int_0^U t^{a-1}(1-t)^{b-1}dt}{B(a, b)}$ is the incomplete beta function and $B(a, b)$ is the beta function. This helps to calculate the pdf function for those distributions that are absolute continuous with respect to a dominant probability measure.¹ The probability density function of

the *j*-th order statistics is

$$q_{[j]}(y) = \frac{1}{B(j, n-j+1)} F^{j-1}(y)[1-F(y)]^{n-j} f(y) \tag{7}$$

where $f(y) = \frac{dF}{dy}(y)$.

DISTRIBUTION-FREE CONFIDENCE INTERVALS FOR VaR

From a practical point of view, without any loss of generality, it is safe to assume that the cumulative distribution function *F* is strictly

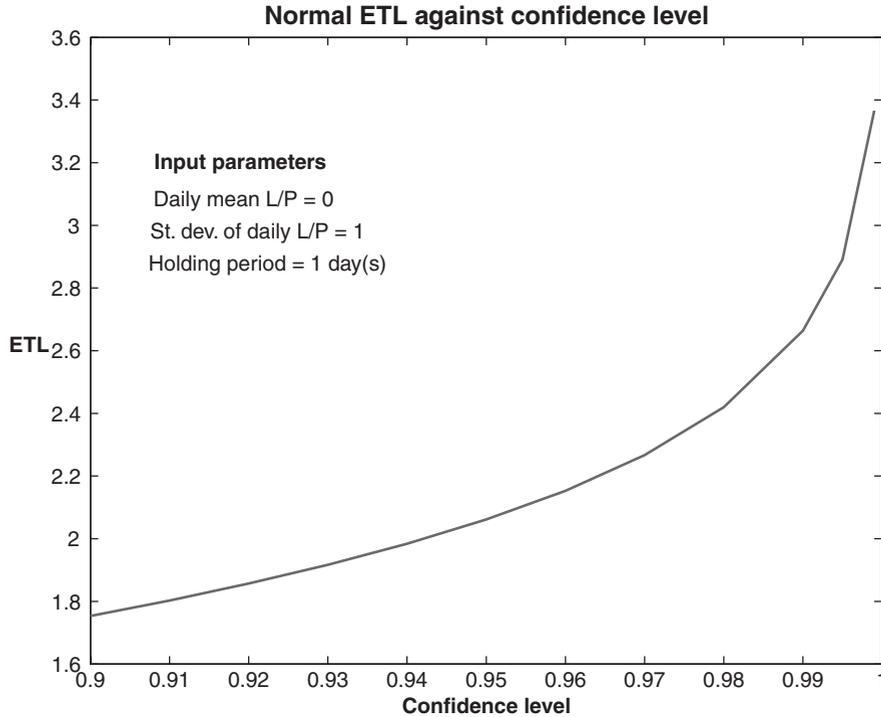

Figure 1 Expected Tail Loss for Normal P/L versus Level of Confidence When the Sample Size Is 100; Calculations Are Done with Order Statistics

increasing. Then, for any $\alpha \in (0, 1)$ the equation

$$F(y) = \alpha \tag{8}$$

has a unique solution. This solution refers to the entire population and it is called the quantile of order α , denoted by z_α . The 95% VaR is $z_{0.05}$.

The order statistics can provide a distribution-free confidence interval for the population quantiles. Thompson (1936) showed that

$$P(Y_{[i]} \leq z_\alpha \leq Y_{[j]}) = \sum_{k=i}^{j-1} \binom{n}{k} \alpha^k (1 - \alpha)^{n-k} \tag{9}$$

This powerful result allows the construction of distribution-free confidence intervals for VaR. For given sample size n and VaR level α , there are many combinations of i and j that make the quantity in (9) larger or equal to $1 - a$, the confidence level desired. There may be several combinations of order statistics $Y_{[i]}, Y_{[j]}$ that satisfy the relationship (9) and the risk manager

may decide to select the combination leading to the shortest confidence interval. Remark that choosing the degree of confidence $1 - a$ is independent of the level of confidence α for VaR point-estimation. In other words, a 95% confidence interval for the population quantile z_α can be calculated for 95% VaR or for 99% VaR.

BIVARIATE ORDER STATISTICS

The risk manager is faced with a dilemma. On one hand the regulators are asking usually for 99%-VaR calculation so that the banks are requested to set aside sufficient capital in order to absorb 99% of all losses. On the other hand, internal models may be used for day-to-day operations to forecast 95% Var. As explained by Brooks and Persand (2002) using an example from Kupiec (1995), the standard error of the

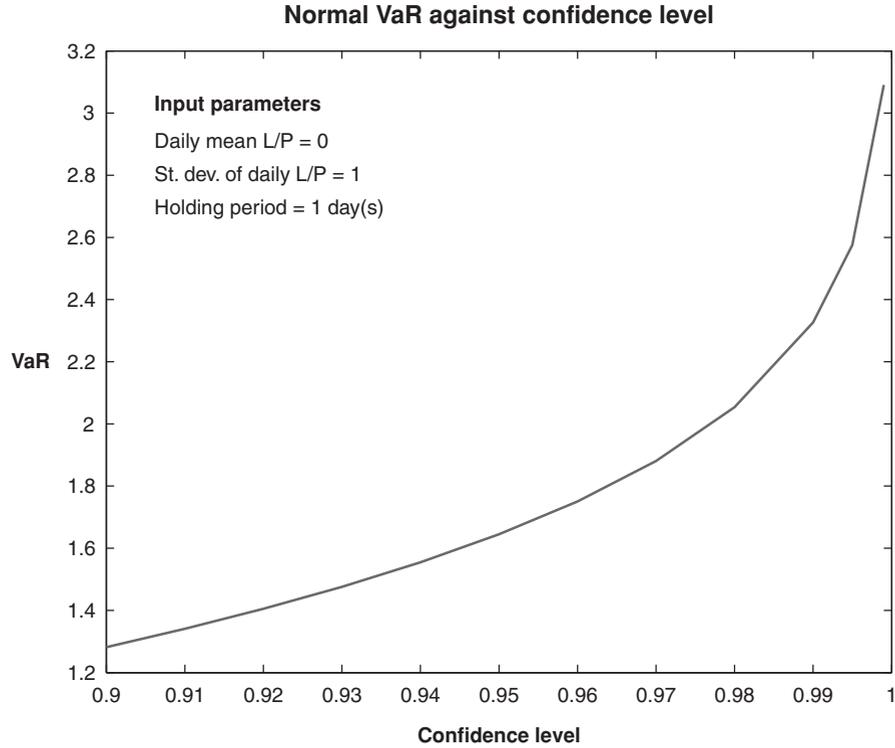

Figure 2 VaR for Normal P/L versus Level of Confidence When the Sample Size Is 100; Calculations Are Done with Order Statistics

99% VaR can be more than 50% larger than the corresponding standard error for the 95% VaR. This is the case for a model using the Gaussian distribution and it can be even worse for fat tail distributions, with the confidence intervals for the first percentile four times wider than confidence intervals for the fifth percentile. For back-testing purposes it would be ideal to do a joint analysis. Thus, the *bivariate* joint distribution of two order statistics will provide the confidence regions (two-dimensional sets) for pairs of VaR estimates. For example, the confidence regions for 1% VaR and 5% VaR are recovered from the bivariate joint distribution of $Y_{[v_1]}, Y_{[v_2]}$ where $v_1 = n \times 1/100 + 1$ and $v_2 = n \times 5/100 + 1$, respectively. This distribution is fully characterized by

$$F_{[i,j]}(x, y) = P(Y_{[i]} \leq x, Y_{[j]} \leq y) \quad (10)$$

with $1 \leq i < j \leq n$. The probability on the right side of equation (10) can be interpreted as the

probability that at least i values from the entire sample Y_1, Y_2, \dots, Y_n are not greater than x and at least j values from the same sample Y_1, Y_2, \dots, Y_n are not greater than y . Hence

$$F_{[i,j]}(x, y) = \sum_{k=j}^n \sum_{s=i}^k P(\text{exactly } i \text{ of } Y_1, Y_2, \dots, Y_n \text{ are } \leq x \text{ and exactly } j \text{ of } Y_1, Y_2, \dots, Y_n \text{ are } \leq y) \quad (11)$$

As in the univariate case, see David (1981), it follows that

$$F_{[i,j]}(x, y) = \sum_{k=j}^n \sum_{s=i}^k \frac{n!}{s!(k-s)!(n-k)!} \times [F(x)]^s [F(y) - F(x)]^{k-s} [1 - F(y)]^{n-k} \quad (12)$$

for any $x < y$. Since for $x \geq y$ the event $\{Y_{[j]} \leq y\}$ implies $Y_{[i]} \leq x$ then $F_{[i,j]}(x, y) = F_{[j]}(y)$.

An interesting corollary following from this result is that any two order statistics, and therefore VaR estimates at different levels, are not independent. This follows because the joint distribution in (12) cannot be factorized as a product of two factors, one depending only on x and the other only on y , up to a proportionality constant. In other words, if both 1% VaR and 5% VaR, for example, are needed for risk management purposes, then the quality of the VaR estimates should be investigated looking at the joint bivariate distribution like that in (12) rather than separate distributions of the type given in (5).

KEY POINTS

- Order statistics can be used as estimators of VaR and ETL and they are easy to compute.
- Banks may have to work with VaR measures at several levels of confidence because of regulatory requirements that may not coincide exactly with internal risk management decisions.
- ETL can be estimated easily with the framework based on order statistics, as the mean of the sample censored by the VaR threshold.
- For a given sample size, the confidence intervals for both VaR and ETL are widening with the increase in the level of confidence. For a prespecified level of confidence, the confidence intervals tend to go narrower with the increase in the sample size.
- There is a closed form solution for the density of any order statistic, which has been advocated here as a VaR estimator. Therefore, it would be easy to perform backtesting of VaR in this setup.
- The bivariate distribution of any two order statistics is known in closed form and therefore could be used for backtesting when banks have to work with two VaR measures simultaneously.

NOTE

1. For practical cases such as those encountered in finance we can safely assume that the random variables describing P/L series are continuous and they have probability density functions.

Risk Measures

Measuring Interest Rate Risk: Effective Duration and Convexity

GERALD W. BUETOW Jr., PhD, CFA
President and Founder, BFRC Services, LLC

ROBERT R. JOHNSON, PhD, CFA, CAIA
Independent Financial Consultant, Charlottesville, VA

Abstract: Modified duration and effective duration are two ways to measure the price sensitivity of a fixed income security. Both measure the percentage price change of a security from an absolute change in yields. Effective duration is a more complete measure of price sensitivity since it incorporates embedded optionality while modified duration does not. Combining effective duration with effective convexity is a superior risk management and measurement approach than using modified duration and convexity. In general, for fixed income securities with embedded options, numerical approaches (effective) to risk measurement are superior to analytic (modified) approaches.

Modified duration ignores any effect on cash flows that might take place as a result of changes in interest rates. *Effective duration* does not ignore the potential for such changes in cash flows. For example, bonds with embedded options will have very different cash flow properties as interest rates (or yields) change. Modified duration ignores these effects completely. In order to apply effective duration, an available interest rate model and corresponding pricing model are needed.¹ The example in this entry shows how to compute the effective duration of securities with cash flows that are dependent on changes in either the level or dynamics of the term structure of interest rates.

There is no difference between modified and effective duration for *option-free* or *straight bonds*. In fact, it can be shown that they are

mathematically identical when the change in rates (or yields) becomes very small. As shown in the example, even for bonds with embedded options, the differences between the two measures are minimal over certain ranges of yields. For example, when the embedded option is far out-of-the-money, the cash flows of the bond are not affected by small changes in yields, resulting in almost no difference in cash flows between the two measures.

Convexity and effective convexity measure the curvature of the price/yield relationship. Convexity (sometimes referred to as *standard convexity*) suffers the same limitations as modified duration and is therefore not generally useful for securities with embedded options. However, similar to the duration measures, in ranges of rates (or yields) where

the cash flows are not materially affected by small changes in yields, the two convexity measures are almost identical.

As with the duration measures, there is no difference between convexity and effective convexity for option-free or straight bonds. In fact, it can be shown that they are mathematically identical when the change in rates (or yields) becomes very small. As shown above, even for bonds with embedded options, the differences between the two measures are minimal over certain ranges of rates depending on the characteristics of the embedded option. For example, when the embedded option is far out-of-the-money, the cash flows of the bond are not affected by small changes in yields.

EFFECTIVE DURATION AND EFFECTIVE CONVEXITY—AN EXAMPLE

The following example illustrates how to calculate and interpret effective duration and effective convexity for straight bonds and bonds with embedded options.²

Suppose we need to measure the interest rate sensitivity of the following three securities:

1. A 5-year, 6.70% coupon straight (noncallable and nonputable) semiannual coupon bond, with a current price of 102.75% of par.
2. A 5-year, 6.25% coupon bond, callable at par in years 2 through 5 on the semiannual coupon dates, with a current price of 99.80% of par.
3. A 5-year, 5.75% coupon bond, putable at par in years 2 through 5 on the semiannual coupon dates, with a current price of 100.11% of par.

The cash flows of these securities are very different as interest rates change. Consequently, the sensitivities to changes in interest rates are also very different.

Using the *Black-Derman-Toy* interest rate model³ that is based on the existing term structure, the term structure of interest rates is shifted up and down by 10 basis points (bps) and the resulting price changes are recorded. P_- corresponds to the price after a downward shift in interest rates, P_+ corresponds to the price after an upward shift in interest rates, P is the current price, and S is the assumed shift in the term structure. (Note that shifting the term structure in a parallel manner will result in a change in yields equal to the shift for option-free bonds.) Table 1 shows these prices for each bond. The

Table 1 Original Prices and Resulting Prices from a Downward and Upward 10 Basis Point Interest Rate Shift and the Corresponding Effective Duration and Effective Convexity for Three Bonds Based on the Black-Derman-Toy Model

Variable	Price Changes Following 10 bp Shift		
	Original Price P	Upward Shift of 10 bp P_+	Downward Shift of 10 bp P_-
Straight Bond Price	102.7509029	102.3191235	103.1848805
Callable Bond Price	99.80297176	99.49321718	100.1085624
Putable Bond Price	100.1089131	99.84237604	100.3819059

<i>Effective Duration and Effective Convexity Measures Calculated from Using the Price Changes Resulting from the 10bp Shifts in the Term Structure</i>		
	Effective duration	Effective convexity

Callable Bond	3.08	-41.72
Putable Bond	2.70	64.49

Table 2 Effective Duration and Effective Convexity for Various Shifts in the Term Structure for Three Bonds

Term Structure Shift (bps)	Straight Bond		Callable Bond		Putable Bond	
	Effective Duration	Effective Convexity	Effective Duration	Effective Convexity	Effective Duration	Effective Convexity
-500	4.40	23.00	1.91	4.67	4.46	23.46
-250	4.30	22.19	1.88	4.55	4.37	22.66
0	4.21	21.39	3.08	-41.72	2.70	64.49
250	4.12	20.62	4.15	20.85	1.87	7.07
500	4.03	19.87	4.07	20.10	1.81	4.23
1000	3.85	18.42	3.89	18.66	1.77	4.03

formulas for calculating effective duration and effective convexity are as follows:

$$\text{Effective duration} = \frac{(P_-) - (P_+)}{2PS} \quad (1)$$

$$\text{Effective convexity} = \frac{(P_-) - (P_+) - 2P}{PS^2} \quad (2)$$

It is critical to understand the importance of the pricing model in this exercise. The model must account for the change in cash flows of the securities as interest rates change. The callable and putable bonds have very different cash flow characteristics that depend on the level of interest rates. The pricing model used must account for this property.⁴

Straight Bond

The effective duration for the *straight bond* is found by recording the price changes from shifting the term structure up (P_+) and down (P_-) by 10 bps and then substituting these values into equation (1). The prices are shown in Table 1. Consequently, the computation is:

$$\begin{aligned} \text{Effective duration} &= \frac{103.1848805 - 102.3191235}{2(102.7509029)(0.001)} \\ &= 4.21 \end{aligned}$$

Similarly, the calculation for effective convexity is found by substituting the corresponding prices into equation (2):

$$\begin{aligned} \text{Effective convexity} &= \frac{103.1848805 + 102.3191235 - 2(102.7509029)}{102.7509029(0.001)^2} \\ &= 21.39 \end{aligned}$$

For the straight bond, the modified duration is 4.21 and the convexity is 21.40. These are very close to the effective measures shown in Table 1. This demonstrates that, for option-free bonds, the two measures are almost the same for small changes in yields.

Table 2 shows the effects of the term structure shifts on the effective duration and effective convexity of the straight bond. The effective duration increases as yields decrease because as yields decrease the slope of the price yield relationship for option-free bonds becomes steeper and effective duration (and modified duration) is directly proportional to the slope of this relationship. For example, the effective duration at very low yields (-500-bp shift) is 4.40 and decreases to 3.85 at very high rates (+1,000 bps), Figure 1 illustrates this phenomenon; as yields increase notice how the slope of the price/yield relationship decreases (becomes more horizontal or flatter).

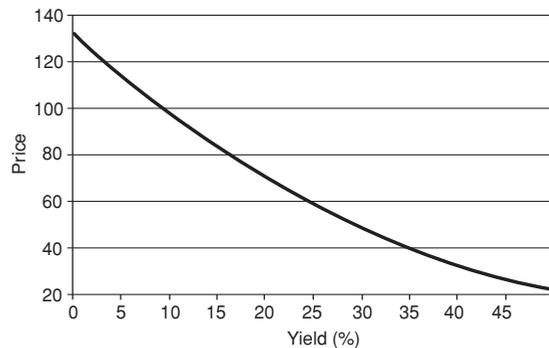

Figure 1 Price/Yield Relationship of the Straight Bond

As the term structure shifts up (that is, as rates rise), the yield to maturity on a straight bond increases by approximately the same amount. As the yield increases, its convexity decreases. Figure 1 illustrates this property. As yields increase, the curvature (or the rate of change of the slope) decreases. The results in Table 2 for the straight bond also bear this out. The effective convexity values become smaller as yields increase. For example, the effective convexity at very low yields (−500-bp shift) is 23.00 and decreases to 18.43 at very high rates (+1,000-bp shift).

These are both well-documented properties of option-free bonds. The modified duration and convexity numbers for the straight bond are almost identical to the effective measures for the straight bond shown in Table 2.

Callable Bond

The effective duration for the *callable bond* is found by recording the price changes from shifting the term structure up (P_+) and down (P_-) by 10 bps and then substituting these values into equation (1). The prices are shown in Table 1. Note that these prices take into account the changing cash flows resulting from the embedded call option. Consequently, the computation is:

$$\begin{aligned} \text{Effective duration} &= \frac{100.1085624 - 99.49321718}{2(99.800297)(0.001)} \\ &= 3.08 \end{aligned}$$

Similarly, the calculation for effective convexity is found by substituting the corresponding prices into equation (2):

$$\begin{aligned} \text{Effective convexity} &= \frac{100.1085624 + 99.49321718 - 2(99.80297176)}{99.80297176(0.001)^2} \\ &= -41.72 \end{aligned}$$

The relationship between the shift in rates and effective duration is shown in Table 2 and in Figure 2. As rates increase, the effective duration of

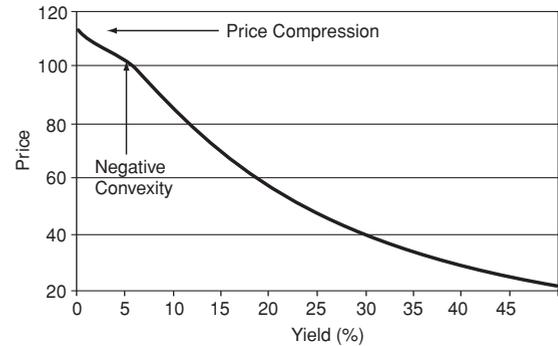

Figure 2 Price/Yield Relationship of the Callable Bond

the callable bond becomes larger. For example, the effective duration at very low yields (−500-bp shift) is 1.91 and increases to 3.89 at very high rates (+1,000 bps). This reflects the fact that as rates increase the likelihood of the bond being called decreases and, as a result, the bond behaves more like a straight bond; hence, its effective duration increases. Conversely, as rates drop, this likelihood increases and the bond and its effective duration behave more like a bond with a two-year maturity because of the call option becoming effective in two years. As rates decrease significantly, the likelihood of the issuer calling the bond in two years increases. Consequently, at very low and intermediate rates the difference between the effective duration measure and modified duration is large and at very high rates the difference is small.

As explained above, effective convexity measures the curvature of the price/yield relationship of bonds. Low values for effective convexity simply mean that the relationship is becoming linear (an effective convexity of zero represents a linear relationship). As shown in Table 2, the effective convexity values of the callable bond at extremely low interest rates (that is, for the −250-bp and −500-bp shifts in the term structure) are very small positive numbers (4.55 and 4.67, respectively). This means that the relationship is almost linear but exhibits slight convexity. This is due to the call option being delayed by two years. At these

extremely low interest rates, the callable bond exhibits slight positive convexity because the price compression at the call price is not complete for another two years. (*Price compression* for a callable bond refers to the property that a callable bond's price appreciation potential is severely limited as yields decline. As shown in Figure 2 as yields fall below a certain level (that is, where the yield corresponds to the call price), the price appreciation of the callable bond is being compressed). If this bond were immediately callable, the price/yield relationship would exhibit positive convexity at high yields and negative convexity at low yields. At the current level of interest rates, the effective convexity is negative as expected. At these rate levels, the embedded call option causes enough price compression to cause the curvature of the price/yield relationship to be *negatively convex* (that is, concave). Figure 2 illustrates these properties. It is at these levels that the embedded option has a significant effect on the cash flows of the callable bond.

Table 2 shows that for large positive yield curve shifts (that is, for the +250-bp, +500-bp, and +1,000-bp shifts in the term structure), the effective convexity of the callable bond becomes positive and very close to the effective convexity values of the straight bond. For example, the effective convexity at the +250-bp shift is 20.85 for the callable bond and 20.62 for the *straight bond*. The only reason they are not the same is because the coupon rates of the bonds are not equal. Consequently, at very low and intermediate rates the difference between effective convexity and the standard convexity is large and at very high rates the difference is small. The intuition behind these findings is straightforward. At low rates, the cash flows of the callable bond are severely affected by the likelihood of the embedded call option being exercised by the issuer. At high rates, the embedded call option is so far out-of-the-money that it has almost no effect on the cash flows of the callable bond and so the callable bond behaves like a straight bond.

Putable Bond

The effective duration for the *puttable bond* is found by recording the price changes from shifting the term structure up (P_+) and down (P_-) by 10 bps and then substituting these values into equation (1). The prices are shown in Table 1. Note that these prices take into account the changing cash flows resulting from the embedded put option. Consequently, the computation is:

$$\begin{aligned} \text{Effective duration} &= \frac{100.3819059 - 99.84237604}{2(100.1089131)(0.001)} \\ &= 2.70 \end{aligned}$$

Similarly, the calculation for effective convexity is found by substituting the corresponding prices into equation (2):

$$\begin{aligned} \text{Effective convexity} &= \frac{100.3819059 + 99.84237604 - 2(100.1089131)}{100.1089131(0.001)^2} \\ &= 64.49 \end{aligned}$$

Because the puttable bond behaves so differently from the other two bonds, the effective duration and effective convexity values are very different. As rates increase, the bond behaves more like a two-year bond because the owner will, in all likelihood, exercise the right to put the bond back at the put price as soon as possible. As a result, effective duration of the puttable bond is expected to decrease as rates increase. This is due to the embedded put option severely affecting the cash flows of the puttable bond. Conversely, as rates fall, the puttable bond behaves more like a five-year straight bond since the embedded put option is so far out-of-the-money and has little effect on the cashflows of the puttable bond. Effective duration should reflect these properties. Table 2 shows that this is indeed the case. For example, the effective duration at very low yields (−500-bp shift) is 4.46 and decreases to 1.77 at very high rates (+1,000 bps). Consequently, at very high rates and intermediate rates the difference between the effective duration and modified duration

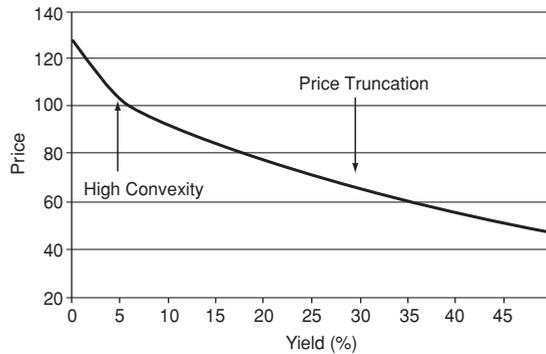

Figure 3 Price/Yield Relationship of the Puttable Bond

measures is large and at low rates the difference is small.

Table 2 shows that the effective convexity of the puttable bond is positive for all rate shifts as would be expected, but it becomes smaller as rates increase (that is, for the +250-bp, +500-bp, and +1,000-bp shifts in the term structure). As rates increase, the puttable bond price/yield relationship will become linear because of the bond's price truncation at the put price. (Price truncation for a puttable bond refers to the property that the puttable bond's price depreciation potential is severely limited as yields increase.) As shown in Figure 3 as yields rise above a certain level (that is, where the yield corresponds to the put price), the *price* depreciation of the puttable bond is *truncated*.) This is the reason for the small effective convexity values for the puttable bond for the three positive shifts in the term structure (7.07, 4.23, and 4.03, respectively). It is at these levels that the embedded put option has a significant effect on the cash flows of the puttable bond. Consequently, at very high rates and intermediate rates the difference between the effective convexity and standard convexity is very large. Figure 3 illustrates these properties.

At very low rates (that is, for the 250-bp and 500-bp downward shifts in the term structure), the puttable bond behaves like a 5-year straight bond because the put option is so far out-of-the-money. Therefore, as the term structure is

shifted downward, the puttable bond's effective convexity values approach those of a comparable 5-year straight bond. Comparing the effective convexity measures for the puttable bond and the straight bond illustrates this characteristic. For example, the effective convexity at the -250-bp shift is 22.66 for the puttable bond and 22.19 for the straight bond. The two convexity measures are almost identical. In fact, they would be identical if their coupon rates were equal.

Figure 2 illustrates these properties. Also notice how the transition from low yields to high yields forces the price/yield relationship to have a very high convexity at intermediate levels of yields. For example, the current effective convexity of the puttable bond is 64.49 compared to 21.39 for the straight bond and -41.72 for the callable bond. This is because of the price truncation of the puttable bond resulting from the embedded put option moving from out-of-the-money and having little influence over the cash flows to in-the-money and having a significant impact on cash flows.

PUTTING IT ALL TOGETHER

Notice in Table 2 how effective duration changes much more across yields for the callable and puttable bonds than it does for the straight bond. This is to be expected because the embedded options have such a significant influence over cash flows as yields change over a wide spectrum. Interestingly, at high (low) yields the callable (puttable) bond's effective duration is very close to the straight bond. This is where the embedded call (put) option is so far out-of-the-money that the two securities behave similarly. The same intuition holds for the effective convexity measures.

A common use of effective duration and effective convexity is to estimate the percentage price changes in fixed income securities for assumed changes in yield. In fact, it is not uncommon for effective duration and effective

Table 3 Percentage Price Changes Assuming an Increase in Yield of 100 bps and Effective Duration and Effective Convexity for Various Shifts in the Term Structure

convexity to be presented in terms of estimated percentage price change for a given change in yield (typically 100 bp): Tables 3 and 4 show this alternative presentation for a ±100 bp change in yield. These results are computed by substituting the values from Table 2 into the following relationship:

$$\begin{aligned} \text{\% Price change} &= \frac{\Delta P}{P} \approx -(ED)(\Delta y)(100) \\ &\quad + \frac{1}{2}(EC)(\Delta y)^2(100) \end{aligned} \quad (3)$$

where *ED* is the effective duration, *EC* is the effective convexity, and Δy is the assumed change in yield (e.g., 100 bp). Equation (3) is the result of a Taylor Series expansion on the bond price function. Also, note that the effective duration (ED) and effective convexity (EC) terms can be

replaced by modified duration and standard convexity, respectively, for option-free bonds.

Table 3 illustrates the resulting percentage price changes resulting from an increase in yield of 100 bps at various levels of the term structure. For example, the percentage price change for the callable bond at the current term structure (0-bp shift) is calculated using the values from Table 2 and substituting them into equation (3) as follows:

$$\begin{aligned} \text{\% Price change} &\approx -(3.08)(0.01)(100) \\ &\quad + \frac{1}{2}(-41.72)(0.01)^2(100) \\ &\approx -3.08 - 0.2086 = -3.2886\% \end{aligned}$$

This example shows that the estimated total percentage price change from effective convexity (-0.2086%) is much smaller than the

Table 4 Percentage Price Changes Assuming a Decrease in Yield of 100 bps and Effective Duration and Effective Convexity for Various Shifts in the Term Structure

Term Structure Shift (bp)	Straight Bond			Callable Bond			Putable Bond		
	% Price Change Using Effective Duration	% Price Change Using Effective Convexity	Total % Price Change	% Price Change Using Effective Duration	% Price Change Using Effective Convexity	Total % Price Change	% Price Change Using Effective Duration	% Price Change Using Effective Convexity	Total % Price Change

percentage price change from effective duration (−3.08).

Table 4 illustrates the resulting percentage price changes resulting from a decrease in yield of 100 bp at the various levels of the term structure. For example, the percentage price change for the callable bond at the current term structure (0-bp shift) is calculated using the values from Table 2 and substituting them into equation (3) as follows:

$$\begin{aligned} \% \text{ Price change} &\approx -(3.08)(-0.01)(100) \\ &\quad + \frac{1}{2}(-41.72)(-0.01)^2(100) \\ &\approx 3.08 - 0.2086 = 2.8714\% \end{aligned}$$

KEY POINTS

- Duration and convexity are measures for estimating the price sensitivity of a security to changes in interest rates.
- Modified duration and effective duration are two ways to measure the price sensitivity of a fixed income security. Both measure the percentage price change of a security from an absolute change in yields.
- There are important differences between effective duration and modified duration and effective convexity and convexity. The differences are due to changing cash flows of the security being evaluated.
- The effective measures account for changing cash flows and the traditional measures do not. The differences between the two are very significant whenever the cash flows are greatly affected by the level of interest rates. However, to properly compute the effective measures both an interest rate and a valuation model are required. Consequently, they are more computationally intensive than the traditional measures.
- The effective and traditional measures are identical for option-free bonds.
- Combining effective duration with effective convexity is a superior risk management and measurement approach than using modified duration and convexity.
- Investors would be best served by always using the effective measures since they properly account for the cash flow characteristics of a security.

NOTES

1. For the impact of interest rate models on duration and convexity, see Buetow, Hanke, and Fabozzi (2001).
2. For an illustration of how duration and convexity are computed for mortgage-backed securities, see Golub (2006) and Fabozzi (1999).
3. Black, Derman, and Toy, 1990.
4. Note that when calculating the measures, users are cautioned to not round values. Since the denominators of both the duration and convexity terms are very small, any rounding will have a significant impact on results.

Yield Curve Risk Measures

Professor of Finance, Moore School of Business, University of South Carolina

Abstract: Duration is a useful metric for assessing a bond portfolio's sensitivity to a parallel shift in the reference yield curve (e.g., the Treasury yield curve). When the yield curve shift is not parallel, however, two bond portfolios with the same duration will not generally experience the same return performance. To evaluate differences in expected performance across portfolios, it is therefore necessary to quantify the price impact due to changes in the shape, as opposed to a parallel shift, of the yield curve. The risk exposure of a portfolio to changes in the yield curve is called yield curve risk. Several approaches have been suggested for measuring yield curve risk.

Duration and convexity are useful measures for approximating how the value of a bond portfolio or a bond index will change for a parallel shift in interest rates. Yet, empirically, both published studies¹ and proprietary studies by asset management firms have found that yield curve changes are not parallel. The exposure of a bond portfolio or a bond index to changes in the shape of the yield curve is called *yield curve risk*.

There are several approaches for measuring yield curve risk. In this entry, we describe some of the more common approaches: cash-flow distribution analysis versus a benchmark, key rate duration, slope elasticity measure, yield curve reshaping duration, and analysis of likely shifts in the yield curve. We begin the entry with an illustration of the drawback of using duration

and convexity measures when the yield curve does not shift in a parallel fashion.

DURATION, CONVEXITY, AND NONPARALLEL YIELD CURVE SHIFTS

To illustrate the limitations of duration and convexity, let's first look at how two portfolios consisting of hypothetical Treasury securities with the same portfolio duration will perform if the yield curve does not shift in a parallel fashion. Consider the three hypothetical Treasury securities shown in Table 1. Security A is the short-term Treasury, security B is the long-term Treasury, and security C is the intermediate-term Treasury. Each Treasury security is selling

Table 1 Three Hypothetical Treasury Securities to Illustrate the Limitations of Duration and Convexity

Information on three Treasury securities:				
Treasury Issue	Coupon Rate (%)	Price	Yield to Maturity (%)	Maturity (years)
A	6.5	100	6.5	5
B	8.0	100	8.0	20
C	7.5	100	7.5	10

Calculation of duration and convexity (shock rates by 10 basis points):				
Treasury issue	Value if rate changes by			
	+10 bp	-10 bp	Duration	Convexity
A	99.5799	100.4222	4.21122	10.67912
B	99.0177	100.9970	9.89681	73.63737
C	99.3083	100.6979	6.49821	31.09724

at par, and it is assumed that the next coupon payment is six months from now. The duration and convexity for each security are calculated in the exhibit. Since all the securities are trading at par value, the durations and convexities are the dollar duration and dollar convexity per \$100 of par value.

Suppose that the following two Treasury portfolios are constructed. The first portfolio consists of only security C, the 10-year issue, and shall be referred to as the "bullet portfolio." The second portfolio consists of 51.86% of security A and 48.14% of security B, and this portfolio shall be referred to as the "barbell portfolio."

The dollar duration of the bullet portfolio is 6.49821. Recall that dollar duration is a measure of the dollar price sensitivity of a security or a portfolio. The dollar duration of the barbell is the weighted average of the dollar duration of the two Treasury securities in the portfolio and is computed below:

$$0.5186(4.21122) + 0.4814(9.89681) = 6.94821$$

The dollar duration of the barbell is equal to the dollar duration of the bullet. In fact, the barbell portfolio was designed to produce this result.

Duration is just a first approximation of the change in price resulting from a change in in-

terest rates. The convexity measure provides a second approximation. The dollar convexity measure of the two portfolios is not equal. The dollar convexity measure of the bullet portfolio is 31.09724. The dollar convexity measure of the barbell is a weighted average of the dollar convexity measure of the two Treasury securities in the portfolio. That is,

$$0.5186(10.67912) + 0.4814(73.63737) = 40.98658$$

Thus, the bullet has a dollar convexity measure that is less than that of the barbell portfolio. Below is a summary of the dollar duration and dollar convexity of the two portfolios:

Parameter	Bullet Portfolio	Barbell Portfolio
Dollar duration	6.49821	6.49821
Dollar convexity	31.09724	40.98658

The better Treasury portfolio depends on the portfolio manager's investment objectives and investment horizon. Let's assume a six-month investment horizon. The last column of Table 2

Table 2 Performance of Bullet and Barbell Treasury Portfolios over a Six-Month Horizon Assuming a Parallel Yield Curve Shift: Scenario Analysis

Yield Change (in bps)	Total Return (%)		
	Bullet Portfolio	Barbell Portfolio	Difference ^a
-300	53.47	55.79	-2.32
-250	44.95	46.38	-1.43
-200	36.79	37.55	-0.76
-150	28.99	29.26	-0.27
-100	21.51	21.47	0.05
-50	14.35	14.13	0.22
-25	10.89	10.63	0.26
0	7.50	7.22	0.28
25	4.18	3.92	0.27
50	0.93	0.70	0.23
100	-5.36	-5.45	0.09
150	-11.39	-11.28	-0.11
200	-17.17	-16.79	-0.38
250	-22.71	-22.01	-0.70
300	-28.03	-26.96	-1.06

^aA positive sign indicates that the bullet portfolio outperformed the barbell portfolio; a negative sign indicates that the barbell portfolio outperformed the bullet portfolio.

shows the difference in the total return over a six-month investment horizon for the two Treasury portfolios, assuming that the yield curve shifts in a “parallel” fashion. By parallel it is meant that the yield for the short-term security (A), the intermediate-term security (C), and the long-term security (B) changes by the same number of basis points, shown in the first column of the table. The total return reported in the second column of Table 2 is:

$$\begin{aligned} & \text{Bullet portfolio's total return} \\ & - \text{Barbell portfolio's total return} \end{aligned}$$

Thus, a positive value in the last column means that the bullet portfolio outperformed the barbell portfolio, while a negative sign means that the barbell portfolio outperformed the bullet portfolio. Note that no assumption is needed for the reinvestment rate since the

three securities comprising the portfolios are assumed to be trading right after a coupon payment has been made and therefore there is no accrued interest.

Which portfolio is the better investment alternative if the yield curve shifts in a parallel fashion and the investment horizon is six months? The answer depends on the amount by which yields change. Notice in the last column that if yields change by less than 100 basis points, the bullet portfolio will outperform the barbell portfolio. The reverse is true if yields change by more than 100 basis points.

Now let's look at what happens if the yield curve does not shift in a parallel fashion. The last column of Tables 3 and 4 show the relative performance of the two Treasury portfolios for a nonparallel shift of the yield curve. Specifically, in Table 3 it is assumed that if the yield on

Table 3 Performance of Bullet and Barbell Treasury Portfolios over a Six-Month Horizon Assuming a Flattening of the Yield Curve: Scenario Analysis

Yield change for C (in bps)	Total return (%)		
	Bullet Portfolio	Barbell Portfolio	Difference ^a
-300	53.47	58.98	-5.51
-250	44.95	49.26	-4.31
-200	36.79	40.15	-3.36
-150	28.99	31.60	-2.62
-100	21.51	23.58	-2.06

150	-11.39	-10.06	-1.33
200	-17.17	-15.70	-1.47
250	-22.71	-21.04	-1.67
300	-28.03	-26.11	-1.92

Assumptions:
 Change in yield of security C results in a change in the yield of security A plus 30 basis points.
 Change in yield of security C results in a change in the yield of security B minus 30 basis points.
^aA positive sign indicates that the bullet portfolio outperformed the barbell portfolio; a negative sign indicates that the barbell portfolio outperformed the bullet portfolio.

Table 4 Performance of Bullet and Barbell Treasury Portfolios over a Six-Month Horizon Assuming a Steepening of the Yield Curve: Scenario Analysis

Yield Change for C (in bps)	Total Return (%)		
	Bullet Portfolio	Barbell Portfolio	Difference ^a
-300	53.47	52.82	0.65
-250	44.95	43.70	1.24
-200	36.79	35.14	1.65
-150	28.99	27.09	1.89
-100	21.51	19.52	1.99
-50	14.35	12.39	1.97
-25	10.89	8.98	1.91
0	7.50	5.66	1.84
25	4.18	2.44	1.74
50	0.93	-0.69	1.63
100	-5.36	-6.70	1.34
150	-11.39	-12.38	0.99
200	-17.17	-17.77	0.60
250	-22.71	-22.88	0.17
300	-28.03	-27.73	-0.30

Assumptions:
 Change in yield of security C results in a change in the yield of security A minus 30 basis points.
 Change in yield of security C results in a change in the yield of security B plus 30 basis points.
^aA positive sign indicates that the bullet portfolio outperformed the barbell portfolio; a negative sign indicates that the barbell portfolio outperformed the bullet portfolio.

C (the intermediate-term security) changes by the amount shown in the first column, A (the short-term security) will change by the same amount plus 30 basis points, whereas B (the long-term security) will change by the same amount shown in the first column less 30 basis points. That is, the nonparallel shift assumed is a flattening of the yield curve. For this yield curve shift, the barbell will outperform the bullet for the yield changes assumed in the first column. While not shown in the table, for changes greater than 300 basis points for C, the opposite would be true.

In Table 4, the nonparallel shift assumes that for a change in C's yield, the yield on A will change by the same amount less 30 basis points, whereas the yield on B will change by the same amount plus 30 basis points. That is, it assumes that the yield curve will steepen. In this case, the bullet portfolio would outperform the barbell portfolio for all but a change in yield greater than 250 basis points for C.

The key point here is that looking at duration or convexity tells us little about performance over some investment horizon because performance depends on the magnitude of the change in yields and how the yield curve shifts.

CASH-FLOW DISTRIBUTION ANALYSIS VERSUS A BENCHMARK

The most straightforward approach to assessing a portfolio's risk exposure to yield curve shifts is by looking at the distribution of the present value of the cash flows for the portfolio being managed versus a benchmark. The benchmark will be either a bond index or a liability structure. The steps are as follows:

Step 1: Determine the discrete time periods for the analysis. The shortest and longest time is determined by the shortest and longest cash flows for the portfolio and the benchmark. Each time period is referred to as a cash-flow vertex.

Step 2: Compute the cash flows for the portfolio and the benchmark for each cash-flow vertex.

Step 3: Compute the present value of the cash flows for the portfolio and the benchmark for each cash-flow vertex. The spot rate used to compute the present value is the spot rate for the cash-flow vertex. For example, if the cash-flow vertex is year 5, the 5-year spot rate is used.

Step 4: Compute the duration contribution at each cash flow vertex for the portfolio and the benchmark.

Step 5: Compute the duration contribution as a percentage of duration for both the portfolio and the benchmark for each cash-flow vertex.

Step 6: Compute the difference in the portfolio percentage and benchmark percentage computed in Step 5 for each cash-flow vertex.

In practice, the application is not straightforward because of the inclusion of bonds with embedded options and mortgage-backed and asset-backed securities. Suppose a bond is a 7-year bond that is callable in three years. The cash flows for this bond depend on the portfolio manager's assessment of the probability that it will be called in three years. For mortgage-backed and asset-backed securities, the cash flows depend on the prepayment assumption.

Another difficulty in the implementation process is the allocation of cash flows to the cash-flow vertices when a cash flow is not exactly on a cash-flow vertex date. For example, consider a bond whose coupon payment of \$1 million is to be received 4.75 years from now and that there is a 4-year and 5-year cash-flow vertex. How should the \$1 million coupon payment be allocated? The procedure would be to allocate 25% to the 4-year cash-flow vertex and 75% to the 5-year cash-flow vertex.

Despite its simplicity, the cash-flow distribution analysis is commonly used as a measure of yield curve risk for index fund managers (see Volpert, 2000).

KEY RATE DURATION

One approach to measure yield curve risk is to change the yield for a particular maturity of the yield curve and determine the sensitivity of a security or portfolio to this change, holding all other yields constant. The sensitivity of the change in value to a particular change in yield is called *rate duration*. There is a rate duration for every point on the yield curve. Consequently, there is not one rate duration, but a vector of durations representing each maturity on the yield curve. The total change in value if all rates change by the same number of basis points is simply the duration of a security or portfolio to a parallel shift in rates.

This approach was first suggested by Chambers and Carleton (1988), who called it *duration vectors*. Reitano (1992) suggested a similar approach and referred to these durations as *partial durations*. The most popular version of this approach is that developed by Ho (1992). This approach examines how changes in Treasury yields at different points on the spot curve affect the value of a bond portfolio. Ho's methodology has three basic steps. The first step is to select several key maturities or "key rates" of the spot rate curve. Ho's approach focuses on 11 key maturities on the spot rate curve. These rate durations are called *key rate durations*. The specific maturities on the spot rate curve for which a key rate duration is measured are 3 months, 1 year, 2 years, 3 years, 5 years, 7 years, 10 years, 15 years, 20 years, 25 years, and 30 years. However, in order to illustrate Ho's methodology, we will select only three key rates: 1 year, 10 years, and 30 years.

The next step is to specify how other rates on the spot curve change in response to key rate changes. Ho's rule is that a key rate's effect on neighboring rates declines linearly and reaches zero at the adjacent key rates. For example, suppose the 10-year key rate increases by 40 basis points. All spot rates between 10 years and 30 years will increase but the amount each

changes will be different and the magnitude of the change diminishes linearly. Specifically, there are 40 semiannual periods between 10 and 30 years. Each spot rate starting with 10.5 years increases by 1 basis point less than the spot rate to its immediate left (that is, 39 basis points) and so forth. The 30-year rate which is the adjacent key rate is assumed to be unchanged. Thus, only one key rate changes at a time. Spot rates between 1 year and 10 years change in an analogous manner such that all rates change but by differing amounts. Changes in the 1-year key rate affect spot rates between 1 and 10 years, while spot rates 10 years and beyond are assumed to be unaffected by changes in the 1-year spot rate. In a similar vein, changes in the 30-year key rate affect all spot rates between 30 years and 10 years while spot rates shorter than 10 years are assumed to be unaffected by changes in the 30-year rate. This process is illustrated in Figure 1. Note that if we add the three rate changes together, we obtain a parallel yield curve shift of 40 basis points.

The third and final step is to calculate the percentage change in the bond's portfolio value when each key rate and neighboring spot rates are changed. There will be as many key rate durations as there are preselected key rates. Let's illustrate this process by calculating the key rate duration for a coupon bond. Our hypothetical 6% coupon bond has a maturity value of \$100 and matures in five years. The bond delivers coupon payments semiannually. Valuation is accomplished by discounting each cash flow using the appropriate spot rate. The bond's current value is \$107.32 and the process is illustrated in Table 5. The initial hypothetical (and short) spot curve is contained in column (3). (Note that the spot rates are annual rates and are reported as bond-equivalent yields. When present values are computed, we use the appropriate semiannual rates that are taken to be one half the annual rate.) The present values of each of the bond's cash flows are presented in the last column.

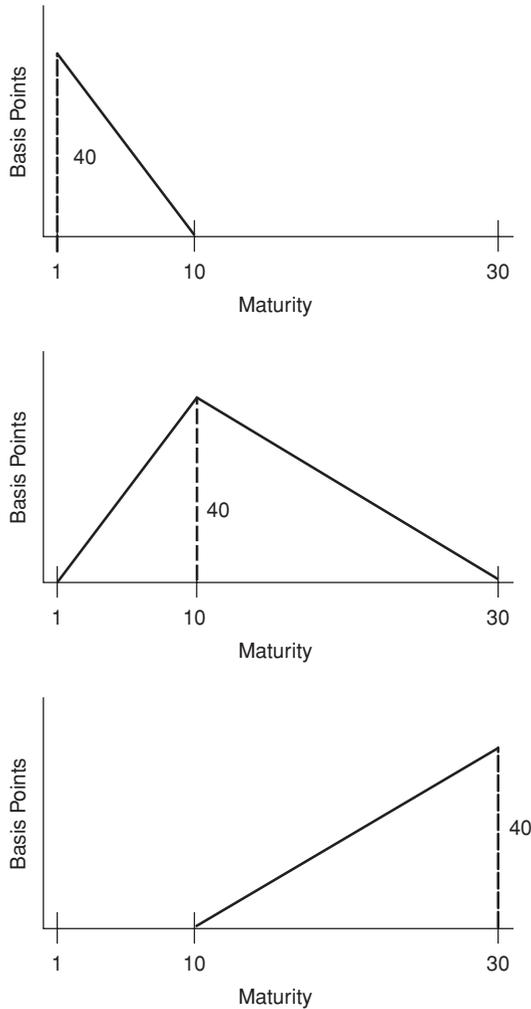

Figure 1 Graph of How Spot Rates Change when Key Rates Change

Table 5 Valuation of 5-Year 6% Coupon Bond Using Spot Rates

Years	Period	Spot Rate (in percent)	Cash Flow (in dollars)	Present Value (in dollars)
0.5	1	3.00	3.0	2.96
1.0	2	3.25	3.0	2.90
1.5	3	3.50	3.0	2.85
2.0	4	3.75	3.0	2.79
2.5	5	4.00	3.0	2.72
3.0	6	4.10	3.0	2.66
3.5	7	4.20	3.0	2.59
4.0	8	4.30	3.0	2.53
4.5	9	4.35	3.0	2.47
5.0	10	4.40	103.0	82.86
			Total	107.32

To compute the key rate duration of the 5-year bond, we must select some key rates. We assume the key rates are 0.5, 3, and 5 years. To compute the 0.5-year key rate duration, we shift the 0.5-year rate upwards by 20 basis points and adjust the neighboring spot rates between 0.5 and 3 years as described earlier. (The choice of 20 basis points is arbitrary.) Figure 2 shows the initial spot curve and the spot curve after the 0.5-year key rate and neighboring rates are shifted. The next step is to compute the bond's new value as a result of the shift. This calculation is shown in Table 6. The bond's value to the shift is \$107.30. To estimate the 0.5-year key rate duration, we divide the percentage change in the bond's price as a result of the shift in the spot curve by the change in the 0.5-year key rate. Accordingly, we employ the following formula:

$$\text{Key rate duration} = \frac{P_0 - P_1}{P_0(\Delta y)}$$

where

P_0 = the bond's value using the initial spot curve

P_1 = the bond's value after the shift in the spot curve

Δy = shift in the key rate (in decimal)

Substituting in numbers from our illustration presented above, we can compute the 0.5-year

Table 6 Valuation of the 5-Year 6% Coupon Bond after 0.5-Year Key Rate and Neighboring Spot Rates Change

Years	Period	Spot Rate (in percent)	Cash Flow (in dollars)	Present Value (in dollars)
0.5	1	3.20	3.0	2.95
1.0	2	3.41	3.0	2.90
1.5	3	3.62	3.0	2.84
2.0	4	3.83	3.0	2.78
2.5	5	4.04	3.0	2.71
3.0	6	4.10	3.0	2.66
3.5	7	4.20	3.0	2.59
4.0	8	4.30	3.0	2.53
4.5	9	4.35	3.0	2.47
5.0	10	4.40	103.0	82.86
			Total	107.30

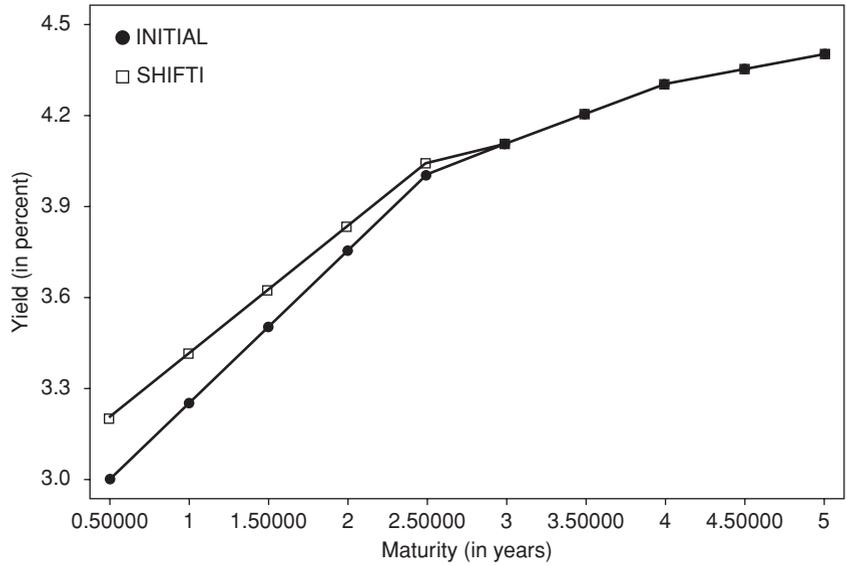

Figure 2 Graph of the Initial Spot Curve and the Spot Curve after the 0.5-Year Key Rate Shift

key rate duration as follows:

$$P_0 = 107.32$$

$$P_1 = 107.30$$

$$\Delta y = 0.002$$

$$\begin{aligned} \text{0.5-year key rate duration} &= \frac{107.32 - 107.30}{107.32(0.002)} \\ &= 0.0932 \end{aligned}$$

To compute the 3-year key rate duration, we repeat this process. We shift the 3-year rate by 20 basis points and adjust the neighboring spot rates as described earlier. Figure 3 shows the initial spot curve and the spot curve after the 3-year key rate and neighboring rates are shifted. Note that in this case the only two spot rates that do not change are the 0.5-year and the

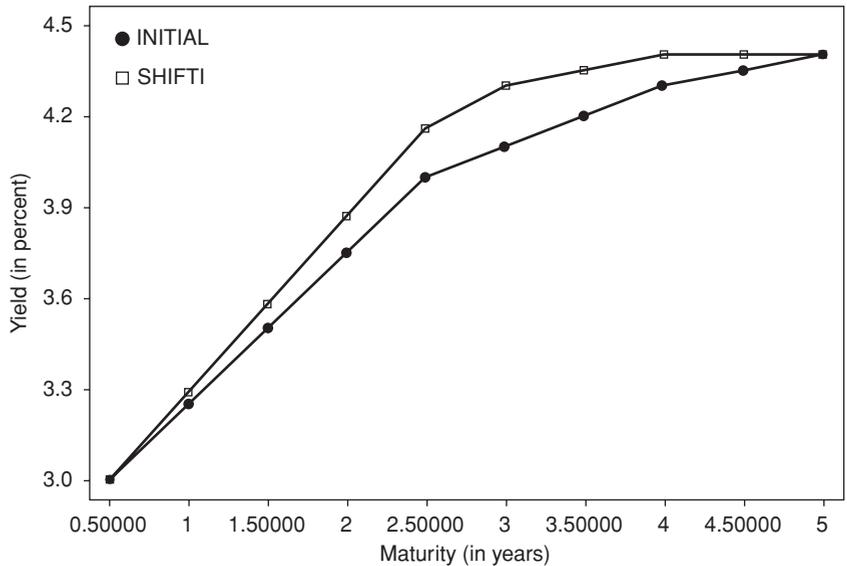

Figure 3 Graph of the Initial Spot Curve and the Spot Curve after the 3-Year Key Rate Shift

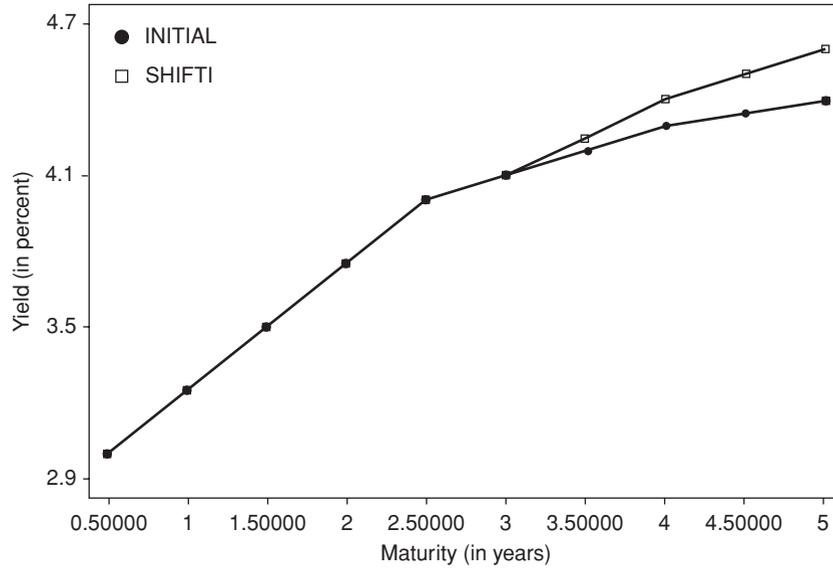

Figure 4 Graph of the Initial Spot Curve and the Spot Curve after the 5-Year Key Rate Shift

5-year key rates. Then, we compute the bond’s new value as a result of the shift. The bond’s postshift value is \$107.25 and the calculation appears in Table 7. Accordingly, the 3-year key rate duration is computed as follows:

$$\begin{aligned} \text{3-year key rate duration} &= \frac{107.32 - 107.25}{107.32(0.002)} \\ &= 0.3261 \end{aligned}$$

The final step is to compute the 5-year key duration. We shift the 5-year rate by 20 basis points

and adjust the neighboring spot rates. Figure 4 presents a graph of the initial spot curve and the spot curve after the 5-year key rate and neighboring rates are shifted. The bond’s postshift value is \$106.48 and the calculation appears in Table 8. Accordingly, the 5-year key rate duration is computed as follows:

$$\begin{aligned} \text{5-year key rate duration} &= \frac{107.32 - 106.48}{107.32(0.002)} \\ &= 3.9135 \end{aligned}$$

Table 7 Valuation of the 5-Year 6% Coupon Bond After 3-Year Key Rate and Neighboring Spot Rates Change

Years	Period	Spot Rate (in percent)	Cash Flow (in dollars)	Present Value (in dollars)
0.5	1	3.00	3.0	2.96

What information can be gleaned from these key rate durations? Each key rate duration by itself means relatively little. However, the distribution of the bond's key rate durations helps us assess its exposure to yield curve risk. Intuitively, the sum of the key rate durations is approximately equal to a bond's duration. (The reason it is only approximate is that modified duration assumes a flat yield curve, whereas key rate duration takes the spot curve as given.)

As a result, it is useful to think of a set of key rate durations as a decomposition of duration into sensitivities to various portions of the yield curve. In our illustration, it is not surprising that the lion's share of the yield curve risk exposure of the coupon bond in our illustration is due to the bond's terminal cash flow, so the 5-year key rate duration is the largest of the three. Simply put, the 5-year bond's value is more sensitive to movements in longer spot rates and less sensitive to movements in shorter spot rates.

Key rate durations are most useful when comparing two (or more) bond portfolios that have approximately the same duration. If the spot curve is flat and experiences a parallel shift, these two bond portfolios can be expected to experience approximately the same percentage change in value. However, the performance of the two portfolios will generally not be the same for a nonparallel shift in the spot curve. The key rate duration profile of each portfolio will give the portfolio manager some clues about the relative performance of the two portfolios when the yield curve changes shape and slope.

SLOPE ELASTICITY MEASURE

The *slope elasticity measure*, introduced by Schumacher, Dektar, and Fabozzi (1994) for managing the yield curve risk of portfolios of collateralized mortgage obligation bonds, also looks at the sensitivity of a position or portfolio to changes in the slope of the yield curve. They define the yield curve slope as the spread between the 30-year on-the-run Treasury yield

and the 3-month Treasury bill yield (that is, basically the longest and the shortest points on the Treasury yield curve).

They find that while this is not a perfect definition, it captures most of the effect of changes in yield curve slope. They then define changes in the yield curve as follows: Half of any basis point change in the yield curve slope results from a change in the 3-month yield and half from a change in the 30-year yield. For example, with a 200-basis-point steepening of the yield curve, the assumption is that 100 basis points of that steepening come from a rise in the 30-year yield, and another 100 basis points come from a fall in the 3-month yield.

The sensitivity of a bond's price to changes in the yield curve is simply its slope elasticity. They define slope elasticity as the approximate negative percentage change in a bond's price resulting from a 100-basis-point change in the slope of the curve. Slope elasticity is calculated as follows: Increase and decrease the yield curve slope, calculate the price change for these two scenarios after adjusting for the price effect of a change in the level of yields, and compare the prices to the initial price. More specifically, the slope elasticity for each scenario is calculated as follows:

$$\frac{\text{Price effect of a change in slope} / \text{Base price}}{\text{Change in yield curve slope}}$$

The slope elasticity is then the average of the slope elasticity for the two scenarios.

A bond or bond portfolio that benefits when the yield curve flattens is said to have positive slope elasticity; a bond or a bond portfolio that benefits when the yield curve steepens is said to have negative slope elasticity. The definition of yield curve risk follows from that of slope elasticity. It is defined as the exposure of the bond to changes in the slope of the yield curve.

YIELD CURVE RESHAPING DURATION

Yield curve reshaping duration, introduced by Klaffky, Ma, and Nozari (1992), focuses on three

points on the yield curve: 2-year, 10-year, and 30-year, and the spread between the 10-year and 2-year issues and the spread between the 30-year and 10-year issues. The former spread is referred to as the short end of the yield curve, and the latter spread the long end of the yield curve. Klaffky, Ma, and Nozari refer to the sensitivity of a portfolio to changes in the short end of the yield curve as *short-end duration (SEDUR)* and to changes in the long end of the yield curve as *long-end duration (LEDUR)*. These concepts, however, are applicable to other points on the yield curve.

To calculate the SEDUR of each security in the portfolio, the percentage change in the security's price is calculated for (1) a steepening of the yield curve at the short end by 50 basis points, and (2) a flattening of the yield curve at the short end of the yield curve by 50 basis points. Then the security's SEDUR is computed as follows:

$$\text{SEDUR} = \frac{P_s - P_f}{2P_0(\Delta y)}$$

where

- P_s = security's price if the short end of the yield curve steepens by 50 basis points
- P_f = security's price if the short end of the yield curve flattens by 50 basis points
- P_0 = security's current market price
- Δy = number of basis points by which the yield curve is changed

To calculate the LEDUR, the same procedure is used for each security in the portfolio: Calculate the price for (1) a flattening of the yield curve at the long end by 50 basis points, and (2) a steepening of the yield curve at the long end of the yield curve by 50 basis points. Then the security's LEDUR is computed as follows:

$$\text{LEDUR} = \frac{P_f - P_s}{2P_0(\Delta y)}$$

For an illustration, see Fabozzi (1999).

ANALYSIS OF LIKELY YIELD CURVE SHIFTS

While key rate duration is a useful measure for identifying the exposure of a portfolio to different potential shifts in the yield curve, it is difficult to employ this approach to yield curve risk in hedging a portfolio. An alternative approach is to investigate how yield curves have changed historically and incorporate typical yield curve change scenarios into the hedging process. This approach of using likely yield curve changes obtained from principal component analysis has been suggested by Richard and Gord (1997), Golub and Tilman (1997), and Axel and Vankudre (2000).

Empirically, studies have found that yield curve changes are not parallel. Rather, when the level of interest rates changes, studies have found that short-term rates move more than longer-term rates. Some firms develop their own proprietary models that decompose historical movements in the rate changes of Treasury strips with different maturities in order to analyze typical or likely rate movements. The statistical technique used to decompose rate movements is principal component analysis.

KEY POINTS

- When using a portfolio's duration and convexity to measure the exposure to interest rates, it is assumed that the yield curve shifts in a parallel fashion.
- For a nonparallel shift in the yield curve, duration and convexity may not provide adequate information about the risk exposure to changes in interest rates.
- Yield curve risk is the exposure of a portfolio to a change in the shape of the yield curve. There are several approaches that have been proposed for measuring a portfolio's yield curve risk.
- A simple approach to measuring yield curve risk, an approach commonly used by index managers, is an analysis of the cash

flow distribution of a portfolio relative to a benchmark.

- Key rate duration measures how changes in Treasury yields at different points on the spot rate curve affect the value of a bond.
- Slope elasticity looks at the sensitivity of a position or portfolio to changes in the slope of the yield curve and is defined as the approximate negative percentage change in a bond's price resulting from a 100-basis-point change in the slope of the curve.
- Yield curve reshaping duration decomposes the yield curve into a short end and a long end. The sensitivity of a portfolio to changes in the short end of the yield curve is called short-end duration (SEDUR) and to changes in the long end of the yield curve is called long-end duration (LEDUR).
- Using principal component analysis, a portfolio manager can determine likely yield curve shifts and use those shifts to assess the exposure of a portfolio to yield curve risk.

Abstract: A risk measure that has been widely accepted since the 1990s is the value-at-risk (VaR). In the late 1980s, it was integrated by JP Morgan on a firmwide level into its risk-management system. In the mid-1990s, the VaR measure was approved by regulators as a valid approach to calculating capital reserves needed to cover market risk. The Basel Committee on Banking Supervision released a package of amendments to the requirements for banking institutions, allowing them to use their own internal systems for risk estimation. In this way, capital reserves, which financial institutions are required to keep, could be based on the VaR numbers computed internally by an in-house risk management system. Generally, regulators demand that the capital reserve equal the VaR number multiplied by a factor between 3 and 4. Thus, regulators link the capital reserves for market risk directly to the risk measure. In practice, there are several approaches for estimating VaR.

In this entry, we cover the most commonly used risk measure used by financial institutions: *value-at-risk* (VaR). We comment on its properties and different calculation methods. Where possible, the definitions and equations are geometrically interpreted, making the ideas more intuitive and understandable.

VALUE-AT-RISK DEFINED

VaR is defined as the minimum level of loss at a given, sufficiently high, confidence level for

a predefined time horizon. The recommended confidence levels are 95% and 99%. Suppose that we hold a portfolio with a 1-day 99% VaR equal to \$1 million. This means that over the horizon of 1 day, the portfolio may lose more than \$1 million with probability equal to 1%.

The same example can be constructed for percentage returns. Suppose that the present value of a portfolio we hold is \$10 million. If the 1-day 99% VaR of the return distribution is 2%, then over the time horizon of 1 day, we lose more than 2% (\$200,000) of the portfolio present value with probability equal to 1%.

Denote by $(1 - \epsilon)100\%$ the confidence level parameter of the VaR. As we explained, losses larger than the VaR occur with probability ϵ . The probability ϵ , we call *tail probability*. Depending on the interpretation of the random variable, VaR can be defined in different ways. Formally, the VaR at confidence level $(1 - \epsilon)100\%$ (tail probability ϵ) is defined as the negative of the lower ϵ -quantile of the return distribution,

$$VaR_\epsilon(X) = - \inf_x \{x | P(X \leq x) \geq \epsilon\} = -F_X^{-1}(\epsilon) \tag{1}$$

where $\epsilon \in (0,1)$ and $F_X^{-1}(\epsilon)$ is the inverse of the distribution function. If the random variable X describes random returns, then the VaR number is given in terms of a return figure. The definition of VaR is illustrated in Figure 1.

If X describes random payoffs, then VaR is a threshold in dollar terms below which the portfolio value falls with probability ϵ ,

$$VaR_\epsilon(X) = \inf_x \{x | P(X \leq x) \geq \epsilon\} = F_X^{-1}(\epsilon) \tag{2}$$

where $\epsilon \in (0,1)$ and $F_X^{-1}(\epsilon)$ is the inverse of the distribution function of the random payoff. VaR

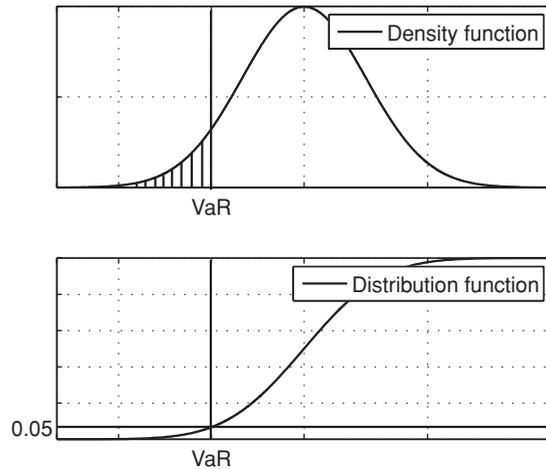

Figure 1 The VaR at 95% Confidence Level of a Random Variable X
Note: The top plot shows the density of X , the marked area equals the tail probability, and the bottom plot shows the distribution function.

can also be expressed as a distance to the present value when considering the profit distribution. The random profit is defined as $X - P_0$ where X is the payoff and P_0 is the present value. The VaR of the random profit equals

$$\begin{aligned} VaR_\epsilon(X - P_0) &= - \inf_x \{x | P(X - P_0 \leq x) \geq \epsilon\} \\ &= P_0 - VaR_\epsilon(X) \end{aligned}$$

in which $VaR_\epsilon(X)$ is defined according to (2) since X is interpreted as a random payoff. In this case, the definition of VaR is essentially given by equation (1).

According to the definition in equation (1), VaR may become a negative number. If $VaR_\epsilon(X)$ is a negative number, then this means that at tail probability ϵ we do not observe losses but profits. Losses happen with even smaller probability than ϵ . If for any tail probability $VaR_\epsilon(X)$ is a negative number, then no losses can occur and, therefore, the random variable X bears no risk as no exposure is associated with it. In this entry, we assume that random variables describe either random returns or random profits and we adopt the definition in equation (1).

We illustrate one aspect in which VaR differs from the deviation measures and all uncertainty measures. As a consequence of the definition, if we add to the random variable X a nonrandom profit C , the resulting VaR can be expressed by the VaR of the initial variable in the following way

$$VaR_\epsilon(X + C) = VaR_\epsilon(X) - C \tag{3}$$

Thus, adding a nonrandom profit decreases the risk of the portfolio. Furthermore, scaling the return distribution by a positive constant λ scales the VaR by the same constant,

$$VaR_\epsilon(\lambda X) = \lambda VaR_\epsilon(X) \tag{4}$$

It turns out that these properties characterize not only VaR. They are identified as key features of a risk measure.

To illustrate, let's use an example. Suppose initially we have a portfolio that consists of a common stock with random monthly return denoted by r_X . We rebalance the portfolio so

that it becomes an equally weighted portfolio of the stock and a default-free government bond with a nonrandom monthly return of 5.26%, $r_B = 5.26\%$. Thus, the portfolio return can be expressed as

$$r_p = r_X(1/2) + r_B(1/2) = r_X/2 + 0.0526/2$$

Using equations (3) and (4), we calculate that if $VaR_\epsilon(r_X) = 12\%$, then $VaR_\epsilon(r_p) \approx 3.365\%$, which is by far less than 6%—half of the initial risk. Any deviation measure would indicate that the dispersion (or the uncertainty) of the portfolio return r_p would be twice as small as the uncertainty of r_X .

A very important remark has to be made with respect to the performance of VaR and, as it turns out, of any other risk measure. It is heavily dependent on the assumed probability distribution of the variable X . An unrealistic hypothesis may result in underestimation or overestimation of true risk. If we use VaR to build reserves in order to cover losses in times of crises, then underestimation may be fatal and overestimation may lead to inefficient use of capital. An inaccurate model is even more dangerous in an optimal portfolio problem in which we minimize risk subject to some constraints, as it may adversely influence the optimal weights and therefore not reduce the true risk.

Even though VaR has been largely adopted by financial institutions and approved by regulators, it turns out that VaR has important deficiencies. While it provides an intuitive description of how much a portfolio may lose, generally, it should be abandoned as a risk measure. The most important drawback is that, in some cases, the reasonable diversification effect that every portfolio manager should expect to see in a risk measure is not present; that is, the VaR of a portfolio may be greater than the sum of the VaRs of the constituents

$$VaR_\epsilon(X + Y) > VaR_\epsilon(X) + VaR_\epsilon(Y) \quad (5)$$

in which X and Y stand for the random payoff of the instruments in the portfolio. This shows that VaR cannot be a true risk measure.

We give a simple example, which shows that VaR may satisfy (5). Suppose that X denotes a bond that either defaults with probability 4.5% and we lose \$50 or it does not default and in this case the loss is equal to zero. Let Y be the same bond but assume that the defaults of the two bonds are independent events. The VaR of the two bonds at 95% confidence level (5% tail probability) is equal to zero,

$$VaR_{0.05}(X) = VaR_{0.05}(Y) = 0$$

Being the 5% quantile of the payoff distribution in this case, VaR fails to recognize losses occurring with probability smaller than 5%. A portfolio of the two bonds has the following payoff profile: It loses \$100 with probability of about 0.2%, loses \$50 with probability of about 8.6%, and the loss is zero with probability 91.2%. Thus, the corresponding 95% VaR of the portfolio equals \$50 and clearly,

$$\begin{aligned} \$50 &= VaR_{0.05}(X + Y) > VaR_{0.05}(X) \\ &\quad + VaR_{0.05}(Y) = 0 \end{aligned}$$

What are the consequences of using a risk measure that may satisfy property (5)? It is going to mislead portfolio managers that there is no diversification effect in the portfolio and they may make the irrational decision to concentrate it only into a few positions. As a consequence, the portfolio risk actually increases.

Besides being sometimes incapable of recognizing the diversification effect, another drawback is that VaR is not very informative about losses beyond the VaR level. It only reports that losses larger than the VaR level occur with probability equal to ϵ but it does not provide any information about the likely magnitude of such losses, for example.

Nonetheless, VaR is not a useless concept to be abandoned altogether. For example, it can be used in risk reporting only as a characteristic of the portfolio return (payoff) distribution since it has a straightforward interpretation. The criticism of VaR is focused on its wide application by practitioners as a true risk measure, which, in view of the deficiencies described

above, is not well grounded and should be reconsidered.

COMPUTING PORTFOLIO VaR IN PRACTICE

In this section, we provide three approaches for portfolio VaR calculation that are used in practice. We assume that the portfolio contains common stocks, which is only to make the description easier to grasp; this is not a restriction of any of the approaches.

Suppose that a portfolio contains n common stocks and we are interested in calculating the daily VaR at 99% confidence level. Denote the random daily returns of the stocks by X_1, \dots, X_n and by w_1, \dots, w_n the weight of each stock in the portfolio. Thus, the portfolio return r_p can be calculated as

$$r_p = w_1 X_1 + w_2 X_2 + \dots + w_n X_n$$

The portfolio VaR is derived from the distribution of r_p . The three approaches vary in the assumptions they make.

The Approach of RiskMetrics

The approach of *RiskMetrics Group* is centered on the assumption that asset returns have a multivariate normal distribution. Under this assumption, the distribution of the portfolio return is also normal. Therefore, in order to calculate the portfolio VaR, we only have to calculate the expected return of r_p and the standard deviation of r_p . The 99% VaR will appear as the negative of the 1% quantile of the $N(Er_p, \sigma_{r_p}^2)$ distribution.

The portfolio expected return can be directly expressed through the expected returns of the assets

$$\begin{aligned} Er_p &= w_1 EX_1 + w_2 EX_2 + \dots + w_n EX_n \\ &= \sum_{k=1}^n w_k EX_k \end{aligned} \quad (6)$$

where E denotes mathematical expectation. Similarly, the variance of the portfolio return

$\sigma_{r_p}^2$ can be computed through the variances of the asset returns and their covariances,

$$\begin{aligned} \sigma_{r_p}^2 &= w_1^2 \sigma_{X_1}^2 + w_2^2 \sigma_{X_2}^2 + \dots + w_n^2 \sigma_{X_n}^2 \\ &\quad + \sum_{i \neq j} w_i w_j \text{cov}(X_i, X_j) \end{aligned}$$

in which the last term appears because we have to sum up the covariances between all pairs of asset returns. There is a more compact way of writing down the expression for $\sigma_{r_p}^2$ using matrix notation,

$$\sigma_{r_p}^2 = w' \Sigma w \quad (7)$$

in which $w = (w_1, \dots, w_n)$ is the vector of portfolio weights and Σ is the covariance matrix of asset returns,

$$\Sigma = \begin{pmatrix} \sigma_{X_1}^2 & \sigma_{12} & \dots & \sigma_{1n} \\ \sigma_{21} & \sigma_{X_2}^2 & \dots & \sigma_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{n1} & \sigma_{n2} & \dots & \sigma_{X_n}^2 \end{pmatrix}$$

in which σ_{ij} , $i \neq j$, is the covariance between X_i and X_j , $\sigma_{ij} = \text{cov}(X_i, X_j)$. As a result, we obtain that the portfolio return has a normal distribution with mean given by equation (6) and variance given by equation (7).

The standard deviation is the scale parameter of the normal distribution and the mean is the location parameter. Due to the normal distribution properties, if $r_p \in N(Er_p, \sigma_{r_p}^2)$, then

$$\frac{r_p - Er_p}{\sigma_{r_p}} \in N(0, 1)$$

Thus, because of the properties (3) and (4) of the VaR, the 99% portfolio VaR can be represented as

$$\text{VaR}_{0.01}(r_p) = q_{0.99} \sigma_{r_p} - Er_p \quad (8)$$

where the standard deviation of the portfolio return σ_{r_p} is computed from equation (7), the expected portfolio return Er_p is given in (6), and $q_{0.99}$ is the 99% quantile of the standard normal distribution.

Note that $q_{0.99}$ is a quantity independent of the portfolio composition; it is merely a constant

that can be calculated in advance. The parameters that depend on the portfolio weights are the standard deviation of portfolio returns σ_{r_p} and the expected portfolio return. As a consequence, VaR under the assumption of normality is symmetric even though, by definition, VaR is centered on the left tail of the distribution; that is, VaR is asymmetric by construction. This result appears because the normal distribution is symmetric around the mean.

The approach of RiskMetrics can be extended for other types of distributions. Lamantia et al. (2006a) and Lamantia et al. (2006b) provide such extensions and comparisons for Student's t and stable distributions.

The Historical Method

The *historical method* does not impose any distributional assumptions; the distribution of portfolio returns is constructed from historical data. Hence, sometimes the historical simulation method is called a nonparametric method. For example, the 99% daily VaR of the portfolio return is computed as the negative of the empirical 1% quantile of the observed daily portfolio returns. The observations are collected from a predetermined time window such as the most recent business year.

While the historical method seems to be more general as it is free of any distributional hypotheses, it has a number of major drawbacks.

1. It assumes that the past trends will continue in the future. This is not a realistic assumption because we may experience extreme events in the future, for instance, which have not happened in the past.
2. It treats the observations as independent and identically distributed (IID), which is not realistic. The daily returns data exhibits clustering of the volatility phenomenon, autocorrelations and so on, which are sometimes a significant deviation from the IID assumption.
3. It is not reliable for estimation of VaR at very high confidence levels. A sample of one year of daily data contains 250 observations, which is a rather small sample for the purpose of the 99% VaR estimation.

The Hybrid Method

The *hybrid method* is a modification of the historical method in which the observations are not regarded as IID but certain weights are assigned to them depending on how close they are to the present. The weights are determined using the exponential smoothing algorithm. The exponential smoothing accentuates the most recent observations and seeks to take into account the time-varying volatility phenomenon.

The algorithm of the hybrid approach consists of the following steps.

1. Exponentially declining weights are attached to historical returns, starting from the current time and going back in time. Let $r_{t-k+1}, \dots, r_{t-1}, r_t$ be a sequence of k observed returns on a given asset, where t is the current time. The i -th observation is assigned a weight

$$\theta_i = c * \lambda^{t-i}$$

where $0 < \lambda < 1$, and $c = \frac{1-\lambda}{1-\lambda^k}$ is a constant chosen such that the sum of all weights is equal to one, $\sum \theta_i = 1$.

2. Similarly to the historical simulation method, the hypothetical future returns are obtained from the past returns and sorted in increasing order.
3. The VaR measure is computed from the empirical c.d.f. in which each observation has probability equal to the weight θ_i .

Generally, the hybrid approach is appropriate for VaR estimation of heavy-tailed time series. It overcomes, to some degree, the first and the second deficiency of the historical method but it is also not reliable for VaR estimation of very high confidence levels.

The Monte Carlo Method

In contrast to the historical method, the *Monte Carlo method* requires specification of a statistical model for asset returns. The statistical model is multivariate, hypothesizing both the behavior of the asset returns on a stand-alone basis and their dependence. For instance, the multivariate normal distribution assumes normal distributions for the asset returns viewed on a stand-alone basis and describes the dependencies by means of the covariance matrix. The multivariate model can also be constructed by specifying explicitly the one-dimensional distributions of the asset returns, and their dependence through a copula function.

The Monte Carlo method consists of the following basic steps.

- Step 1. *Selection of a statistical model.* The statistical model should be capable of explaining a number of observed phenomena in the data, for example, heavy tails, clustering of the volatility, and so on, which we think influence the portfolio risk.
- Step 2. *Estimation of the statistical model parameters.* A sample of observed asset returns is used from a predetermined time window, for instance the most recent 250 daily returns.
- Step 3. *Generation of scenarios from the fitted model.* Independent scenarios are drawn from the fitted model. Each scenario is a vector of asset returns, which depend on each other according to the presumed dependence structure of the statistical model.
- Step 4. *Calculation of portfolio risk.* Compute portfolio risk on the basis of the portfolio return scenarios obtained from the previous step.

The Monte Carlo method is a very general numerical approach to risk estimation. It does not require any closed-form expressions and, by choosing a flexible statistical model, accurate risk numbers can be obtained. A disadvantage is that the computed portfolio VaR is dependent on the generated sample of scenarios and will

fluctuate a little if we regenerate the sample. This side effect can be reduced by generating a larger sample. An illustration is provided in the following example.

Suppose that the daily portfolio return distribution is standard normal and, therefore, at Step 4 of the algorithm we have scenarios from the standard normal distribution. Under the assumption of normality, we can use the approach of RiskMetrics and compute the 99% daily VaR directly from formula (8). Nevertheless, we will use the Monte Carlo method to gain more insight into the deviations of the VaR based on scenarios from the VaR computed according to formula (8).

In order to investigate how the fluctuations of the 99% VaR change about the theoretical value, we generate samples of different sizes: 500, 1,000, 5,000, 10,000, 20,000, and 100,000 scenarios. The 99% VaR is computed from these samples and the numbers are stored. We repeat the experiment 100 times. In the end, we have 100 VaR numbers for each sample size. We expect that as the sample size increases, the VaR values will fluctuate less about the theoretical value which is $VaR_{0.01}(X) = 2.326$, $X \in N(0,1)$.

Table 1 contains the result of the experiment. From the 100 VaR numbers, we calculate the 95% confidence interval for the true value given in the third column. The confidence intervals cover the theoretical value 2.326 and also we notice that the length of the confidence interval

Table 1 The 99% VaR of the Standard Normal Distribution Computed from a Sample of Scenarios

Number of Scenarios	99% VaR	95% Confidence Interval
500	2.067	[1.7515, 2.3825]
1,000	2.406	[2.1455, 2.6665]
5,000	2.286	[2.1875, 2.3845]
10,000	2.297	[2.2261, 2.3682]
20,000	2.282	[2.2305, 2.3335]
50,000	2.342	[2.3085, 2.3755]
100,000	2.314	[2.2925, 2.3355]

Note: The 95% confidence interval is calculated from 100 repetitions of the experiment. The true value is $VaR_{0.01}(X) = 2.326$.

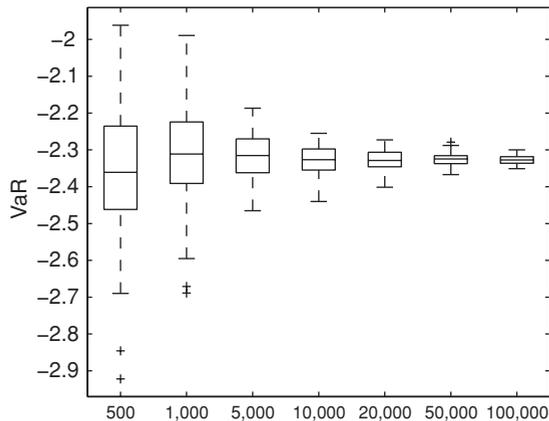

Figure 2 Boxplot Diagrams of the Fluctuation of the 99% VaR of the Standard Normal Distribution Based on Scenarios

Note: The horizontal axis shows the number of scenarios and the boxplots are computed from 100 independent samples.

decreases as the sample size increases. This effect is best illustrated with the help of the boxplot diagrams¹ shown in Figure 2. A sample of 100,000 scenarios results in VaR numbers that are tightly packed around the true value while a sample of only 500 scenarios may give a very inaccurate estimate.

This simple experiment shows that the number of scenarios in the Monte Carlo method has to be carefully chosen. The approach we used to determine the fluctuations of the VaR based on scenarios is a statistical method called parametric bootstrap. The bootstrap methods in general are powerful statistical methods that are used to compute confidence intervals when the problem is not analytically tractable but the calculations may be quite computationally intensive.

The true merits of the Monte Carlo method can only be realized when the portfolio contains complicated instruments such as derivatives. In this case, it is no longer possible to use a closed-form expression for the portfolio VaR (and any risk measure in general) because the distribution of portfolio return (or payoff) becomes quite arbitrary. The Monte Carlo method provides the general framework to generate scenar-

ios for the risk-driving factors, then reevaluates the financial instruments in the portfolio under each scenario, and, finally, estimates portfolio risk on the basis of the computed portfolio returns (or payoffs) in each state of the world.

While it may seem a straightforward approach, the practical implementation is a very challenging endeavor from both the software development and financial modeling points of view. The portfolios of big financial institutions often contain products that require yield curve modeling, development of fundamental and statistical factor models, and, on top of that, a probabilistic model capable of describing the heavy tails of the risk-driving factor returns, the autocorrelation, clustering of the volatility, and the dependence between these factors. Processing large portfolios is related to manipulation of colossal data structures, which requires excellent skills of software developers in order to be efficiently performed.

BACK-TESTING OF VaR

If we adopt VaR for analysis of portfolio exposure, then a reasonable question is whether the VaR calculated according to any of the methods discussed in the previous section is realistic. Suppose that we calculate the 99% daily portfolio VaR. This means that according to our assumption for the portfolio return (payoff) distribution, the portfolio loses more than the 99% daily VaR with 1% probability. The question is whether this estimate is correct; that is, does the portfolio really lose more than this amount with 1% probability? This question can be answered by back-testing of VaR.

Generally, the procedure consists of the following steps.

- Step 1. Choose a time window for the back-testing. Usually the time window is the most recent one or two years.
- Step 2. For each day in the time window, calculate the VaR number.

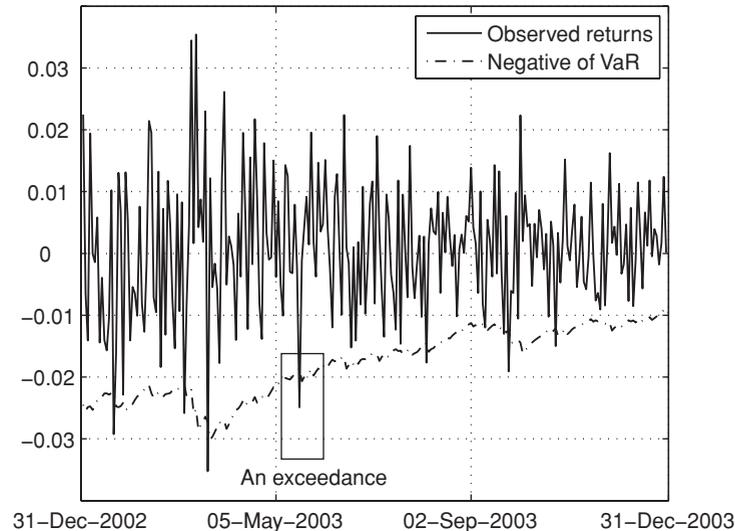

Figure 3 The Observed Daily Returns of the S&P 500 Index between December 31, 2002 and December 31, 2003 and the Negative of VaR

Note: The marked observation is an example of an exceedance.

Step 3. Check if the loss on a given day is below or above the VaR number computed the day before. If the observed loss is larger, then we say that there is a case of an exceedance. Figure 3 provides an example.

Step 4. Count the number of exceedances. Check if there are too many or too few of them by verifying if the number of exceedances belong to the corresponding 95% confidence interval.

If in Step 4 we find out that there are too many exceedances, then the VaR numbers produced by the model are too optimistic. Losses exceeding the corresponding VaR happen too frequently. If capital reserves are determined on the basis of VaR, then there is a risk of being incapable of covering large losses. Conversely, if we find out that there are too few exceedances, then the VaR numbers are too pessimistic. This is also an undesirable situation. Note that the actual size of the exceedances is immaterial; we only count them.

The confidence interval for the number of exceedances is constructed on the basis of the indicator-type events “we observe an exceedance,” “we do not observe an exceedance”

on a given day. If we consider the 99% VaR, then the probability of the first event, according to the model, is 1%. Let us associate a number with each of the events similar to a coin tossing experiment. If we observe an exceedance on a given day, then we say that the number 1 has occurred, otherwise 0 has occurred. If the backtesting time window is two years, then we have a sequence of 500 zeros and ones and the expected number of exceedances is 5. Thus, finding the 95% confidence interval for the number of exceedances reduces to finding an interval around 5 such that the probability of the number of ones belonging to this interval is 95%.

If we assume that the corresponding events are independent, then there is a complete analogue of this problem in terms of coin tossing. We toss an unfair coin independently 500 times with probability of success equal to 1%. What is the range of the number of success events with 95% probability? In order to find the 95% confidence interval, we can resort to the normal approximation to the binomial distribution. The formula is

$$\begin{aligned} \text{left bound} &= N\epsilon - F^{-1}(1 - 0.05/2)\sqrt{N\epsilon(1 - \epsilon)} \\ \text{right bound} &= N\epsilon + F^{-1}(1 - 0.05/2)\sqrt{N\epsilon(1 - \epsilon)} \end{aligned}$$

where N is the number of indicator-type events, ϵ is the tail probability of the VaR, and $F^{-1}(t)$ is the inverse distribution function of the standard normal distribution. In the example, $N = 500$, $\epsilon = 0.01$, and the 95% confidence interval for the number of exceedances is $[0, 9]$. Similarly, if we are back-testing the 95% VaR, under the same circumstances the confidence interval is $[15, 34]$.

Note that the statistical test based on the back-testing of VaR at a certain tail probability cannot answer the question if the distributional assumptions for the risk-driving factors are correct in general. For instance, if the portfolio contains only common stocks, then we presume a probabilistic model for stocks returns. By back-testing the 99% daily VaR of portfolio return, we verify if the probabilistic model is adequate for the 1% quantile of the portfolio return distribution; that is, we are back-testing if a certain point in the left tail of the portfolio return distribution is sufficiently accurately modeled. This should not be confused with statistical tests such as the Kolmogorov test or the Kolmogorov-Smirnov test, which concern accepting or rejecting a given distributional hypothesis.

COHERENT RISK MEASURES

Even though VaR has an intuitive interpretation and has been widely adopted as a risk measure, it does not always satisfy the important property that the VaR of a portfolio should not exceed the sum of the VaRs of the portfolio positions. This means that VaR is not always capable of representing the diversification effect.

This fact raises an important question. Can we find a set of desirable properties that a risk measure should satisfy? An answer is given by Artzner et al. (1998). They provide an axiomatic definition of a functional, which they call a *coherent risk measure*. The axioms follow with remarks given below each axiom. We denote the risk measure by the functional $\rho(X)$ assigning a real-valued number to a random

variable. Usually, the random variable X is interpreted as a random payoff and the motivation for the axioms in Artzner et al. (1998) follows this interpretation. In the remarks below each axiom, we provide an alternative interpretation, which holds if X is interpreted as random return.

The Monotonicity Property

Monotonicity $\rho(Y) \leq \rho(X)$,
if $Y \geq X$ in almost sure sense

Monotonicity states that if investment A has random return (payoff) Y , which is not less than the return (payoff) X of investment B at a given horizon in all states of the world, then the risk of A is not greater than the risk of B. This is quite intuitive but it really does matter whether the random variables represent random return or profit because an inequality in an almost sure sense between random returns may not translate into the same inequality between the corresponding random profits and vice versa.

Suppose that X and Y describe the random percentage returns on two investments A and B and let $Y = X + 3\%$. Apparently, $Y > X$ in all states of the world. The corresponding payoffs are obtained according to the equations

$$\text{Payoff}(X) = I_A(1 + X)$$

$$\text{Payoff}(Y) = I_B(1 + Y) = I_B(1 + X + 3\%)$$

where I_A is the initial investment in opportunity A and I_B is the initial investment in opportunity B. If the initial investment I_A is much larger than I_B , then $\text{Payoff}(X) > \text{Payoff}(Y)$ irrespective of the inequality $Y > X$. In effect, investment A may seem less risky than investment B in terms of payoff but in terms of return, the converse may hold.

The Positive Homogeneity Property

Positive Homogeneity $\rho(0) = 0$, $\rho(\lambda X) = \lambda\rho(X)$,
for all X and all $\lambda > 0$

The *positive homogeneity property* states that scaling the return (payoff) of the portfolio by

a positive factor scales the risk by the same factor. The interpretation for payoffs is obvious—if the investment in a position doubles, so does the risk of the position. We give a simple example illustrating this property when X stands for a random percentage return.

Suppose that today the value of a portfolio is I_0 and we add a certain amount of cash C . The value of our portfolio becomes $I_0 + C$. The value tomorrow is random and equals $I_1 + C$ in which I_1 is the random payoff. The return of the portfolio equals

$$\begin{aligned} X &= \frac{I_1 + C - I_0 - C}{I_0 + C} = \frac{I_1 - I_0}{I_0} \left(\frac{I_0}{I_0 + C} \right) \\ &= h \frac{I_1 - I_0}{I_0} = hY \end{aligned}$$

where $h = I_0/(I_0 + C)$ is a positive constant. The axiom positive homogeneity property implies that $\rho(X) = h\rho(Y)$; that is, the risk of the new portfolio will be the risk of the portfolio without the cash but scaled by h .

The Subadditivity Property

$$\begin{aligned} \text{Subadditivity} \quad \rho(X + Y) &\leq \rho(X) + \rho(Y), \\ &\text{for all } X \text{ and } Y \end{aligned}$$

If X and Y describe random payoffs, then the subadditivity property states that the risk of the portfolio is not greater than the sum of the risks of the two random payoffs.

The positive homogeneity property and the subadditivity property imply that the functional is convex

$$\begin{aligned} \rho(\lambda X + (1 - \lambda)Y) &\leq \rho(\lambda X) + \rho((1 - \lambda)Y) \\ &= \lambda\rho(X) + (1 - \lambda)\rho(Y) \end{aligned}$$

where $\lambda \in [0, 1]$. If X and Y describe random returns, then the random quantity $\lambda X + (1 - \lambda)Y$ stands for the return of a portfolio composed of two financial instruments with returns X and Y having weights λ and $1 - \lambda$ respectively. Therefore, the convexity property states that the risk of a portfolio is not greater than the sum of the risks of its constituents, meaning that it is the

convexity property that is behind the diversification effect that we expect in the case of X and Y denoting random returns.

The Invariance Property

$$\begin{aligned} \text{Invariance} \quad \rho(X + C) &= \rho(X) - C, \\ &\text{for all } X \text{ and } C \in \mathbb{R} \end{aligned}$$

The invariance property has various labels. Originally, it was called translation invariance while in other texts it is called cash invariance.² If X describes a random payoff, then the invariance property suggests that adding cash to a position reduces its risk by the amount of cash added. This is motivated by the idea that the risk measure can be used to determine capital requirements. As a consequence, the risk measure $\rho(X)$ can be interpreted as the minimal amount of cash necessary to make the position free of any capital requirements

$$\rho(X + \rho(X)) = 0$$

The invariance property has a different interpretation when X describes random return. Suppose that the random variable X describes the return of a common stock and we build a long-only portfolio by adding a government bond yielding a risk-free rate r_B . The portfolio return equals $wX + (1 - w)r_B$, where $w \in [0, 1]$ is the weight of the common stock in the portfolio. Note that the quantity $(1 - w)r_B$ is nonrandom by assumption. The invariance property states that the risk of the portfolio can be decomposed as

$$\begin{aligned} \rho(wX + (1 - w)r_B) &= \rho(wX) - (1 - w)r_B \\ &= w\rho(X) - (1 - w)r_B \end{aligned} \tag{9}$$

where the second equality appears because of the positive homogeneity property. In effect, the risk measure admits the following interpretation: Assume that the constructed portfolio is equally weighted, that is, $w = 1/2$, then the risk measure equals the level of the risk-free rate such that the risk of the equally weighted

portfolio consisting of the risky asset and the risk-free asset is zero. The investment in the risk-free asset will be, effectively, the reserve investment.

Alternative interpretations are also possible. Suppose that the present value of the position with random percentage return X is I_0 . Assume that we can find a government security earning return r_B^* at the horizon of interest. Then we can ask the question in the opposite direction: How much should we reallocate from I_0 and invest in the government security in order to hedge the risk $\rho(X)$? The needed capital C should satisfy the equation

$$\frac{I_0 - C}{I_0} \rho(X) - \frac{C}{I_0} r_B^* = 0$$

which is merely a restatement of equation (9) with the additional requirement that the risk of the resulting portfolio should be zero. The solution is

$$C = I_0 \frac{\rho(X)}{\rho(X) + r_B^*}$$

Note that if in the invariance property the constant is nonnegative, $C \geq 0$, then it follows that $\rho(X + C) \leq \rho(X)$. This result is in agreement with the monotonicity property as $X + C \geq X$. In fact, the invariance property can be regarded as an extension of the monotonicity property when the only difference between X and Y is in their means.

According to the discussion in the previous section, VaR is not a coherent risk measure because it may violate the subadditivity property.

An example of a coherent risk measure is the Average Value-at-Risk (AVaR), defined as the average of the VaRs that are larger than the VaR at a given tail probability ϵ . The accepted notation is $AVaR_\epsilon(X)$ in which ϵ stands for the tail probability level. A larger family of coherent risk measures is the family of spectral risk measures, which includes the AVaR as a representative. The spectral risk measures are defined as weighted averages of VaRs.

KEY POINTS

- VaR is defined as the minimum level of loss at a given, sufficiently high confidence level for a predefined time horizon.
- The performance of VaR, as well as any other risk measure, is heavily dependent on the assumed probability distribution for the economic measure of interest.
- Despite VaR's wide acceptance in the finance industry, it has important deficiencies so that, in general, it should be abandoned as a risk measure. However, it is not a useless concept to be abandoned altogether. For example, it can be used in risk reporting only as a characteristic of the portfolio return (pay-off) distribution since it has a straightforward interpretation.
- The most important drawback of VaR is that, in some cases, the reasonable diversification effect that every portfolio manager should expect to see in a risk measure is not present.
- The criticism of VaR is focused on its wide application by practitioners as a true risk measure, which, in view of its deficiencies, is not well grounded and should be reconsidered.
- Three approaches for portfolio VaR calculation that are used in practice are the Risk-Metrics approach, the historical method approach, and the Monte Carlo approach.

NOTES

1. A boxplot, or a box-and-whiskers diagram, is a convenient way of depicting several statistical characteristics of the sample. The size of the box equals the difference between the third and the first quartile (75% quantile–25% quantile), also known as the interquartile range. The line in the box corresponds to the median of the data (50% quantile). The lines extending out of the box are called whiskers and each of them is long up to 1.5 times the interquartile range. All

observations outside the whiskers are labeled outliers and are depicted by a plus sign.

2. This label can be found in Föllmer and Schied (2002).

Abstract: Despite the fact that the value-at-risk (VaR) measure has been adopted as a standard risk measure in the financial industry, it has a number of deficiencies recognized by financial professionals. It is not a coherent risk measure. This is because it does not satisfy the subadditivity property requirement of a coherent risk measure. That is, there are cases in which the portfolio VaR is larger than the sum of the VaRs of the portfolio constituents, supporting the view that VaR cannot be used as a true risk measure. Unlike VaR, the average value-at-risk measure (AVaR)—also referred to as conditional value-at-risk and expected shortfall—is a coherent risk measure and has other advantages that result in its greater acceptance in risk modeling.

The *average value-at-risk* (AVaR) is a risk measure that is a superior alternative to VaR. Not only does it lack the deficiencies of VaR, but it also has an intuitive interpretation. There are convenient ways for computing and estimating AVaR, which allows its application in optimal portfolio problems. Moreover, it satisfies all axioms of *coherent risk measures* and it is consistent with the preference relations of risk-averse investors.

In this entry, we explore in detail the properties of AVaR and illustrate its superiority to VaR. We develop new geometric interpretations of AVaR and the various calculation methods.

We also provide closed-form expressions for the AVaR of the normal distribution, Student's t distribution, and a practical formula for Lévy stable distributions. Finally, we describe different estimation methods and remark on potential pitfalls.

AVERAGE VALUE-AT-RISK DEFINED

A disadvantage of VaR is that it does not give any information about the severity of losses beyond the VaR level. Consider the following example. Suppose that X and Y describe the

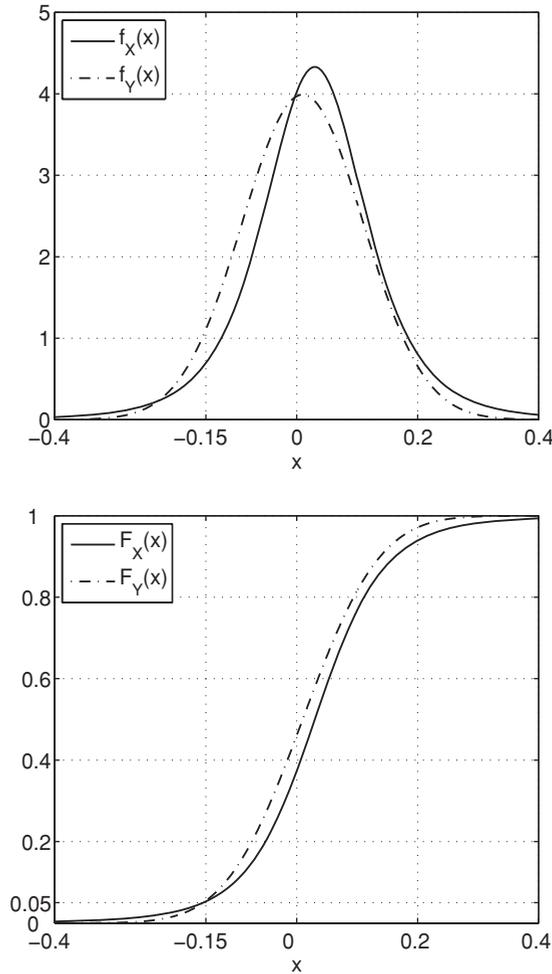

Figure 1 Note: The top plot shows the densities of X and Y and the bottom plot shows their c.d.f.s. The 95% VaRs of X and Y are equal to 0.15 but X has a thicker tail and is more risky.

random returns of two financial instruments with densities and distribution functions such as the ones in Figure 1. The expected returns are 3% and 1%, respectively. The standard deviations of X and Y are equal to 10%.¹ The cumulative distribution functions (c.d.f.s) $F_X(x)$ and $F_Y(x)$ cross at $x = -0.15$ and $F_X(-0.15) = F_Y(-0.15) = 0.05$. According to the definition of VaR, the 95% VaRs of both X and Y are equal to 15%. That is, the two financial instruments lose more than 15% of their present values with probability of 5%. In effect, we may conclude

that their risks are equal because their 95% VaRs are equal.

This conclusion is wrong because we pay no attention to the losses that are larger than the 95% VaR level. It is visible in Figure 1 that the left tail of X is heavier than the left tail of Y .² Therefore, it is more likely that the losses of X will be larger than the losses of Y , on condition that they are larger than 15%. Thus, looking only at the losses occurring with probability smaller than 5%, the random return X is riskier than Y . Note that both X and Y have equal standard deviations. If we base the analysis on the standard deviation and the expected return, we would conclude that not only is the uncertainty of X equal to the uncertainty of Y , but X is actually preferable because of the higher expected return. In fact, we realize that it is exactly the opposite, which shows how important it is to ground the reasoning on a proper risk measure.

The disadvantage of VaR, that it is not informative about the magnitude of the losses larger than the VaR level, is not present in the risk measure known as *average value-at-risk*. In the literature, it is also called *conditional value-at-risk*³ or *expected shortfall* but we will use average value-at-risk (AVaR) as it best describes the quantity it refers to.

The AVaR at tail probability ϵ is defined as the average of the VaRs, which are larger than the VaR at tail probability ϵ . Therefore, by construction, the AVaR is focused on the losses in the tail, which are larger than the corresponding VaR level. The average of the VaRs is computed through the integral

$$AVaR_\epsilon(X) = \frac{1}{\epsilon} \int_0^\epsilon VaR_p(X) dp \quad (1)$$

where $VaR_p(X)$ is defined by $VaR_\epsilon(X) = -\inf_x \{x \mid P(X \leq x) \geq \epsilon\} = -F_X^{-1}(\epsilon)$. As a matter of fact, the AVaR is not well defined for all real-valued random variables but only for those with finite mean; that is $AVaR_\epsilon(X) < \infty$ if $E|X| < \infty$. This should not be disturbing because random variables with infinite mathematical

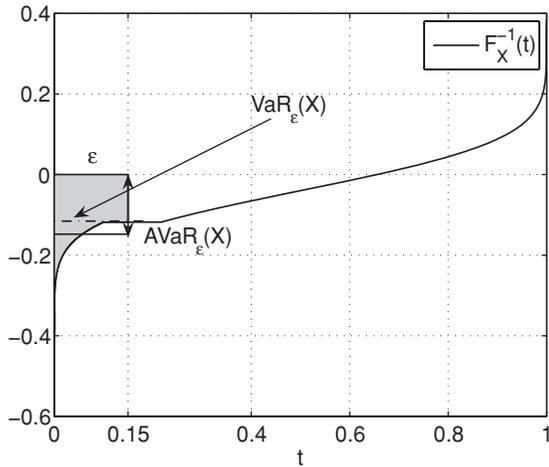

Figure 2 Geometrically, $AVaR_\epsilon(X)$ is the height for which the area of the drawn rectangle equals the shaded area closed between the graph of the inverse c.d.f. and the horizontal axis for $t \in [0, \epsilon]$. The $VaR_\epsilon(X)$ value is shown by a dash-dotted line.

expectation have limited application in the field of finance. For example, if such a random variable is used for a model of stock returns, then it is assumed that the common stock has infinite expected return, which is not realistic.

The AVaR satisfies all the axioms of coherent risk measures. One consequence is that, unlike VaR, it is convex for all possible portfolios, which means that it always accounts for the diversification effect.

A geometric interpretation of the definition in equation (1) is provided in Figure 2. In this figure, the inverse c.d.f. of a random variable X is plotted. The shaded area is closed between the graph of $F_X^{-1}(t)$ and the horizontal axis for $t \in [0, \epsilon]$ where ϵ denotes the selected tail probability. $AVaR_\epsilon(X)$ is the value for which the area of the drawn rectangle, equal to $\epsilon \times AVaR_\epsilon(X)$, coincides with the shaded area, which is computed by the integral in equation (1). The $VaR_\epsilon(X)$ value is always smaller than $AVaR_\epsilon(X)$. In Figure 2, $VaR_\epsilon(X)$ is shown by a dash-dotted line and is indicated by an arrow.

Let us revisit the example developed at the beginning of this section. We concluded that even

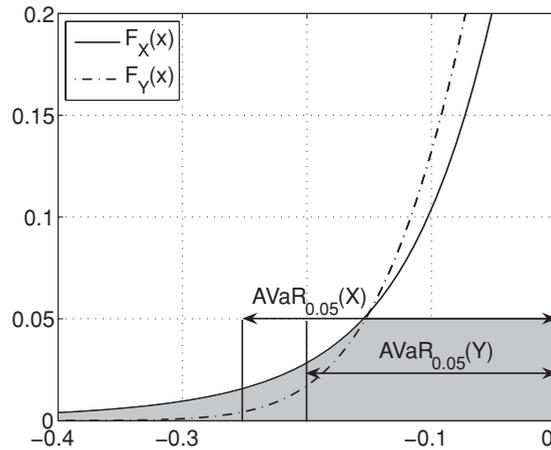

Figure 3 The AVaRs of the Return Distributions from Figure 1 in Line with the Geometric Intuition *Note:* Even though the 95% VaRs are equal, the AVaRs at 5% tail probability differ, $AVaR_{0.05}(X) > AVaR_{0.05}(Y)$.

though the VaRs at 5% tail probability of both random variables are equal, X is riskier than Y because the left tail of X is heavier than the left tail of Y ; that is, the distribution of X is more likely to produce larger losses than the distribution of Y on condition that the losses are beyond the VaR at the 5% tail probability. We apply the geometric interpretation illustrated in Figure 2 to this example. First, notice that the shaded area in Figure 2, which concerns the graph of the inverse of the c.d.f., can also be identified through the graph of the c.d.f. This is done in Figure 3, which shows a magnified section of the left tails of the c.d.f.s plotted in Figure 1. The shaded area appears as the intersection of the area closed below the graph of the distribution function and the horizontal axis, and the area below a horizontal line shifted at the tail probability above the horizontal axis. In Figure 3, we show the area for $F_X(x)$ at 5% tail probability. The corresponding area for $F_Y(x)$ is smaller because $F_Y(x) \leq F_X(x)$ to the left of the crossing point of the two c.d.f.s, which is exactly at 5% tail probability.

In line with the geometric interpretation, the $AVaR_{0.05}(X)$ is a number such that if we draw

a rectangle with height 0.05 and width equal to $AVaR_{0.05}(X)$, the area of the rectangle ($0.05 \times AVaR_{0.05}(X)$) equals the shaded area in Figure 3. The same exercise for $AVaR_{0.05}(Y)$ shows that $AVaR_{0.05}(Y) < AVaR_{0.05}(X)$ because the corresponding shaded area is smaller and both rectangles share a common height of 0.05.

Besides the definition in equation (1), AVaR can be represented through a minimization formula,⁴

$$AVaR_{\epsilon}(X) = \min_{\theta \in \mathbb{R}} \left(\theta + \frac{1}{\epsilon} E(-X - \theta)_+ \right) \quad (2)$$

where $(x)_+$ denotes the maximum between x and zero, $(x)_+ = \max(x, 0)$ and X describes the portfolio return distribution. It turns out that this formula has an important application in optimal portfolio problems based on AVaR as a risk measure. In the appendix to this entry, we provide an illuminating geometric interpretation of equation (2), which shows the connection to the definition of AVaR.

How can we compute the AVaR for a given return distribution? Throughout this section, we assume that the return distribution function is a continuous function, that is, there are no point masses. Under this condition, after some algebra and using the fact that VaR is the negative of a certain quantile, we obtain that the AVaR can be represented in terms of a conditional expectation,

$$\begin{aligned} AVaR_{\epsilon}(X) &= -\frac{1}{\epsilon} \int_0^{\epsilon} F_X^{-1}(t) dt \\ &= -E(X | X < -VaR_{\epsilon}(X)) \end{aligned} \quad (3)$$

which is called expected tail loss (ETL) and is denoted by $ETL_{\epsilon}(X)$. The conditional expectation implies that the AVaR equals the average loss provided that the loss is larger than the VaR level. In fact, the average of VaRs in equation (1) equals the average of losses in equation (3) only if the c.d.f. of X is continuous at $x = VaR_{\epsilon}(X)$. If there is a discontinuity, or a point mass, the relationship is more involved. The general formula is given in the appendix to this entry.

Equation (3) implies that AVaR is related to the conditional loss distribution. In fact, under certain conditions, it is the mathematical expectation of the conditional loss distribution, which represents only one characteristic of it. In the appendix to this entry, we introduce several sets of characteristics of the conditional loss distribution, which provide a more complete picture of it. Also, in the appendix, we introduce the more general concept of higher-order AVaR.

For some continuous distributions, it is possible to calculate explicitly the AVaR through equation (3). We provide the closed-form expressions for the normal distribution and Student's t distribution. In the appendix to this entry, we give a semi-explicit formula for the class of stable distributions.

1. The normal distribution

Suppose that X is distributed according to a normal distribution with standard deviation σ_X and mathematical expectation EX . The AVaR of X at tail probability ϵ equals

$$AVaR_{\epsilon}(X) = \frac{\sigma_X}{\epsilon \sqrt{2\pi}} \exp\left(-\frac{(VaR_{\epsilon}(Y))^2}{2}\right) - EX \quad (4)$$

where Y has the standard normal distribution, $Y \in N(0,1)$.

2. The Student's t distribution

Suppose that X has Student's t distribution with ν degrees of freedom, $X \in t(\nu)$. The AVaR of X at tail probability ϵ equals

$$AVaR_{\epsilon}(X) = \begin{cases} \frac{\Gamma\left(\frac{\nu+1}{2}\right)}{\Gamma\left(\frac{\nu}{2}\right)} \frac{\sqrt{\nu}}{(\nu-1)\epsilon\sqrt{\pi}} \left(1 + \frac{(VaR_{\epsilon}(X))^2}{\nu}\right)^{\frac{1-\nu}{2}}, & \nu > 1 \\ \infty, & \nu = 1 \end{cases}$$

where the notation $\Gamma(x)$ stands for the gamma function. It is not surprising that for $\nu = 1$ the AVaR explodes because the Student's t distribution with one degree of freedom, also known as the Cauchy distribution, has infinite mathematical expectation.⁵

Note that equation (4) can be represented in a more compact way,

$$AVaR_\epsilon(X) = \sigma_X C_\epsilon - E X \tag{5}$$

where C_ϵ is a constant which depends only on the tail probability ϵ . Therefore, the AVaR of the normal distribution has the same structure as the normal VaR—the difference between the properly scaled standard deviation and the mathematical expectation. In effect, similar to the normal VaR, the normal AVaR properties are dictated by the standard deviation. Even though AVaR is focused on the extreme losses only, due to the limitations of the normal assumption, it is symmetric.

Exactly the same conclusion holds for the AVaR of Student's t distribution. The true merits of AVaR become apparent if the underlying distributional model is skewed.

AVaR ESTIMATION FROM A SAMPLE

Suppose that we have a sample of observed portfolio returns and we are not aware of their distribution. Provided that we do not impose any distributional model, the AVaR of portfolio return can be estimated from the sample of observed portfolio returns. Denote the observed portfolio returns by r_1, r_2, \dots, r_n at time instants t_1, t_2, \dots, t_n . The numbers in the sample are given in order of observation. Denote the sorted sample by $r_{(1)} \leq r_{(2)} \leq \dots \leq r_{(n)}$. Thus, $r_{(1)}$ equals the smallest observed portfolio return and $r_{(n)}$ is the largest. The AVaR of portfolio returns at tail probability ϵ is estimated according to the formula⁶

$$\widehat{AVaR}_\epsilon(r) = -\frac{1}{\epsilon} \left(\frac{1}{n} \sum_{k=1}^{\lceil n\epsilon \rceil - 1} r_{(k)} + \left(\epsilon - \frac{\lceil n\epsilon \rceil - 1}{n} \right) r_{(\lceil n\epsilon \rceil)} \right) \tag{6}$$

where the notation $\lceil x \rceil$ stands for the smallest integer larger than x .⁷ The “hat” above AVaR denotes that the number calculated by equation (6) is an estimate of the true value because it is

based on a sample. This is a standard notation in statistics.

We demonstrate how equation (6) is applied in the following example. Suppose that the sorted sample of portfolio returns is -1.37% , -0.98% , -0.38% , -0.26% , 0.19% , 0.31% , 1.91% and our goal is to calculate the portfolio AVaR at 30% tail probability. In this case, the sample contains 7 observations and $(n\epsilon) = (7 \times 0.3) = 3$. According to equation (6), we calculate

$$\begin{aligned} \widehat{AVaR}_{0.3}(r) &= -\frac{1}{0.3} \left(\frac{1}{7} (-1.37\% - 0.98\%) \right. \\ &\quad \left. + (0.3 - 2/7)(-0.38\%) \right) \\ &= 1.137\%. \end{aligned}$$

Formula (6) can be applied not only to a sample of empirical observations. We may want to work with a statistical model for which no closed-form expressions for AVaR are known. Then we can simply sample from the distribution and apply formula (6) to the generated simulations.

Besides formula (6), there is another method for calculation of AVaR. It is based on the minimization formula (2) in which we replace the mathematical expectation by the sample average,

$$\widehat{AVaR}_\epsilon(r) = \min_{\theta \in \mathbb{R}} \left(\theta + \frac{1}{n\epsilon} \sum_{i=1}^n \max(-r_i - \theta, 0) \right) \tag{7}$$

Even though it is not obvious, equations (6) and (7) are completely equivalent.

The minimization formula in equation (7) is appealing because it can be calculated through the methods of linear programming. It can be restated as a linear optimization problem by introducing auxiliary variables d_1, \dots, d_n , one for each observation in the sample,

$$\begin{aligned} &\min_{\theta, d} \quad \theta + \frac{1}{n\epsilon} \sum_{k=1}^n d_k \\ &\text{subject to} \quad -r_k - \theta \leq d_k, \quad k = 1, n \\ &\quad \quad \quad d_k \geq 0, \quad k = 1, n \\ &\quad \quad \quad \theta \in \mathbb{R} \end{aligned} \tag{8}$$

The linear problem (8) is obtained from (7) through standard methods in mathematical programming. We briefly demonstrate the equivalence between them. Let us fix the value of θ to θ^* . Then the following choice of the auxiliary variables yields the minimum in (8). If $-r_k - \theta^* < 0$, then $d_k = 0$. Conversely, if it turns out that $-r_k - \theta^* \geq 0$, then $-r_k - \theta^* = d_k$. In this way, the sum in the objective function becomes equal to the sum of maxima in equation (7).

Applying (8) to the sample in the example above, we obtain the optimization problem

$$\begin{aligned} \min_{\theta, d} \quad & \theta + \frac{1}{7 \times 0.3} \sum_{k=1}^7 d_k \\ \text{subject to} \quad & 0.98\% - \theta \leq d_1 \\ & -0.31\% - \theta \leq d_2 \\ & -1.91\% - \theta \leq d_3 \\ & 1.37\% - \theta \leq d_4 \\ & 0.38\% - \theta \leq d_5 \\ & 0.26\% - \theta \leq d_6 \\ & -0.19\% - \theta \leq d_7 \\ & d_k \geq 0, \quad k = 1, 7 \\ & \theta \in \mathbb{R} \end{aligned}$$

The solution to this optimization problem is the number 1.137%, which is attained for $\theta = 0.38\%$. In fact, this value of θ coincides with the VaR at 30% tail probability and this is not by chance but a feature of the problem, which is demonstrated in the appendix to this entry. We verify that the solution of the problem is indeed the number 1.137% by calculating the objective in equation (7) for $\theta = 0.38\%$,

$$\begin{aligned} AVaR_\epsilon(r) &= 0.38\% + \frac{0.98\% - 0.38\% + 1.37\% - 0.38\%}{7 \times 0.3} \\ &= 1.137\% \end{aligned}$$

Thus, we obtain the number calculated through equation (6).

COMPUTING PORTFOLIO AVaR IN PRACTICE

The ideas behind the approaches of VaR estimation are applied to AVaR. We assume that there

are n assets with random returns described by the random variables X_1, \dots, X_n . Thus, the portfolio return is represented by

$$r_p = w_1 X_1 + \dots + w_n X_n$$

where w_1, \dots, w_n are the weights of the assets in the portfolio.

The Multivariate Normal Assumption

If the asset returns are assumed to have a multivariate normal distribution, then the portfolio return has a normal distribution with variance $w' \Sigma w$, where w is the vector of weights and Σ is the covariance matrix between stock returns. The mean of the normal distribution is

$$Er_p = \sum_{k=1}^n w_k E X_k$$

where E stands for the mathematical expectation. Thus, under this assumption the AVaR of portfolio return at tail probability ϵ can be expressed in closed-form through equation (4),

$$\begin{aligned} AVaR_\epsilon(r_p) &= \frac{\sqrt{w' \Sigma w}}{\epsilon \sqrt{2\pi}} \exp\left(-\frac{(VaR_\epsilon(Y))^2}{2}\right) - Er_p \\ &= C_\epsilon \sqrt{w' \Sigma w} - Er_p \end{aligned} \quad (9)$$

where C_ϵ is a constant independent of the portfolio composition and can be calculated in advance. In effect, due to the limitations of the multivariate normal assumption, the portfolio AVaR appears symmetric and is representable as the difference between the properly scaled standard deviation of the random portfolio return and portfolio expected return.

The Historical Method

The historical method is not related to any distributional assumptions. We use the historically observed portfolio returns as a model for the future returns and apply formula (6) or (7).

The historical method has several drawbacks. It is very inaccurate for low tail probabilities, for example, 1% or 5%. Even with one year of daily

returns, which amounts to 250 observations, in order to estimate the AVaR at 1% probability, we have to use the 3 smallest observations, which is quite insufficient. What makes the estimation problem even worse is that these observations are in the tail of the distribution; that is, they are the smallest ones in the sample. The implication is that when the sample changes, the estimated AVaR may change a lot because the smallest observations tend to fluctuate a lot.

The Hybrid Method

According to the hybrid method, different weights are assigned to the observations by which the more recent observations get a higher weight. The rationale is that the observations far back in the past have less impact on the portfolio risk at the present time.

The hybrid method can be adapted for AVaR estimation. The weights assigned to the observations are interpreted as probabilities and, thus, the portfolio AVaR can be estimated from the resulting discrete distribution according to the formula

$$\widehat{AVaR}_\epsilon(r) = -\frac{1}{\epsilon} \left(\sum_{j=1}^{k_\epsilon} p_j r_{(j)} + \left(\epsilon - \sum_{j=1}^{k_\epsilon} p_j \right) r_{(k_\epsilon+1)} \right) \tag{10}$$

where $r_{(1)} \leq r_{(2)} \leq \dots \leq r_{(k_m)}$ denotes the sorted sample of portfolio returns or payoffs and p_1, p_2, \dots, p_{k_m} stand for the probabilities of the sorted observations; that is, p_1 is the probability of $r_{(1)}$. The number k_ϵ in equation (10) is an integer satisfying the inequalities

$$\sum_{j=1}^{k_\epsilon} p_j \leq \epsilon < \sum_{j=1}^{k_\epsilon+1} p_j$$

Equation (10) follows directly from the definition of AVaR⁸ under the assumption that the underlying distribution is discrete without the additional simplification that the outcomes are

equally probable. In the appendix to this entry, we demonstrate the connection between equation (10) and the definition of AVaR in equation (1).

The Monte Carlo Method

The Monte Carlo method assumes and estimates a multivariate statistical model for the asset return distribution. Then we sample from it, and we calculate scenarios for portfolio return. On the basis of these scenarios, we estimate portfolio AVaR using equation (6) in which r_1, \dots, r_n stands for the vector of generated scenarios.

Similar to the case of VaR, an artifact of the Monte Carlo method is the variability of the risk estimate. Since the estimate of portfolio AVaR is obtained from a generated sample of scenarios, by regenerating the sample, we will obtain a slightly different value.

Suppose that the portfolio daily return distribution is the standard normal law, $r_p \in N(0,1)$. By the closed-form expression in equation (4), we calculate that the AVaR of the portfolio at 1% tail probability equals

$$AVaR_{0.01}(r_p) = \frac{1}{0.01\sqrt{2\pi}} \exp\left(-\frac{2.326^2}{2}\right) = 2.665$$

In order to investigate how the fluctuations of the 99% AVaR change about the theoretical value, we generate samples of different sizes: 500, 1,000, 5,000, 10,000, 20,000, and 100,000 scenarios. The 99% AVaR is computed from these samples using equation 6 and the numbers are stored. We repeat the experiment 100 times. In the end, we have 100 AVaR numbers for each sample size. We expect that as the sample size increases, the AVaR values will fluctuate less about the theoretical value which is $AVaR_{0.01}(X) = 2.665, X \in N(0,1)$.

Panel A of Table 1 contains the result of the experiment. From the 100 AVaR numbers, we calculate the 95% confidence interval reported in the third column. The confidence intervals

Table 1 Confidence Intervals Calculated for AVaR and VaR

Number of Scenarios	AVaR at 99%	95% Confidence Interval
500	2.646	[2.2060, 2.9663]
1,000	2.771	[2.3810, 2.9644]
5,000	2.737	[2.5266, 2.7868]
10,000	2.740	[2.5698, 2.7651]
20,000	2.659	[2.5955, 2.7365]
50,000	2.678	[2.6208, 2.7116]
100,000	2.669	[2.6365, 2.6872]

Panel A: The 99% AVaR of the standard normal distribution computed from a sample of scenarios. The 95% confidence interval is calculated from 100 repetitions of the experiment. The true value is $AVaR_{0.01}(X) = 2.665$.

Number of Scenarios	99% VaR	95% Confidence Interval
500	2.067	[1.7515, 2.3825]
1,000	2.406	[2.1455, 2.6665]
5,000	2.286	[2.1875, 2.3845]
10,000	2.297	[2.2261, 2.3682]
20,000	2.282	[2.2305, 2.3335]
50,000	2.342	[2.3085, 2.3755]
100,000	2.314	[2.2925, 2.3355]

Panel B: The 99% VaR of the standard normal distribution computed from a sample of scenarios. The 95% confidence interval is calculated from 100 repetitions of the experiment. The true value is $VaR_{0.01}(X) = 2.326$.

cover the theoretical value 2.665 and also we notice that the length of the confidence interval decreases as the sample size increases. This effect is illustrated in Figure 4 with boxplot diagrams. A sample of 100,000 scenarios results in AVaR numbers, which are tightly packed around the true value while a sample of only 500 scenarios may give a very inaccurate estimate.

By comparing, Panel A of Table 1 to Panel B of the table, which shows the results for VaR, we notice that the length of the 95% confidence intervals for AVaR are larger than the corresponding confidence intervals for VaR. This result is not surprising. Given that both quantities are at the same tail probability of 1%, the AVaR has larger variability than the VaR for a fixed number of scenarios because the AVaR is the average of terms fluctuating more than the 1%

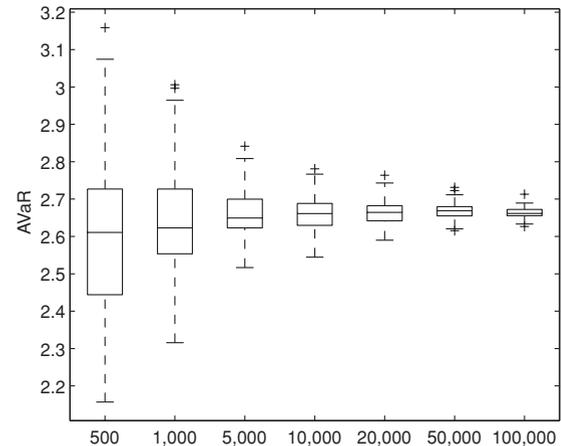

Figure 4 Boxplot Diagrams of the Fluctuation of the AVaR at 1% Tail Probability of the Standard Normal Distribution Based on Scenarios

Note: The horizontal axis shows the number of scenarios and the boxplots are computed from 100 independent samples.

VaR. This effect is more pronounced the more heavy-tailed the distribution is.

BACK-TESTING OF AVaR

Suppose that we have selected a method for calculating the daily AVaR of a portfolio. A reasonable question is how we can verify if the estimates of daily AVaR are realistic. This is done by back-testing. In the case of VaR back-testing consists of computing the portfolio VaR for each day back in time using the information available up to that day only. In this way, we have the VaR numbers back in time as if we had used exactly the same methodology in the past. On the basis of the VaR numbers and the realized portfolio returns, we can use statistical methods to assess whether the forecasted loss at the VaR tail probability is consistent with the observed losses. If there are too many observed losses larger than the forecasted VaR, then the model is too optimistic. Conversely, if there are too few losses larger than the forecasted VaR, then the model is too pessimistic.

Note that in the case of VaR back-testing, we are simply counting the cases in which there is an exceedance; that is, when the size of the observed loss is larger than the predicted VaR. The magnitude of the exceedance is immaterial for the statistical test.

Unlike VaR, back-testing of AVaR is not straightforward and is a much more challenging task. By definition, the AVaR at tail probability ϵ is the average of VaRs larger than the VaR at tail probability ϵ . Thus, the most direct approach to test AVaR would be to perform VaR back-tests at all tail probabilities smaller than ϵ . If all these VaRs are correctly modeled, then so is the corresponding AVaR.

One general issue with this approach is that it is impossible to perform in practice. Suppose that we consider the AVaR at tail probability of 1%, for example. Back-testing VaRs deeper in the tail of the distribution can be infeasible because the back-testing time window is too short. The lower the tail probability, the larger the time window we need in order for the VaR test to be conclusive. Another general issue is that this approach is too demanding. Even if the VaR back-testing fails at some tail probability ϵ_1 below ϵ , this does not necessarily mean that the AVaR is incorrectly modeled because the test failure may be due to purely statistical reasons and not to incorrect modeling.

These arguments illustrate why AVaR back-testing is a difficult problem—we need the information about the entire tail of the return distribution describing the losses larger than the VaR at tail probability ϵ and there may be too few observations from the tail upon which to base the analysis. For example, in one business year, there are typically 250 trading days. Therefore, a one-year back-testing results in 250 daily portfolio returns, which means that if $\epsilon = 1\%$, then there are only 2 observations available from the losses larger than the VaR at 1% tail probability.

As a result, in order to be able to back-test AVaR, we can assume a certain “structure” of

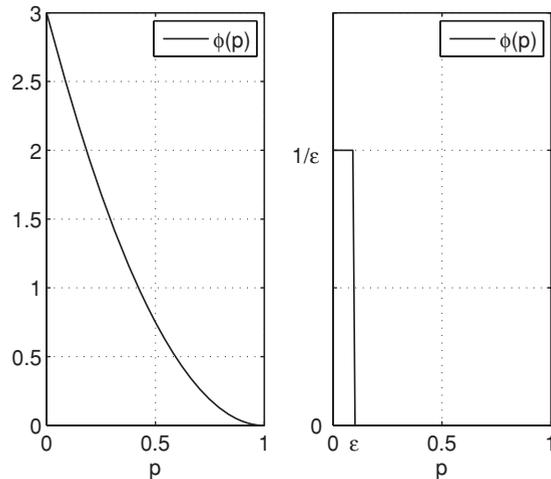

Figure 5 Examples of Risk-Aversion Functions
Note: The right plot shows the risk-aversion function yielding the AVaR at tail probability ϵ .

the tail of the return distribution that would compensate for the lack of observations. There are two general approaches:

1. Use the tails of the Lévy stable distributions as a proxy for the tail of the loss distribution and take advantage of the practical semi-analytic formula for the AVaR given in the appendix to this entry to construct a statistical test.
2. Make the weaker assumption that the loss distribution belongs to the domain of attraction of a max-stable distribution. Thus, the behavior of the large losses can be approximately described by the limit max-stable distribution and a statistical test can be based on it.

The rationale of the first approach is that, generally, the Lévy stable distribution provides a good fit to the stock returns data and, thus, the stable tail may turn out to be a reasonable approximation. Moreover, from the generalized central limit theorem we know that stable distributions have domains of attraction, which makes them an appealing candidate for an approximate model.

The second approach is based on a weaker assumption. The family of max-stable distributions arises as the limit distribution of properly scaled and centered maxima of IID random variables. If the random variable describes portfolio losses, then the limit max-stable distribution can be used as a model for the large losses (i.e., the ones in the tail). Unfortunately, as a result of the weaker assumption, estimators of poor quality have to be used to estimate the parameters of the limit max-stable distribution, such as the Hill estimator, for example. This represents the basic trade-off in this approach.

TECHNICAL APPENDIX

In this appendix, we start with a more general view that better describes the conditional loss distribution in terms of certain characteristics in which AVaR appears as a special case. We continue with the notion of higher-order AVaR, generating a family of coherent risk measures. Next, we provide an intuitive geometric interpretation of the minimization formula for the AVaR calculation. We also provide a semi-analytic expression for the AVaR of stable distributions and compare the expected tail loss measure to AVaR. Finally, we comment on the proper choice of a risk-aversion function in spectral risk measures, which does not result in an infinite risk measure.

Characteristics of Conditional Loss Distributions

In the entry, we defined AVaR as a risk measure and showed how it can be calculated in practice. While it is an intuitive and easy to use coherent risk measure, AVaR represents the average of the losses larger than the VaR at tail probability ϵ , which is only one characteristic of the distribution of extreme losses. We remarked that if the distribution function is continuous, then AVaR coincides with ETL, which is the mathematical expectation of the condi-

tional loss distribution. Besides the mathematical expectation, there are other important characteristics of the conditional loss distribution. For example, AVaR does not provide any information about how dispersed the conditional losses are around the AVaR value. In this section, we state a couple of families of useful characteristics in which AVaR appears as one example.

Consider the following tail moment of order n at tail probability ϵ ,

$$m_\epsilon^n(X) = \frac{1}{\epsilon} \int_0^\epsilon (F_X^{-1}(t))^n dt \quad (\text{A.1})$$

where $n = 1, 2, \dots$, $F_X^{-1}(t)$ is the inverse c.d.f. of the random variable X . If the distribution function of X is continuous, then the tail moment of order n can be represented through the following conditional expectation

$$m_\epsilon^n(X) = E(X^n | X < VaR_\epsilon(X)) \quad (\text{A.2})$$

where $n = 1, 2, \dots$. In the general case, if the c.d.f. has a jump at $VaR_\epsilon(X)$, a link exists between the conditional expectation and equation (A.1), which is similar to formula (A.12) later in this appendix for AVaR. In fact, AVaR appears as the negative of the tail moment of order one, $AVaR_\epsilon(X) = -m_\epsilon^1(X)$.

The higher-order tail moments provide additional information about the conditional distribution of the extreme losses. We can make a parallel with the way the moments of a random variable are used to describe certain properties of it. In our case, it is the conditional distribution that we are interested in.

In addition to the moments $m_\epsilon^n(X)$, we introduce the central tail moments of order n at tail probability ϵ ,

$$M_\epsilon^n(X) = \frac{1}{\epsilon} \int_0^\epsilon (F_X^{-1}(t) - m_\epsilon^1(X))^n dt \quad (\text{A.3})$$

where $m_\epsilon^1(X)$ is the tail moment of order one. If the distribution function is continuous, then the central moments can be expressed in terms of the conditional expectation

$$M_\epsilon^n(X) = E((X - m_\epsilon^1(X))^n | X < VaR_\epsilon(X))$$

The tail variance of the conditional distribution appears as $M_\epsilon^2(X)$ and the tail standard deviation equals

$$(M_\epsilon^2(X))^{1/2} = \left(\frac{1}{\epsilon} \int_0^\epsilon (F_X^{-1}(t) - m_\epsilon^1(X))^2 dt \right)^{1/2}$$

There is a formula expressing the tail variance in terms of the tail moments introduced in (A.2),

$$\begin{aligned} M_\epsilon^2(X) &= m_\epsilon^2(X) - (m_\epsilon^1(X))^2 \\ &= m_\epsilon^2(X) - (AVaR_\epsilon(X))^2 \end{aligned}$$

This formula is similar to the representation of variance in terms of the first two moments,

$$\sigma_X^2 = EX^2 - (EX)^2$$

The tail standard deviation can be used to describe the dispersion of conditional losses around AVaR as it satisfies the general properties of dispersion measures. It can be viewed as complementary to AVaR in the sense that if there are two portfolios with equal AVaRs of their return distributions but different tail standard deviations, the portfolio with the smaller standard deviation is preferable.

Another central tail moment that can be interpreted is $M_\epsilon^3(X)$. After proper normalization, it can be employed to measure the skewness of the conditional loss distribution. In fact, if the tail probability is sufficiently small, the tail skewness will be quite significant. In the same fashion, by normalizing the central tail moment of order 4, we obtain a measure of kurtosis of the conditional loss distribution.

In a similar way, we introduce the absolute central tail moments of order n at tail probability ϵ ,

$$\mu_\epsilon^n(X) = \frac{1}{\epsilon} \int_0^\epsilon |F_X^{-1}(t) - m_\epsilon^1(X)|^n dt \quad (A.4)$$

The tail moments $\mu_\epsilon^n(X)$ raised to the power of $1/n$, $(\mu_\epsilon^n(X))^{1/n}$, can be applied as measures of dispersion of the conditional loss distribution if the distribution is such that they are finite.

In the entry, we remarked that the tail of the random variable can be so heavy that AVaR becomes infinite. Even if it is theoretically finite, it can be hard to estimate because the heavy

tail will result in the AVaR estimator having a large variability. Thus, under certain conditions it may turn out to be practical to employ a robust estimator instead. The median tail loss (MTL), defined as the median of the conditional loss distribution, is a robust alternative to AVaR. It has the advantage of always being finite no matter the tail behavior of the random variable. Formally, it is defined as

$$MTL_\epsilon(X) = -F_X^{-1}(1/2|X < -VaR_\epsilon(X)) \quad (A.5)$$

where $F_X^{-1}(p|X < -VaR_\epsilon(X))$ stands for the inverse distribution function of the c.d.f. of the conditional loss distribution

$$\begin{aligned} F_X(x|X < -VaR_\epsilon(X)) &= P(X \leq x|X < -VaR_\epsilon(X)) \\ &= \begin{cases} P(X \leq x)/\epsilon, & x < -VaR_\epsilon(X) \\ 1, & x \geq -VaR_\epsilon(X) \end{cases} \end{aligned}$$

In effect, MTL, as well as any other quantile of the conditional loss distribution, can be directly calculated as a quantile of the distribution of X ,

$$\begin{aligned} MTL_\epsilon(X) &= -F_X^{-1}(\epsilon/2) \\ &= VaR_{\epsilon/2}(X) \end{aligned} \quad (A.6)$$

where $F_X^{-1}(p)$ is the inverse c.d.f. of X and ϵ is the tail probability of the corresponding VaR in equation (A.5). Thus, MTL shares the properties of VaR. Equation (A.6) shows that MTL is not a coherent risk measure even though it is a robust alternative to AVaR, which is a coherent risk measure.

In the universe of the three families of moments that we introduced, AVaR is one special case providing only limited information. It may be the only coherent risk measure among them but the other moments can be employed in addition to AVaR in order to gain more insight into the conditional loss distribution. Furthermore, it could appear that other reasonable risk measures can be based on some of the moments. Thus, we believe that they all should be considered in financial applications.

Higher-Order AVaR

By definition, AVaR is the average of VaRs larger than the VaR at tail probability ϵ . In the same fashion, we can pose the question of what happens if we average all AVaRs larger than the AVaR at tail probability ϵ . In fact, this quantity is an average of coherent risk measures and, therefore, is a coherent risk measure itself since it satisfies all defining properties of coherent risk measures. We call it *AVaR of order one* and denote it by $AVaR_\epsilon^{(1)}(X)$ because it is a derived quantity from AVaR. In this section, we consider similar derived quantities from AVaR which we call higher-order AVaRs.

Formally, the AVaR of order one is represented in the following way

$$AVaR_\epsilon^{(1)} = \frac{1}{\epsilon} \int_0^\epsilon AVaR_p(X) dp$$

where $AVaR_p(X)$ is the AVaR at tail probability p . Replacing AVaR by the definition given in equation (1), we obtain

$$\begin{aligned} AVaR_\epsilon^{(1)} &= -\frac{1}{\epsilon} \int_0^\epsilon \left(\int_0^1 F_X^{-1}(y) g_p(y) dy \right) dp \\ &= -\frac{1}{\epsilon} \int_0^1 F_X^{-1}(y) \left(\int_0^\epsilon g_p(y) dp \right) dy \end{aligned}$$

where

$$g_p(y) = \begin{cases} 1/p, & y \in [0, p] \\ 0, & y > p \end{cases}$$

and after certain algebraic manipulations, we get the expression

$$\begin{aligned} AVaR_\epsilon^{(1)}(X) &= -\frac{1}{\epsilon} \int_0^\epsilon F_X^{-1}(y) \log \frac{\epsilon}{y} dy \\ &= \int_0^\epsilon VaR_y(X) \phi_\epsilon(y) dy \quad (\text{A.7}) \end{aligned}$$

In effect, the AVaR of order one can be expressed as a weighted average of VaRs larger than the VaR at tail probability ϵ with a weighting function $\phi_\epsilon(y)$ equal to

$$\phi_\epsilon(y) = \begin{cases} \frac{1}{\epsilon} \log \frac{\epsilon}{y}, & 0 \leq y \leq \epsilon \\ 0, & \epsilon < y \leq 1 \end{cases}$$

The AVaR of order one can be viewed as a spectral risk measure with $\phi_\epsilon(y)$ being the risk aversion function.

Similarly, we define the higher-order AVaR through the recursive equation

$$AVaR_\epsilon^{(n)}(X) = \frac{1}{\epsilon} \int_0^\epsilon AVaR_p^{(n-1)}(X) dp \quad (\text{A.8})$$

where $AVaR_p^{(0)}(X) = AVaR_p(X)$ and $n = 1, 2, \dots$. Thus, the AVaR of order two equals the average of AVaRs of order one, which are larger than the AVaR of order one at tail probability ϵ . The AVaR of order n appears as an average of AVaRs of order $n - 1$.

The quantity $AVaR_\epsilon^{(n)}(X)$ is a coherent risk measure because it is an average of coherent risk measures. This is a consequence of the recursive definition in (A.8). It is possible to show that AVaR of order n admits the representation

$$AVaR_\epsilon^{(n)}(X) = \frac{1}{\epsilon} \int_0^\epsilon VaR_y(X) \frac{1}{n!} \left(\log \frac{\epsilon}{y} \right)^n dy \quad (\text{A.9})$$

and $AVaR_\epsilon^{(n)}(X)$ can be viewed as a spectral risk measure with a risk aversion function equal to

$$\phi_\epsilon^{(n)}(y) = \begin{cases} \frac{1}{\epsilon n!} \left(\log \frac{\epsilon}{y} \right)^n, & 0 \leq y \leq \epsilon \\ 0, & \epsilon < y \leq 1 \end{cases}$$

As a simple consequence of the definition, the sequence of higher-order AVaRs is monotonic,

$$AVaR_\epsilon(X) \leq AVaR_\epsilon^{(1)}(X) \leq \dots \leq AVaR_\epsilon^{(n)}(X) \leq \dots$$

In the entry, we remarked that if the random variable X has a finite mean, $E|X| < \infty$, then AVaR is also finite. This is not true for spectral risk measures and the higher-order AVaR in particular. In line with the general theory developed later in this appendix, $AVaR_\epsilon^{(n)}(X)$ is finite if all moments of X exist. For example, if

the random variable X has an exponential tail, then $AVaR_\epsilon^{(n)}(X) < \infty$ for any $n < \infty$.

The Minimization Formula for AVaR

In this section, we provide a geometric interpretation of the minimization formula (2) for AVaR. We restate equation (2) in the following equivalent form,

$$AVaR_\epsilon(X) = \frac{1}{\epsilon} \min_{\theta \in \mathbb{R}} (\epsilon\theta + E(-X - \theta)_+) \quad (\text{A.10})$$

where $(x)_+ = \max(x, 0)$. Note the similarity between equation (A.10) and the definition of AVaR in (A.2). Instead of the integral of the quantile function in the definition of AVaR, a minimization formula appears in (A.10). We interpreted the integral of the inverse c.d.f. as the shaded area in Figure 2. Similarly, we will find the area corresponding to the objective function in the minimization formula and we will demonstrate that as θ changes, there is a minimal area that coincides with the area corresponding to the shaded area in Figure 2. Moreover, the minimal area is attained for $\theta = VaR_\epsilon(X)$ when the c.d.f. of X is continuous at $VaR_\epsilon(X)$. In fact, all illustrations in this section are based on the assumption that X has a continuous distribution function.

Consider first the expectation in equation (A.10). Assuming that X has a continuous c.d.f., we obtain an expression for the expectation involving the inverse c.d.f.,

$$\begin{aligned} E(-X - \theta)_+ &= \int_{\mathbb{R}} \max(-x - \theta, 0) dF_X(x) \\ &= \int_0^1 \max(-F_X^{-1}(t) - \theta, 0) dt \\ &= - \int_0^1 \min(F_X^{-1}(t) + \theta, 0) dt \end{aligned}$$

This representation implies that the expectation $E(-X - \theta)_+$ equals the area closed between the graph of the inverse c.d.f. and a line parallel to the horizontal axis passing through the point $(0, -\theta)$. This is the shaded area on the right plot in Figure A.1. The same area can be represented

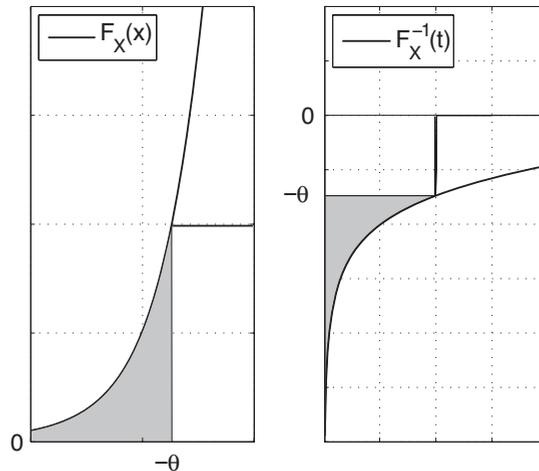

Figure A.1 Note: The shaded area is equal to the expectation $E(-X - \theta)_+$ in which X has a continuous distribution function.

in terms of the c.d.f. This is done on the left plot in Figure A.1.

Let us get back to equation (A.10). The tail probability ϵ is fixed. The product $\epsilon \times \theta$ equals the area of a rectangle with sides equal to ϵ and θ . This area is added to $E(-X - \theta)_+$. Figure A.2 shows the two areas together. The shaded areas on the top and the bottom plots equal $\epsilon \times AVaR_\epsilon(X)$. The top plot shows the case in which $-\theta < -VaR_\epsilon(X)$. Comparing the plot to Figure A.1, we find out that adding the marked area to the shaded area we obtain the total area corresponding to the objective in the minimization formula, $\epsilon\theta + E(-X - \theta)_+$. If $-\theta > -VaR_\epsilon(X)$, then we obtain a similar case shown on the bottom plot. Again, adding the marked area to the shaded area we obtain the the total area computed by the objective in the minimization formula. By varying θ , the total area changes but it always remains larger than the shaded area unless $\theta = VaR_\epsilon(X)$.

Thus, when $\theta = VaR_\epsilon(X)$ the minimum area is attained, which equals exactly $\epsilon \times AVaR_\epsilon(X)$. According to equation (A.10), we have to divide the minimal area by ϵ in order to obtain the AVaR. As a result, we have demonstrated that the minimization formula in equation (2) calculates the AVaR.

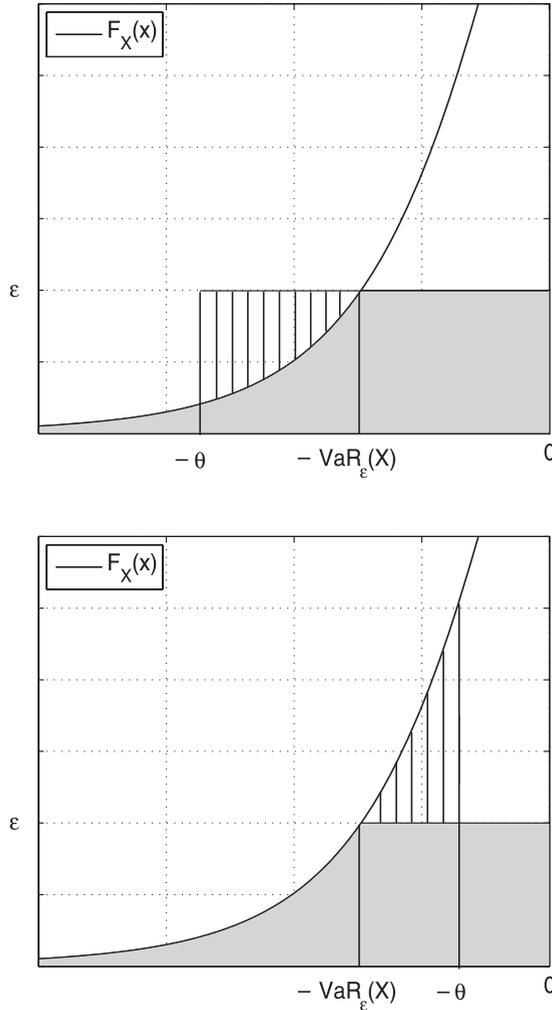

Figure A.2 Note: The marked area is in addition to the shaded one. The marked area is equal to zero if $\theta = \text{VaR}_\epsilon(X)$

AVaR for Stable Distributions

Working with the class of stable distributions in practice is difficult because there are no closed-form expressions for their densities and distribution functions. Thus, practical work relies on numerical methods.

Stoyanov et al. (2006) give an account of the approaches to estimating AVaR of stable distributions. It turns out that there is a formula that is not exactly a closed-form expression, such as the ones for the normal and Student's t AVaR stated in the entry, but is suit-

able for numerical work. It involves numerical integration but the integrand is nicely behaved and the integration range is a bounded interval. Numerical integration can be performed by standard toolboxes in many software packages, such as MATLAB, for example. Moreover, there are libraries freely available on the Internet. Therefore, numerical integration itself is not a severe restriction for applying a formula in practice. Since the formula involves numerical integration, we call it a semi-analytic expression.

Suppose that the random variable X has a stable distribution with tail exponent α , skewness parameter β , scale parameter σ , and location parameter μ , $X \in S_\alpha(\sigma, \beta, \mu)$. If $\alpha \leq 1$, then $\text{AVaR}_\epsilon(X) = \infty$. The reason is that stable distributions with $\alpha \leq 1$ have infinite mathematical expectation and the AVaR is unbounded.

If $\alpha > 1$ and $\text{VaR}_\epsilon(X) \neq 0$, then the AVaR can be represented as

$$\text{AVaR}_\epsilon(X) = \sigma A_{\epsilon, \alpha, \beta} - \mu$$

where the term $A_{\epsilon, \alpha, \beta}$ does not depend on the scale and the location parameters. In fact, this representation is a consequence of the positive homogeneity and the invariance property of AVaR. Concerning the term $A_{\epsilon, \alpha, \beta}$,

$$A_{\epsilon, \alpha, \beta} = \frac{\alpha}{1 - \alpha} \frac{|\text{VaR}_\epsilon(X)|}{\pi \epsilon} \int_{-\bar{\theta}_0}^{\pi/2} g(\theta) \exp(-|\text{VaR}_\epsilon(X)|^{\frac{\alpha}{\alpha-1}} v(\theta)) d\theta$$

where

$$g(\theta) = \frac{\sin(\alpha(\bar{\theta}_0 + \theta) - 2\theta)}{\sin \alpha(\bar{\theta}_0 + \theta)} - \frac{\alpha \cos^2 \theta}{\sin^2 \alpha(\bar{\theta}_0 + \theta)},$$

$$v(\theta) = (\cos \alpha \bar{\theta}_0)^{\frac{1}{\alpha-1}} \left(\frac{\cos \theta}{\sin \alpha(\bar{\theta}_0 + \theta)} \right)^{\frac{\alpha}{\alpha-1}} \frac{\cos(\alpha \bar{\theta}_0 + (\alpha - 1)\theta)}{\cos \theta},$$

in which $\bar{\theta}_0 = \frac{1}{\alpha} \arctan(\beta \tan \frac{\pi \alpha}{2})$, $\bar{\beta} = -\text{sign}(\text{VaR}_\epsilon(X))\beta$, and $\text{VaR}_\epsilon(X)$ is the VaR of the stable distribution at tail probability ϵ .

If $VaR_\epsilon(X) = 0$, then the AVaR admits a very simple expression,

$$AVaR_\epsilon(X) = \frac{2\Gamma\left(\frac{\alpha-1}{\alpha}\right) \cos \theta_0}{(\pi - 2\theta_0) (\cos \alpha\theta_0)^{1/\alpha}}$$

in which $\Gamma(x)$ is the gamma function and $\theta_0 = \frac{1}{\alpha} \arctan(\beta \tan \frac{\pi\alpha}{2})$.

ETL vs. AVaR

The expected tail loss and the average value-at-risk are two related concepts. In the entry, we remarked that ETL and AVaR coincide if the portfolio return distribution is continuous at the corresponding VaR level. However, if there is a discontinuity, or a point mass, then the two notions diverge. Still, the AVaR can be expressed through the ETL and the VaR at the same tail probability. In this section, we illustrate this relationship and show why the AVaR is more appealing. Moreover, it will throw light on why equation (6) should be used when considering a sample of observations.

The ETL at tail probability ϵ is defined as the average loss provided that the loss exceeds the VaR at tail probability ϵ ,

$$ETL_\epsilon(X) = -E(X|X < -VaR_\epsilon(X)) \quad (A.11)$$

As a consequence of the definition, the ETL can be expressed in terms of the c.d.f. and the inverse c.d.f. Suppose additionally, that the c.d.f. of X has a jump at $-VaR_\epsilon(X)$. In this case, the loss $VaR_\epsilon(X)$ occurs with probability equal to the size of the jump and, because of the strict inequality in (A.11), it will not be included in the average.

Figure A.3 shows the graphs of the c.d.f. and the inverse c.d.f. of a random variable with a point mass at $-VaR_\epsilon(X)$. If ϵ splits the jump of the c.d.f. as on the left plot in Figure A.3, then the ETL at tail probability ϵ equals

$$\begin{aligned} ETL_\epsilon(X) &= -E(X|X < -VaR_\epsilon(X)) \\ &= -E(X|X < -VaR_{\epsilon_0}(X)) \\ &= ETL_{\epsilon_0}(X) \end{aligned}$$

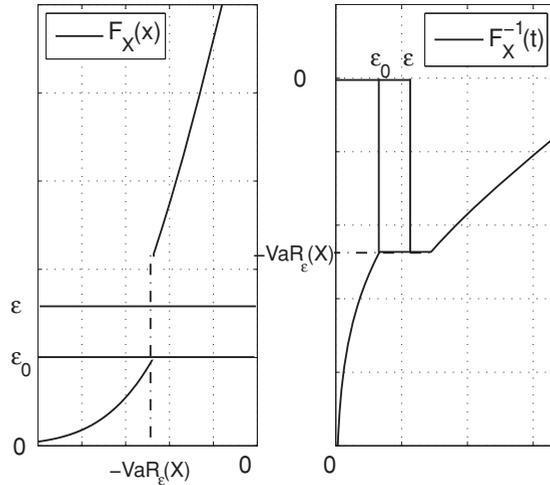

Figure A.3 The C.D.F. and the Inverse C.D.F. of a Random Variable X with a Point Mass at $-VaR_\epsilon(X)$
 Note: The tail probability ϵ splits the jump of the c.d.f.

In terms of the inverse c.d.f., the quantity $ETL_{\epsilon_0}(X)$ can be represented as

$$ETL_{\epsilon_0}(X) = -\frac{1}{\epsilon_0} \int_0^{\epsilon_0} F_X^{-1}(t) dt$$

The relationship between AVaR and ETL follows directly from the definition of AVaR.⁹ Suppose that the c.d.f. of the random variable X is as on the left plot in Figure A.3. Then,

$$\begin{aligned} AVaR_\epsilon(X) &= -\frac{1}{\epsilon} \int_0^\epsilon F_X^{-1}(t) dt \\ &= -\frac{1}{\epsilon} \left(\int_0^{\epsilon_0} F_X^{-1}(t) dt + \int_{\epsilon_0}^\epsilon F_X^{-1}(t) dt \right) \\ &= -\frac{1}{\epsilon} \int_0^{\epsilon_0} F_X^{-1}(t) dt + \frac{\epsilon - \epsilon_0}{\epsilon} VaR_\epsilon(X) \end{aligned}$$

where the last inequality holds because the inverse c.d.f. is flat in the interval $[\epsilon_0, \epsilon]$ and the integral is merely the surface of the rectangle shown on the right plot in Figure A.3. The integral in the first summand can be related to the ETL at tail probability ϵ and, finally, we arrive at the expression

$$AVaR_\epsilon(X) = \frac{\epsilon_0}{\epsilon} ETL_\epsilon(X) + \frac{\epsilon - \epsilon_0}{\epsilon} VaR_\epsilon(X) \quad (A.12)$$

Equation (A.12) shows that $AVaR_\epsilon(X)$ can be represented as a weighted average between the ETL and the VaR at the same tail probability as the coefficients in front of the two summands are positive and sum up to one. In the special case in which there is no jump, or if $\epsilon = \epsilon_1$, then AVaR equals ETL.

Why is equation (A.12) important if in all statistical models we assume that the random variables describing return or payoff distribution have densities? Under this assumption, not only are the corresponding c.d.f.s continuous but they are also smooth. Equation (A.12) is important because if the estimate of AVaR is based on the Monte Carlo method, then we use a sample of scenarios that approximate the nicely behaved hypothesized distribution. Even though we are approximating a smooth distribution function, the sample c.d.f. of the scenarios is completely discrete, with jumps at the scenarios the size of which equals the $1/n$, where n stands for the number of scenarios.

In fact, equation (6) given in the entry is actually equation (A.12) restated for a discrete random variable. The outcomes are the available scenarios, which are equally probable. Consider a sample of observations or scenarios r_1, \dots, r_n and denote by $r_{(1)} \leq r_{(2)} \leq \dots \leq r_{(n)}$ the ordered sample. The natural estimator of the ETL at tail probability ϵ is

$$\widehat{ETL}_\epsilon(r) = -\frac{1}{\lceil n\epsilon \rceil - 1} \sum_{k=1}^{\lceil n\epsilon \rceil - 1} r_{(k)} \quad (\text{A.13})$$

where $\lceil x \rceil$ is the smallest integer larger than x . Formula (A.13) means that we average $\lceil n\epsilon \rceil - 1$ of the $\lceil n\epsilon \rceil$ smallest observations, which is, in fact, the definition of the conditional expectation in (A.11) for a discrete distribution. The VaR at tail probability ϵ is equal to the negative of the empirical quantile,

$$\widehat{VaR}_\epsilon(r) = -r_{(\lceil n\epsilon \rceil)} \quad (\text{A.14})$$

It remains to determine the coefficients in (A.12). Having in mind that the observations in the sample are equally probable, we calculate

that

$$\epsilon_0 = \frac{\lceil n\epsilon \rceil - 1}{n}$$

Plugging ϵ_0 , (A.14), and (A.13) into equation (A.12), we obtain (6), which is the sample AVaR.

Similarly, equation (10) also arises from (A.12). The assumption is that the underlying random variable has a discrete distribution but the outcomes are not equally probable. Thus, the corresponding equation for the average loss on condition that the loss is larger than the VaR at tail probability ϵ is given by

$$\widehat{ETL}_\epsilon(r) = -\frac{1}{\epsilon_0} \sum_{j=1}^{k_\epsilon} p_j r_{(j)} \quad (\text{A.15})$$

where $\epsilon_0 = \sum_{j=1}^{k_\epsilon} p_j$ and k_ϵ is the integer satisfying the inequalities

$$\sum_{j=1}^{k_\epsilon} p_j \leq \epsilon < \sum_{j=1}^{k_\epsilon+1} p_j$$

The sum $\sum_{j=1}^{k_\epsilon} p_j$ stands for the cumulative probability of the losses larger than the the VaR at tail probability ϵ . Note that equation (A.15) turns into equation (A.13) when the outcomes are equally probable. With these remarks, we have demonstrated the connection between equations (6), (10), and (A.12).

The differences between ETL and AVaR are not without any practical importance. In fact, ETL is not a coherent risk measure. Furthermore, the sample ETL in (A.13) is not a smooth function of the tail probability while the sample AVaR is smooth. This is illustrated in Figure A.4. The top plot shows the graph of the sample ETL and AVaR with the tail probability varying between 1% and 10%. The sample contains 100 independent observations on a standard normal distribution, $X \in N(0,1)$. The bottom plot shows the same but the sample is larger. It contains 250 independent observations on a standard normal distribution.

Both plots demonstrate that the sample ETL is a step function of the tail probability while the AVaR is a smooth function of it. This is not

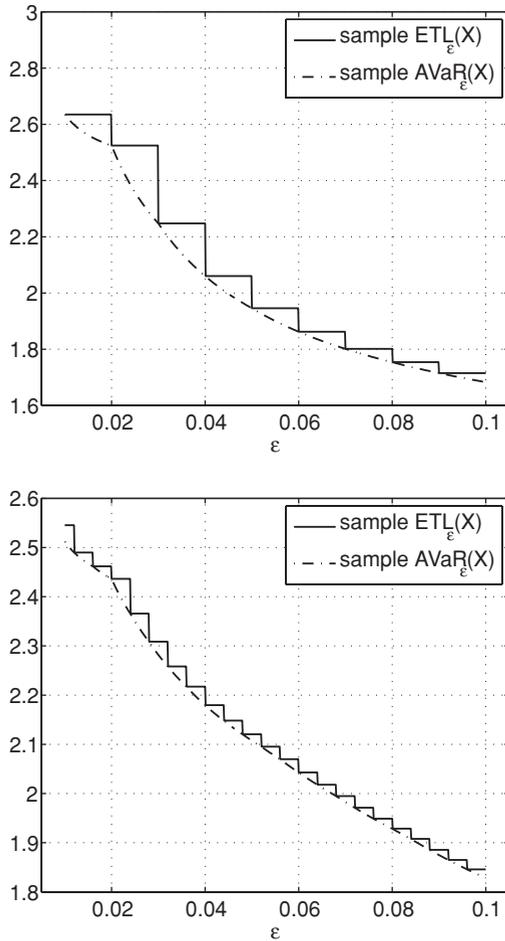

Figure A.4 The Graphs of the Sample ETL and AVaR with Tail Probability Varying between 1% and 10%

Note: The top plot is produced from a sample of 100 observations and the bottom plot from a sample of 250 observations. In both cases, $X \in N(0, 1)$.

surprising because, as ϵ increases, new observations appear in the sum in (A.13) producing the jumps in the graph of the sample ETL. In contrast, the AVaR changes gradually as it is a weighted average of the ETL and the VaR at the same tail probability. Note that, as the sample size increases, the jumps in the graph of the sample ETL diminish. In a sample of 5,000 scenarios, both quantities almost overlap. This is because the standard normal distribu-

tion has a smooth c.d.f. and the sample c.d.f. constructed from a larger sample better approximates the theoretical c.d.f. In this case, as the sample size approaches infinity, the AVaR becomes indistinguishable from the ETL at the same tail probability.¹⁰

KEY POINTS

- Although the value-at-risk (VaR) measure is a popular risk measure in the financial industry, it has a number of deficiencies. It is not a coherent risk measure because it does not satisfy the subadditivity property requirement of a coherent risk measure.
- In contrast to VaR, the average value-at-risk measure (AVaR)—also referred to as conditional value-at-risk and expected shortfall—is a coherent risk measure and has other advantages that results in its greater acceptance in risk modeling.
- There are convenient ways for computing and estimating AVaR that allow its application in optimal portfolio problems.
- A more general family of coherent risk measures is the spectral risk measure. The AVaR is a spectral risk measure with a specific risk-aversion function and is important for the proper selection of the risk-aversion function to avoid explosion of the risk measure.
- There is connection between the theory of probability metrics and risk measures. Basically, by choosing an appropriate probability metric one can guarantee that if two portfolio return distributions are close to each other, their risk profiles are also similar.

NOTES

1. In fact, $X = 0.05\sqrt{3}Z + 0.03$ where Z has Student's t distribution with 4 degrees of freedom and Y has a normal distribution with standard deviation equal to 0.1 and mathematical expectation equal to 0.01. The coefficient of Z is chosen so that the standard deviation of X is also equal to 0.1.

2. By comparing the c.d.f.s, we notice that the c.d.f. of X is “above” the c.d.f. of Y to the left of the crossing point, $F_X(x) \geq F_Y(x)$, $x \leq -0.15$.
3. This term is adopted in Rockafellar and Uryasev (2002).
4. Equation (2) was first studied by Pflug (2000). A proof that equation (1) is indeed the AVaR can be found in Rockafellar and Uryasev (2002).
5. As we remarked, $AVaR_\epsilon(X)$ can be infinite only if the mathematical expectation of X is infinite. Nevertheless, if this turns out to be an issue, one can use instead of AVaR the median of the loss distribution provided that the loss is larger than $VaR_\epsilon(X)$ as a robust version of AVaR. The median of the conditional loss is always finite and, therefore, the issue disappears but at the cost of violating the coherence axioms. The appendix to this entry provides more details.
6. This formula is a simple consequence of the definition of AVaR for discrete distributions; see the appendix to this entry. A detailed derivation is provided by Rockafellar and Uryasev (2002).
7. For example, $\lceil 3.1 \rceil = \lceil 3.8 \rceil = 4$.
8. A formal proof can be found in Rockafellar and Uryasev (2002). The reasoning in Rockafellar and Uryasev (2002) is based on the assumption that the random variable describes losses while in equation (10), the random variable describes the portfolio return or payoff.
9. Formal derivation of this relationship can be found, for example, in Rockafellar and Uryasev (2002).
10. In fact, this is a consequence of the celebrated Glivenko-Cantelli theorem claiming that the sample c.d.f. converges almost surely to the true c.d.f.

Abstract: The standard assumption in financial models is that the distribution for the return on financial assets follows a normal (or Gaussian) distribution and therefore the standard deviation (or variance) is an appropriate measure of risk in the portfolio selection process. This is the risk measure that is used in the well-known Markowitz portfolio selection model (that is, mean-variance model) which is the foundation for modern portfolio theory. With mounting evidence since the early 1960s that return distributions do not follow a normal distribution, researchers have proposed alternative risk measures for portfolio selection. These risk measures fall into two disjointed categories: dispersion measures and safety-first measures. In addition, there has been considerable theoretical work in defining the features of a desirable risk measure.

Most of the concepts in theoretical and empirical finance that have been developed over the last 50 years rest upon the assumption that the return or price distribution for financial assets follow a normal distribution. Yet, with rare exception, studies that have investigated the validity of this assumption since the 1960s fail to find support for the normal distribution. Moreover, there is ample empirical evidence that many—if not most—financial return series are heavy-tailed and, possibly, skewed. The “tails” of the distribution are where the extreme values

occur. Empirical distributions for stock prices and returns have found that the extreme values are more likely than would be predicted by the normal distribution. This means that between periods where the market exhibits relatively modest changes in prices and returns, there will be periods where there are changes that are much higher (that is, crashes and booms) than predicted by the normal distribution. This is not only of concern to financial theorists, but also to practitioners seeking, for example, to produce probability estimates for financial

risk assessment. To more effectively implement portfolio selection, alternative risk measures are needed.

In this entry, we review alternative risk measures that can be employed in portfolio selection, which can accommodate non-normal return distributions. These risk measures are classified as dispersion measures and safety-first measures. We begin with a discussion of the desirable features of investment risk measures.

DESIRABLE FEATURES OF INVESTMENT RISK MEASURES

In portfolio theory, the variance of a portfolio's return has been historically the most commonly used measure of investment risk. However, different investors adopt different investment strategies in seeking to realize their investment objectives. Consequently, intuitively, it is difficult to believe that investors have come to accept only one definition of risk. Regulators of financial institutions and commentators to risk measures proposed by regulators have proffered alternative definitions of risk. As noted by Dowd (2002, p. 1):

The theory and practice of risk management—and, included with that, risk measurement—have developed enormously since the pioneering work of Harry Markowitz in the 1950s. The theory has developed to the point where risk management/measurement is now regarded as a distinct sub-field of the theory of finance. . . .

Szegö (2004, p. 1) categorizes risk measures as one of the three major revolutions in finance and places the start of that revolution in 1997. The other two major revolutions are mean-variance analysis (1952–1956) and continuous-time models (1969–1973). He notes that alternative risk measures have been accepted by practitioners but “rejected by the academic establishment and, so far discarded by regulators!” (Szegö, 2004, p. 4).

Basic Features of Investment Risk Measures

Balzer (2001) argues that a risk measure is investor specific and, therefore, there is “no single universally acceptable risk measure.” He suggests several features that an investment risk measure should capture. Here we describe the following three features:

- Relativity of risk
- Multidimensionality of risk
- Asymmetry of risk

The *relativity of risk* means that risk should be related to performing worse than some alternative investment or benchmark. Balzer (1994, 2001) and Sortino and Satchell (2001), among others, have proposed that investment risk might be measured by the probability of the investment return falling below a specified risk benchmark. The risk benchmark might itself be a random variable, such as a liability benchmark (e.g., an insurance product), the inflation rate or possibly inflation plus some safety margin, the risk-free rate of return, the bottom percentile of return, a sector index return, a budgeted return, or other alternative investments. Each benchmark can be justified in relation to the goal of the portfolio manager. Should performance fall below the benchmark, there could be major adverse consequences for the portfolio manager.

In addition, the same investor could have multiple objectives and, hence, multiple risk benchmarks. Thus, risk is also a *multidimensional* phenomenon. However, an appropriate choice of the benchmarks is necessary in order to avoid an incorrect evaluation of opportunities available to investors. For example, too often, little recognition is given to liability targets. This is the major factor contributing to the underfunding of U.S. corporate pension sponsors of defined benefit plans.¹

Intuition suggests that risk is an *asymmetric* concept related to the downside outcomes, and any realistic risk measure has to value and

consider upside and downside differently. The standard deviation considers the positive and the negative deviations from the mean as a potential risk. In this case overperformance relative to the mean is penalized just as much as underperformance.

Intertemporal Dependence and Correlation with Other Sources of Risk

The standard deviation is a measure of dispersion and it cannot always be used as a measure of risk. The preferred investment does not always present better returns than the other. It could happen that the worst investment presents the greatest return in some periods. Hence, time could influence the investor's choices.

Clearly, if the degree of uncertainty changes over time, the risk has to change during the time as well. In this case, the investment return process is not stationary; that is, we cannot assume that returns maintain their distribution unvaried in the course of time. In much of the research published, stationary and independent realizations are assumed. The latter assumption implies that history has no impact on the future. More concrete, the distribution of tomorrow's return is the same independent of whether the biggest stock market crash ever recorded took place yesterday or yesterday's return equaled 10%.

As a result, the oldest observations have the same weight in our decisions as the most recent ones. Is this assumption realistic? Recent studies on investment return processes have shown that historical realizations are not independent and present a clustering of the volatility effect (time-varying volatility). Those phenomena lead to the fundamental time-series model autoregressive conditional heteroscedasticity (ARCH) formulated by Engle (1981). In particular, the last observations have a greater impact in investment decisions than the oldest ones. Thus, any realistic measure of

risk changes and evolves over time taking into consideration the heteroscedastic (time-varying volatility) behavior of historical series. An examination of the returns of say the equity return indexes such as the S&P 500 over some time period would show a *propagation effect* on another equity market, say the DAX 30. When we observe the highest peaks in one return index series, for example, there is an analogous peak in the other return index series. This propagation effect is known as cointegration of the return series, introduced by the fundamental work of Granger (1981) and elaborated upon further by Engle and Granger (1987). The propagation effect in this case is a consequence of the globalization of financial markets—the risk of a country/sector is linked to the risk of the other countries/sectors. Therefore, it could be important to limit the propagation effect by diversifying the risk. As a matter of fact, it is largely proven that the diversification, opportunistically modeled, diminishes the probability of big losses. Hence, an adequate risk measure values and models correctly the correlation among different investments, sectors, and markets.

ALTERNATIVE RISK MEASURES FOR PORTFOLIO SELECTION

The goal of portfolio selection is the construction of portfolios that maximize expected returns consistent with individually acceptable levels of risk. Using both historical data and investor expectations of future returns, portfolio selection uses modeling techniques to quantify “expected portfolio returns” and “acceptable levels of portfolio risk,” and provides methods to select an optimal portfolio.

It would not be an overstatement to say that modern portfolio theory as developed by Harry Markowitz (1952, 1959) has revolutionized the world of investment management. Allowing managers to appreciate that the investment risk and expected return of a portfolio can be

quantified has provided the scientific and objective complement to the subjective art of investment management. More importantly, whereas previously the focus of portfolio management used to be the risk of individual assets, the theory of portfolio selection has shifted the focus to the risk of the entire portfolio. This theory shows that it is possible to combine risky assets and produce a portfolio whose expected return reflects its components, but with considerably lower risk. In other words, it is possible to construct a portfolio whose risk is smaller than the sum of all its individual parts.

Though practitioners realized that the risks of individual assets were related, prior to modern portfolio theory they were unable to formalize how combining them into a portfolio impacted the risk at the entire portfolio level or how the addition of a new asset would change the return/risk characteristics of the portfolio. This is because practitioners were unable to quantify the returns and risks of their investments. Furthermore, in the context of the entire portfolio, they were also unable to formalize the interaction of the returns and risks across asset classes and individual assets. The failure to quantify these important measures and formalize these important relationships made the goal of constructing an optimal portfolio highly subjective and provided no insight into the return investors could expect and the risk they were undertaking. The other drawback, before the advent of the theory of portfolio selection and asset pricing theory, was that there was no measurement tool available to investors for judging the performance of their investment managers.

The theory of portfolio selection set forth by Markowitz was based on the assumption that asset returns are normally distributed. As a result, Markowitz suggested that the appropriate risk measure is the variance of the portfolio's return and portfolio selection involved only two parameters of the asset return distribution: mean and variance. Hence, the approach to portfolio selection he proposed is popularly referred to as *mean-variance analysis*.

Markowitz recognized that an alternative to the variance is the *semivariance*.² The semivariance is similar to the variance except that, in the calculation, no consideration is given to returns above the expected return. Portfolio selection could be recast in terms of mean-semivariance. However, if the return distribution is symmetric, Markowitz (1959, p. 190) notes that "an analysis based on (expected return) and (standard deviation) would consider these . . . (assets) as equally desirable." He rejected the semivariance noting that the variance "is superior with respect to cost, convenience, and familiarity" and when the asset return distribution is symmetric, either measure "will produce the same set of efficient portfolios." (Markowitz 1959, pp. 193–194).

There is a heated debate on risk measures used for valuing and optimizing the investor's risk portfolio. In this section and the one to follow, we describe the various portfolio risk measures proposed in the literature and more carefully look at the properties of portfolio risk measures.

According to the literature on portfolio theory, two disjointed categories of risk measures can be defined: *dispersion measures* and *safety-first risk measures*. In the remainder of this entry, we review some of the most well-known dispersion measures and safety-first measures along with their properties.³

In the following, we consider a portfolio of N assets whose individual returns are given by r_1, \dots, r_N . The relative weights of the portfolio are denoted as x_1, \dots, x_n and, therefore, the portfolio return r_p can be expressed as

$$r_p = x_1 \cdot r_1 + \dots + x_N \cdot r_N = \sum_{i=1}^N x_i \cdot r_i$$

We also provide a sample version of the discussed risk measures. The sample version will be based on a sample of length T of independent and identically distributed observations $r_p^{(k)}$, $k = 1, \dots, T$ of the portfolio return r_p . These

observations can be obtained from a corresponding sample of the individual assets.

DISPERSION MEASURES

Several portfolio mean dispersion approaches have been proposed in the last few decades. The most significant ones are discussed below, and we provide for each measure an example to illustrate the calculation.

Mean Standard Deviation

In the *mean standard deviation* approach the dispersion measure is the standard deviation of the portfolio return r_p (see Markowitz, 1959, and Tobin, 1958):

$$\sigma(r_p) = \sqrt{E(r_p - E(r_p))^2} \quad (1)$$

The standard deviation is a special case of the mean absolute moment discussed below. The sample version can be obtained from the general case by setting $p = 2$.

Mean Absolute Deviation

In the *mean absolute deviation (MAD)* approach, the dispersion measure is based on the absolute deviations from the mean rather than the squared deviations as in the case of the standard deviation.⁴ The MAD is more robust with respect to outliers. The MAD for the portfolio return r_p is defined as

$$\text{MAD}(r_p) = E(|r_p - E(r_p)|) \quad (2)$$

Mean Absolute Moment

The *mean absolute moment (MAM)(q)* approach is the logical generalization of the MQ approach. Under this approach the dispersion measure is defined as

$$\text{MAM}(r_q, p) = (E(|r_p - E(r_p)|^q))^{1/q}, \quad q \geq 1 \quad (3)$$

Note that the mean absolute moment for $q = 2$ coincides with the standard deviation and for

$q = 1$ the mean absolute moment reduces to the mean absolute deviation. One possible sample version of (3) is given by

$$\text{MAM}(r_p, q) = \sqrt[q]{\frac{1}{T} \sum_{k=1}^T |r_p^{(k)} - \bar{r}_p|^q}$$

where

$$\bar{r}_p = \frac{1}{T} \sum_{k=1}^T r_p^{(k)}$$

denotes the sample mean of the portfolio return.

Gini Index of Dissimilarity

The *index of dissimilarity* is based on the measure introduced by Gini (1912, 1921).⁵ Gini objected to the use of the variance or the MAD because they measure deviations of individuals from the individual observations of the mean or location of a distribution. Consequently, these measures linked location with variability, two properties that Gini argued were distinct and do not depend on each other. He then proposed the pairwise deviations between all observations as a measure of dispersion, which is now referred to as the *Gini measure*.

While this measure has been used for the past 80 years as a measure of social and economic conditions, its interest as a measure of risk in the theory of portfolio selection is relatively recent. Interest in a Gini-type risk measure has been fostered by Rachev (1991) and Rachev and Gamrowski (1995). Mathematically, the Gini risk measure for the random portfolio return r_p is defined as

$$\text{GM}(r_p, r_b) = \text{Min}\{E|r_p - r_b|\} \quad (4)$$

where the minimum is taken over all joint distributions of (r_p, r_b) with fixed marginal distribution functions F and G :

$$\begin{aligned} F(x) &= P(r_p \leq x) \text{ and} \\ G(x) &= P(r_b \leq x), \quad x \text{ real} \end{aligned}$$

Here r_b is the benchmark return, say, the return of a market index, or just the risk-free rate (U.S. Treasury rate or LIBOR, for example).

Expression (4) can be represented as the mean absolute deviation between the two distribution functions F and G :

$$GM(r_p, r_b) = \int_{-\infty}^{+\infty} |F(x) - G(x)| dx$$

Given a sample or a distributional assumption for the benchmark return r_b , the latter expression can be used for estimating the Gini index by calculating the area between the graphs of the empirical distribution function of r_p and the (empirical) distribution function of r_b .

Mean Entropy

In the *mean entropy* (M-entropy) approach, the dispersion measure is the exponential entropy. Exponential entropy is a dispersion measure only for portfolios with continuous return distribution because the definition of entropy for discrete random variables is formally different and does not satisfy the properties of the dispersion measures (positive and positively homogeneous). The concept of entropy was introduced in the last century in the classical theory of thermodynamics. Roughly speaking, it represents the average uncertainty in a random variable.

Probably its most important application in finance is to derive the probability density function of the asset underlying an option on the basis of the information that some option prices provide.⁶ Entropy was used also in portfolio theory by Philippatos and Wilson (1972) and Philippatos and Gressis (1975) and is defined as

$$\text{Entropy} = -E(\log f(r_p))$$

where f is the density of the portfolio return. Thus, the exponential entropy is given by

$$EE(r_p) = e^{-E(\log f(r_p))} \quad (5)$$

The valuation of entropy can be done either by considering the empirical density of a portfolio or assuming that portfolio returns belong to a given family of continuous distributions and estimate their unknown parameters.

Mean Colog

In the *mean colog* (M-colog) approach, the dispersion measure is the covariance between the random variable and its logarithm.⁷ That is, the colog of a portfolio return is defined as

$$\begin{aligned} \text{Colog}(1 + r_p) &= E(r_p \log(1 + r_p)) \\ &\quad - E(r_p)E(\log(1 + r_p)) \quad (6) \end{aligned}$$

Colog can easily be estimated based on a sample of the portfolio return distribution by:

$$\begin{aligned} \text{Colog}(1 + r_p) &\approx \frac{1}{T} \sum_{k=1}^T (r_p^{(k)} - \bar{r}_p) \cdot (\log(1 + r_p^{(k)})) \\ &\quad - \overline{\log(1 + r_p)} \end{aligned}$$

where

$$\overline{\log(1 + r_p)} = \frac{1}{T} \sum_{k=1}^T \log(1 + r_p^{(k)})$$

denotes the sample mean of the logarithm of one plus the portfolio return.

SAFETY-FIRST RISK MEASURES

Many researchers have suggested the safety-first rules as a criterion for decision making under uncertainty.⁸ In these models, a subsistence, a benchmark, or a disaster level of returns is identified. The objective is the maximization of the probability that the returns are above the benchmark. Thus, most of the *safety-first risk measures* proposed in the literature are linked to the benchmark-based approach.

Even if there are not apparent connections between the expected utility approach and a more appealing benchmark-based approach, Castagnoli and LiCalzi (1996) have proven that the expected utility can be reinterpreted in terms of the probability that the return is above a given benchmark. Hence, when it is assumed that investors maximize their expected utility, it is implicitly assumed that investors minimize

the probability of the investment return falling below a specified risk benchmark.

Although it is not always simple to identify the underlying benchmark, expected utility theory partially justifies the using of the benchmark-based approach. Moreover, it is possible to prove that the two approaches are in many cases equivalent even if the economic reasons and justifications are different.⁹

Some of the most well-known safety-first risk measures proposed in the literature are described in the next section.

Classical Safety First

In the *classical safety-first* portfolio choice problem the risk measure is the probability of loss or, more generally, the probability $P_\lambda = P(r_p \leq \lambda)$ of portfolio return less than λ . Generally, safety-first investors have to solve a complex, mixed integer linear programming problem to find the optimal portfolios. However, when short sales are allowed and return distributions are elliptical, depending on a dispersion matrix Q and a vector mean μ , then there exists a closed-form solution to the investor's portfolio selection problem:

$$\begin{aligned} & \text{Minimize: } P(r_p \leq \lambda) \\ & \text{Subject to: } \sum_{i=1}^N x_i = 1, \quad x_i \geq 0 \end{aligned}$$

The interesting property of this optimization problem is that we are able to express the set of optimal portfolios explicitly as a function of the shortfall barrier λ , the mean vector μ , and the dispersion matrix Q . The mean m and the dispersion σ^2 of these optimal portfolios can again be expressed as a function of the threshold λ , the mean vector μ , and the dispersion matrix Q . In the case where the elliptical family has finite variance (as, for example, the normal distribution), then the dispersion σ^2 corresponds to the variance.

As the risk measure consists of the probability that the return falls below a given barrier λ , we can estimate the risk measure by the ratio between the number of observations being

smaller than λ and the total number of observations in the sample.

Value at Risk

Value at risk ($\text{VaR}_{1-\alpha}$) is a closely related possible safety-first measure of risk defined by the following equality:

$$\text{VaR}_{1-\alpha}(r_p) = -\min\{z | (P(r_p \leq z) > \alpha)\} \quad (7)$$

Here, $1 - \alpha$ is denoted as the confidence level and α usually takes values like 1% or 5%. Theoretically, the VaR figure defined by equation (7) can admit negative values. In reality, however, it is likely and often implicitly assumed that the VaR is positive, and it can be interpreted as the level at which the losses will not exceed with a probability of $1 - \alpha\%$. Sometimes VaR is, therefore, defined as the maximum of zero and the expression defined in equation (7) to guarantee a positive value for VaR.

VaR can be used as a risk measure to determine reward-risk optimal portfolios. Moreover, this simple risk measure can also be used by financial institutions to evaluate the market risk exposure of their trading portfolios. The main characteristic of VaR is that of synthesizing in a single value the possible losses that could occur with a given probability in a given temporal horizon. This feature, together with the (very intuitive) concept of maximum probable loss, allows the nonexpert investor to figure out how risky the position is and the correcting strategies to adopt. Based on a sample of return observations, VaR estimates coincide with the empirical alphaquantile. VaR and sophisticated methodologies for estimating VaR are explained in Chapter 14 of Rachev, Menn, and Fabozzi (2005).

Conditional Value at Risk/Expected Tail Loss

The *conditional value at risk* ($\text{CVaR}_{1-\alpha}$) or *expected tail loss* (ETL) is defined as:

$$\begin{aligned} \text{CVaR}_{1-\alpha}(r_p) &= E(\max(-r_p, 0) | -r_p) \\ &\geq \text{VaR}_{1-\alpha}(r_p) \end{aligned} \quad (8)$$

where $\text{VaR}_{1-\alpha}(X)$ is defined in equation (7) and we assume that portfolio return distribution is continuous.¹⁰ From this definition we observe that the CVaR can be seen as the expected shortfall assuming the $\text{VaR}_{1-\alpha}(X)$ as the benchmark.

A sophisticated estimation of CVaR depends strongly on the estimation of VaR. An explanation and illustration of the calculation of CVaR is provided in Rachev, Menn, and Fabozzi (2005). Based on a large sample of observations, a natural estimate for CVaR can be obtained by averaging all observations in the sample that are smaller than the corresponding VaR estimate.

MiniMax

An alternative way to derive some safety-first optimal portfolios is minimizing the *MiniMax* (MM) risk measure (see Young, 1998). The MiniMax of a portfolio return is given by:

$$MM(r_p) = -\sup\{c | P(r_p \leq c) = 0\} \quad (9)$$

This risk measure can be seen as an extreme case of CVaR.

Lower Partial Moment

A natural extension of semivariance is the *lower partial moment* risk measure (see Bawa, 1976, and Fishburn, 1977) also called *downside risk* or *probability-weighted function of deviations below a specified target return*. This risk measure depends on two parameters:

1. A power index that is a proxy for the investor's degree of risk aversion.
2. The target rate of return that is the minimum return that must be earned to accomplish the goal of funding the plan within a cost constraint.

The lower partial moment of a portfolio r_p bounded from below is given by

$$\text{LPM}(r_p, q) = \sqrt[q]{E(\max(t - r_p, 0)^q)} \quad (10)$$

where q is the power index and t is the target rare of return.

Given a sample of return observations, we can approximate equation (10) as follows:

$$\text{LPM}(r_p, q) = \sqrt[q]{\frac{1}{T} \sum_{k=1}^T \max(r_p^{(k)} - \bar{r}_p, 0)^q}$$

where as before

$$\bar{r} = \frac{1}{T} \sum_{k=1}^T r_p^{(k)}$$

denotes the sample mean of the portfolio return.

Power Conditional Value at Risk

The *power conditional value at risk* measure, introduced in Rachev, Jasic, Biglova, and Fabozzi (2005), is the CVaR of the lower partial moment of the return. It depends on a power index that varies with respect to an investor's degree of risk aversion. Power CVaR generalizes the concept of CVaR and is defined as

$$\begin{aligned} \text{CVaR}_{q,1-\alpha}(r_p) &= E(\max(-r_p, 0)^q | -r_p \\ &\geq \text{VaR}_{1-\alpha}(r_p)) \end{aligned} \quad (11)$$

A sample version of power CVaR can be obtained in the same way as sample version for the regular CVaR, that is, one calculates the q -th sample moment of all observations in the sample that are smaller than the corresponding VaR estimate.

KEY POINTS

- While the underpinning of financial theory is that the distribution of the return on financial assets is normally distributed, little evidence supports this assumption. Consequently, the justification for the use of the standard deviation or variance as a measure of risk in financial applications such as portfolio selection is difficult to justify.
- Alternative risk measures that can accommodate the properties of asset returns that have been observed in financial markets have been proposed.

- Alternative risk measures include dispersion measures and safety-first risk measures.
- Dispersion measures include mean standard deviation, mean absolute deviation, mean absolute moment, index of dissimilarity, mean entropy, and mean colog.
- Safety-first risk measures include classical safety first, value at risk, conditional value at risk, expected tail loss, MiniMax, lower partial moment, downside risk, probability-weighted function of deviations below a specified target return, and power conditional value at risk.

Back-Testing Market Risk Models

KEVIN DOWD, PhD

Partner, Cobden Partners, London

Abstract: Back-testing is the quantitative evaluation of a model, and back-testing a risk or probability density forecasting model involves a comparison of the model's density forecasts against subsequently realized outcomes of the random variable whose density is forecast. One purpose of back-testing is to determine whether the forecasts are sufficiently close to realized outcomes to enable us to conclude that the forecasts are statistically compatible with those outcomes. Back-tests conducted for this purpose involve statistical hypothesis tests to determine if a model's forecasts are acceptable. Hypothesis tests can be applied to observations involving a loss that exceeds the value-at-risk at a given confidence interval, or they can be applied to forecasts of VaRs at multiple confidence intervals. A second purpose of back-testing is to assist risk managers to diagnose problems with their risk models and so help improve them. A third purpose of back-testing is to rank the performance of a set of alternative risk models to determine which model gives the "best" density forecast evaluation performance.

To back-test a model is to evaluate it in quantitative terms, and *back-testing* a risk (or probability density forecasting) model involves a comparison of the model's density forecasts against subsequently realized outcomes of the underlying random variable whose density is forecast. The importance of back-testing is self-evident: If risk managers are to have confidence in their risk models, then those models need to be properly back-tested and to have performed well under those back-tests.

Back-tests can be used for three complementary purposes. The first is to assess whether a model's density forecasts are statistically compatible with the realized values of the underlying random variable. The second purpose is diagnostic: to generate feedback about the model's potential weaknesses to assist the

model builder and help him/her to "correct" the model. The third purpose is to rank alternative models. A good risk model should fare well by all three criteria: It should pass its statistical tests, should not generate any worrying diagnostics, and should rank well in comparison to alternative models.

The archetypal *market risk model* is a model that forecasts the *value at risk* (VaR) of a portfolio over one or more confidence levels, for a specified horizon. We will assume for the most part that the horizon is a trading day.

To back-test such a model, we need a dataset that consists of the model's forecasts, on the one hand, and the daily profits or losses (P/L) generated by the portfolio, on the other. The first task in back-testing is therefore to assemble such a dataset. For most market risk managers,

the forecasts themselves should be readily available. However, obtaining suitable profit and loss data is a more difficult problem than it might initially appear to be. The reason is that we do not need data on the profits or losses actually generated by a portfolio, but data on the profits or losses attributable to the market risks taken: We want P/L data that reflect underlying market volatility rather than accounting prudence. We also need to clean our P/L data to get rid of components that are not directly related to current or recent market risk-taking. Such components include fee income, hidden and unrealized P/L, earnings attributable to nonmarket risks, such as yields on corporate bonds, and the impact of intraday trading on P/L.

Having obtained our dataset, the next stage is to carry out a preliminary data analysis. We should plot a back-testing chart—a plot of the realized P/L over time with the VaR forecasts superimposed on it—and look for any odd or outstanding features. It is also good practice to supplement back-testing charts with P/L histograms, which sometimes give a clearer indication of the empirical P/L distribution, and quantile-quantile (QQ) charts, which plot the quantiles of an empirical P/L distribution against those of a forecasted P/L distribution. It is also a good idea to examine summary P/L statistics, including the obvious statistics of mean, variance, skewness, kurtosis, range, and so on and the number and size of extreme observations. A preliminary data analysis can be very helpful in enabling practitioners to get to know their data and get a feel for any problems they might encounter.

STATISTICAL BACK-TESTING

The first type of back-tests are statistical tests based on a hypothesis-testing paradigm. We first specify the null hypothesis that we wish to test—typically the null hypothesis is that the model is adequate—and select an alternative

hypothesis to be accepted if the null is rejected. We then select a significance level and estimate the probability associated with the null hypothesis being “true.” We would accept the null hypothesis if the estimated value of this probability, the estimated prob-value, exceeds the chosen significance level, and we would reject it otherwise. The higher the significance level, the more likely we are to accept the null hypothesis, and the less likely we are to incorrectly reject a true model (that is, to make a Type I error). Unfortunately, it also means that we are more likely to incorrectly accept a false model (that is, to make a Type II error). Any test therefore involves a trade-off between these two types of possible error. Ideally, we should select a significance level that takes account of the likelihoods and costs of these errors and strikes an appropriate balance between them. However, in practice, it is common to select some arbitrary significance level such as 5% and apply that level in all our tests. A significance level of this magnitude gives the model a certain benefit of the doubt, and implies that we would reject the model only if the evidence against it is reasonably strong.

EXCEEDANCE-BASED STATISTICAL APPROACHES

Suppose that we have a sample of n daily VaR forecasts VaR_t and a corresponding sample of n realized loss outcomes L_t , where t goes from 1 to n . L_t is denominated in units in which realized losses are positive and realized profits are negative.

Some common approaches to back-testing involve exceedance observations, where an exceedance observation (also called a tail loss) is a loss that exceeds the VaR. These exceedance observations h_t are obtained by putting our sample observations through the following transformation:

$$h_t = \begin{cases} 1 \\ 0 \end{cases} \quad \text{if} \quad \begin{cases} L_t > VaR_t \\ L_t \leq VaR_t \end{cases} \quad (1)$$

This transformation gives a unit value to all observations where there is a loss exceeding VaR and a zero value to all other observations.

Binomial (Kupiec) Approach

We can now apply the basic frequency (or binomial) test suggested by Kupiec (1995): We test whether the observed frequency of exceedances is consistent with the frequency predicted by the model. In particular, under the null hypothesis that the model is “good,” the number of exceedances x follows a *binomial distribution* with probability p , where p is the tail probability or 1 minus the confidence level. The probability of x exceedances given n observations is therefore:

$$\text{Prob}(x|n, p) = \binom{n}{x} p^x (1-p)^{n-x} \quad (2)$$

Equation (2) also tells us that the only information required to implement a binomial test is information about the values of n , p , and x . This probability is then calculated using a suitable calculation engine (e.g., using the “binomdist” function in Excel).

To illustrate, suppose $n = 1,000$ and we take the confidence level α to be 0.95. Our model therefore predicts that $p = 1 - \alpha = 0.05$ and the null hypothesis is $H_0: p = 0.05$. We then expect $np = 50$ exceedances under the null. Now suppose that the number of exceedances, x , is 60. This corresponds to an empirical frequency, \hat{p} , equal to 0.060. Since \hat{p} exceeds 0.05; we might specify a one-sided alternative hypothesis $H_1: p > 0.05$. The prob-value of the test is the probability under the null that $x \geq 60$. This is most easily calculated as $1 - \text{Pr}[x \leq 59]$, which equals 0.0867 given the values of n and p . At a conventional significance level such as 5%, we would then “pass” the model as acceptable. It is also clear that as x gets larger and moves further away from its predicted value of 50, then the probability of observing x exceedances will fall. Values of x with prob-values lower than our significance level would lead to rejections of

the null hypothesis and a “fail” result for the model. In fact, if we work with a 5% significance level, it is straightforward to show that we would accept the null if $x \leq 62$ and reject it if $x \geq 63$.

We can also apply binomial tests using a two-sided alternative hypothesis $H_1: p \neq 0.05$. We could do so by estimating a confidence interval for the number of exceedances and checking whether x lies within this interval. For example, if we want to test using a 5% significance level, we would estimate a 95% confidence interval for x , the bounds of which would delineate the lower and upper 5% tails of x 's density function. With $n = 1,000$ and $p = 0.05$, the 95% confidence interval for x is [36, 66]. We would then accept the null if x falls within this range and otherwise reject it.

A Normal Approximation

Testing can be simplified further if we work with a normal approximation to the binomial. Provided n is sufficiently large—and n would be sufficiently large with the sample sizes that risk managers typically work with—then the distribution of x is approximately normal with mean np and variance $np(1-p)$. This implies, in turn, that the variable $z = (x - np)/\sqrt{np(1-p)}$ is distributed as standard normal, and we can test whether the observed value of z is compatible with this distribution. For instance, if we wished to carry out a two-sided test, we know that the 95% confidence interval for a standard normal is [−1.96, +1.96], so we would accept the null if (and only if) z falls in this range.

Tests of Independence

Besides predicting that x should be binomial or approximately normal with large samples, the null hypothesis of model adequacy often leads to the prediction that x should be independent. “Independence” means that there should be no temporal pattern in the x series that is, the probability of the next observation being an

exceedance should be independent of whether any previous observation was an exceedance or not. Where this prediction arises, it is important that it be tested too: A bad model might pass the earlier tests, but still be inadequate because it produces predictable exceedances or clusters of exceedances that ought not to arise. Evidence of exceedance clustering would suggest that the model is misspecified, even if the model has the correct exceedance frequency.

One of the simplest independence tests is a *runs test*, in which we test whether the number of runs in a time series is consistent with what we would expect under independence. We can apply a runs test to any data that are time-ordered and expressed in binary form, as is the case with observations in our x series that either take the value 0 or the value 1. A run is then a sequence of consecutive identical numbers, and the number of runs R is equal to the number of sign changes plus 1. If u is the number of observations taking one value and v the number taking the other value, then under the independence null the mean and variance of the number of runs are, respectively:

$$\mu_R = 1 + \frac{2uv}{u+v} \quad (3)$$

$$\sigma_R^2 = \frac{2uv(2uv - u - v)}{(u+v)^2(u+v-1)} \quad (4)$$

If the total number of observations is large, then R is approximately normal and $z = (R - \mu_R)/\sigma_R$ approximately standard normal, and we can test accordingly.

A more sophisticated version of the same idea is suggested by Engle and Manganelli (2004): They propose estimating a binary regression model—that is, they regress h_i against possible explanatory variables, such as lagged returns or lagged squared returns—and then test for the joint insignificance of the explanatory variables. A binary regression approach is more powerful than a basic runs test because it can take account of the impact of other possible variables, which a runs test does not.

Conditional Testing (Christoffersen) Approach

We can also carry out tests of the distribution and independence of x within the same testing framework, and this takes us to the *conditional back-testing approach* of Christoffersen (1998). His idea is to separate out the particular predictions being tested and then test each prediction separately. We begin by rephrasing the earlier frequency or unconditional coverage test in likelihood ratio (LR) form.

Given that the observed frequency of exceedances is x/n , then under the hypothesis/prediction of correct unconditional coverage, the test statistic

$$LR_{uc} = -2 \ln[(1-p)^{n-x} p^x] + 2 \ln[(1-x/n)^{n-x} (x/n)^x] \quad (5)$$

is distributed as a $\chi^2(1)$, a chi-squared with 1 degree of freedom. As we can see from equation (5), this boils down to a test of whether the empirical frequency x/n is “close” to the predicted frequency p .

Turning to the independence prediction, let n_{ij} be the number of days that state j occurred after state i occurred the previous day, where the states refer to the occurrence or not of an exceedance, and let π_{ij} be the probability of state j in any given day, given that the previous day’s state was i . Under the hypothesis of independence, the test statistic

$$LR_{ind} = -2 \ln \left[(1 - \hat{\pi}_2)^{n_{00} + n_{11}} \hat{\pi}_2^{n_{01} + n_{11}} \right] + 2 \ln \left[(1 - \hat{\pi}_{01})^{n_{00}} \hat{\pi}_{01}^{n_{01}} (1 - \hat{\pi}_{11})^{n_{10}} \pi_{11}^{n_{11}} \right] \quad (6)$$

is also distributed as a $\chi^2(1)$, and note that we can recover estimates of the probabilities from

$$\begin{aligned} \hat{\pi}_{01} &= \frac{n_{01}}{n_{00} + n_{01}} \\ \hat{\pi}_{11} &= \frac{n_{11}}{n_{10} + n_{11}} \\ \hat{\pi}_2 &= \frac{n_{01} + n_{11}}{n_{00} + n_{10} + n_{01} + n_{11}} \end{aligned} \quad (7)$$

It follows that under the combined hypothesis of correct coverage and independence the test statistic

$$LR_{cc} = LR_{uc} + LR_{ind} \quad (8)$$

is distributed as $\chi^2(2)$. The *Christoffersen approach* enables us to test both coverage and independence hypotheses at the same time. Moreover, if the model fails such a test, this approach enables us to test each hypothesis separately, and so establish whether the model fails because of incorrect coverage or because of lack of independence.

Strengths and Limitations of Exceedance-Based Approaches

These exceedance tests have the advantages that they have a simple intuition, are easy to apply, and do not require a great deal of information. However, they often lack power (that is, the ability to identify bad models) except with very large sample sizes, because they throw potentially valuable information away: Focusing on tests of exceedances over VaR at a given confidence level is equivalent to throwing away information about the model's forecasts of VaRs at other confidence levels, and this discarded information often includes useful information about the sizes of tail losses predicted by a risk model (or information about VaRs at higher confidence levels). This can mean that a "bad" risk model will pass an exceedance-based test if it generates an acceptably accurate frequency of exceedances, even if its forecasts of losses larger than VaR are very poor.

STATISTICAL BACK-TESTING OF VaRs AT MULTIPLE CONFIDENCE LEVELS

This line of reasoning suggests that we should consider back-testing the performance of a model's VaR forecasts over multiple confidence

levels. Indeed, pushed to the limit, it suggests that we consider back-testing a model's VaR forecasts over all confidence levels at the same time. We would proceed by applying the following transformation:

$$p_t = F_t(X_t) \quad (9)$$

where $F_t(\cdot)$ is the (typically time-dependent) *probability-integral transformation* (PIT) that maps the realized one-day loss or profit, X_t , to its cumulative density value, where the forecast is made the previous day. So, for example, if our model specifies that losses are standard normal, then a value $X_t = 1.645$ would give us $p_t = F_t(1.645) = 0.95$, and so forth.

We can now deduce that p_t is stationary and distributed as standard uniform under the hypothesis that the VaR model is adequate. p_t is also independent because consecutive values of p_t have no common factors. Hence p_t is predicted to be independent and identically distributed (IID) $U(0,1)$ under the null hypothesis.

As an aside, it is worth noting at this point that the independence assumption does not arise in cases where we have a multi-step-ahead as opposed to a one-step-ahead VaR model: An example of the latter is a VaR model that produces daily VaR forecasts over a daily forecast horizon; an example of the former is a VaR model that produces daily VaR forecasts over a multi-day horizon. The forecast horizon is equal to one day in the one case, and equal to more than one day in the other. The p_t are predicted to be independent for one-day-ahead VaR forecasts because consecutive observations are not affected by common shocks; however, for multi-day forecasts, there is no independence prediction because consecutive p_t observations are subject to at least one common random factor. For example, the two-day return over Monday and Tuesday and the two-day return over Tuesday and Wednesday are both affected by the Tuesday daily return. This means that they have a common random factor and are therefore not independent. We will ignore multistep-ahead models in the rest of our discussion, but the

reader should keep in mind that we cannot assume independence for multi-step-ahead models or regard independence tests applied to such models as tests of model adequacy.

Testing Uniformity

Returning to the one-step-ahead case, we can now test our model by applying conventional uniformity tests. One of the best known of these is the Kolmogorov-Smirnov (KS) test. The KS test statistic D is then the maximum distance between the predicted cumulative density $F(x)$, which is a 45-degree line, and the empirical cumulative density $\hat{F}(x)$, evaluated over each data point X_t :

$$D = \max_t |F(X_t) - \hat{F}(X_t)| \quad (10)$$

The test value of the KS statistic is then compared to the relevant critical value and the null is accepted or rejected accordingly. This test is easy to implement because the test statistic is straightforward to calculate and its critical values are easily obtained using Monte Carlo simulation. However, the KS test tends to be more sensitive to the distributional differences near the center of the distribution, and is less sensitive at the tails. This is obviously a drawback when back-testing VaR models, where we are usually much more interested in the tail than in the central mass of a distribution.

A way around this latter problem is to replace the KS test with a Kuiper test. The Kuiper test statistic D^* is the sum of the maximum amount by which each distribution exceeds the other:

$$D^* = \max_t |F(X_t) - \hat{F}(X_t)| + \max_t |\hat{F}(X_t) - F(X_t)| \quad (11)$$

The Kuiper test can be implemented in much the same way as the KS test: Its test statistic is straightforward to calculate and its critical values can be obtained by Monte Carlo simulation. The Kuiper test has the advantage over the KS test that it is more sensitive to deviations in the tail regions. It is also believed to be more robust

to transformations in the data, and to be good at detecting cyclical and other features in the data. However, there is also evidence that it is very data intensive and needs large datasets to get reliable results.

We can also test uniformity by applying a textbook χ^2 test to binned (or classified) data). We divide the data into k classes and then compute the test statistic:

$$\sum_{i=1}^k \frac{(O_i - E_i)^2}{E_i} \quad (12)$$

where O_i is the observed frequency of data in bin i , and E_i is the expected frequency of data in bin i . Under the null hypothesis, this test statistic is distributed as $\chi^2(k - c)$, where c is the number of estimated parameters in the VaR model. The main disadvantage of the χ^2 test is that results are dependent on the way in which the data are binned and binning is (largely) arbitrary. In using it, we should be careful to check the sensitivity of results to alternative ways of binning the data.

Applying the Berkowitz Transformation and Testing for Standard Normality

It is often more convenient to put the p_t through a second (or *Berkowitz*) transformation to make them standard normal under the null of model adequacy; that is, we work with the transformed variable:

$$z_t = \Phi^{-1}(p_t) \quad (13)$$

where $\Phi(\cdot)$ is the standard normal distribution function (see Berkowitz, 2001). This second transformation is helpful because *testing for standard normality* is more convenient than testing for standard uniformity, and because a normal variable is more convenient when dealing with temporal dependence. Under the null, z_t will be distributed as IID standard normal [denoted by IID $N(0,1)$].

Testing model adequacy now boils down to testing whether z_t is distributed as IID $N(0,1)$. There are two distinct tasks here:

1. We need to test whether z_t is $N(0,1)$, taking as given that z_t is IID, and there are various tests we might apply. If z_t is standard normal, then it should have a zero mean, a variance of 1, a zero skew, and a kurtosis of 3. Assuming IID, we can test the mean prediction using a z -test or t -test, we can test the variance prediction using a variance ratio test, and we can test the skewness and kurtosis predictions using a Jarque-Bera test, which can also be regarded as a test of normality itself. All these tests are conventional textbook tests and are easy to apply.
2. We need to test whether z_t is IID, and there are many tests of the IID prediction. These include runs and binary regression tests, which we have already discussed above. We can also estimate the autocorrelation structure of our z_t observations or fit an autoregressive moving average (ARMA) process to them. All the parameters in an autocorrelation function or an ARMA process should be insignificant, and we can test for their significance using standard tests such as a Box-Pierce Q test. Another possibility, if we have enough data, is to test independence using a BDS test (Brock et al., 1987): a BDS test is very powerful, but also data-intensive.

Since the hypothesis of model adequacy predicts both $N(0,1)$ and IID, it is important to note that the model must “pass” both types of test if it is to “pass” overall.

Tests Applied to Truncated Distributions

There are also situations where we are only interested in part of the P/L distribution: For example, we might be interested only in the distribution of losses in excess of VaR. If we are working to a confidence level α , we can take our earlier p_t series and delete all nontail obser-

vations from it. We then end up with a series that is IID uniformly distributed over the interval $[0, 1 - \alpha]$, and this implies that $p_t/(1 - \alpha)$ is IID uniformly distributed over the interval $[0, 1]$. We can test this prediction using one of the uniformity tests discussed earlier. If we wish to, we can apply the Berkowitz transformation to $p_t/(1 - \alpha)$ to obtain the series $z_t = \Phi^{-1}(p_t/(1 - \alpha))$, which is distributed as IID $N(0,1)$ under the null. We can then apply the tests just discussed.

USING BACK-TESTS FOR DIAGNOSTIC PURPOSES

We can also modify many of these back-test procedures to help diagnose problems with our VaR model. Model diagnosis is a key ingredient to successful model building, and requires the modeler to be on the lookout for evidence of possible problems. So, to use an earlier example, if we have 60 exceedances out of a sample of 1,000 and we are operating to a VaR at the 95% confidence level, then we know that this is associated with a prob-value of 0.0867. Were we carrying out a formal back-test of model adequacy at a conventional significance level such as 5%, we would dismiss this result as statistically insignificant because the significance level gives the model the benefit of the doubt. However, for diagnostic purposes we do not wish to give the model the benefit of the doubt: Instead, we are looking for evidence “against” the model, even if that evidence is statistically “weak.” In these circumstances, a result like this would lead us to suspect whether the model has a tendency to underestimate the VaR. A wise risk manager would then start to ask whether other evidence could be found that would confirm or refute this suspicion. And, to put the same point a little differently, the last thing a risk manager should do in the face of such evidence is to wait and do nothing till the evidence has become overwhelming: The risk manager should act in a timely manner on the basis of any reasonable evidence available.

Independence tests can also be useful diagnostic tools. If we apply an independence test and the test result gives us some (not necessarily strong) reason to suspect that the model does not satisfy a valid independence prediction, then we can interpret this evidence as suggesting that there might be some dynamic misspecification in our model: Even if the broad coverage is about right, there might still be something wrong with the updating of our VaR forecasts from one day to the next. So, for example, if we have a parametric VaR model, then we might suspect that a key parameter in the model was not being updated efficiently, and the obvious suspects would be volatility or correlation parameters. Again, the evidence might be statistically “weak,” but even weak evidence can be useful in pointing to areas of weakness in the model.

Another useful *diagnostic* is provided by empirical moments of the Berkowitz-transformed series (see equation (13) above), which we saw earlier are predicted to be standard normal under the null of model adequacy. Some very useful diagnostic information can then be obtained by estimating their sample moments and considering any departures from their predicted values:

- If the sample mean is different from zero, we might suspect whether the model’s forecasts are biased in one direction or the other.
- If sample variance is less than 1, we might suspect that the model’s predicted dispersion is too low, in which case the model might overestimate risk; and if the sample variance is greater than 1, we might suspect that the predicted dispersion is too high and the model underestimates risk.
- If the sample skew is positive or negative, we might suspect that the forecasts are skewed in one direction or the other.
- If the sample kurtosis is less than 3 or (as is more likely in risk management contexts) bigger than 3, we might ask ourselves if the model is overestimating or underestimating its tails.

In each of these cases, we should also check the strength of the evidence and we can do so by applying the relevant tests and checking out their prob-values: The lower the prob-value, the stronger the evidence against the model. However, since we are especially concerned in risk management with the possibility that the model might underestimate risks, then a sample variance that considerably exceeds 1 or a sample kurtosis that considerably exceeds 3 is potentially important evidence that might warrant further scrutiny.

RANKING ALTERNATIVE MODELS

It is often the case that we are interested in how different models compare to each other. We can compare models using *forecast evaluation* methods that give each model a score in terms of some loss function; we then use the loss scores to rank the models—the lower the loss, the better the model. These approaches are not statistical tests of model adequacy and this means that they do not suffer from the low power of tests such as frequency tests: This makes them attractive for back-testing with the datasets typically available in real-world applications. In addition, they also allow us to tailor the loss function to take account of particular concerns: For example, we might be more concerned about higher losses than lower losses, and might therefore wish to give higher losses a greater weight in our loss function.

The ranking process has four key ingredients for each model:

1. A set of n paired observations—paired observations of losses or profits for each period and their associated VaR forecasts.
2. A loss function that gives each observation a score C_t depending on how the observed loss or profit compares to the VaR forecasted for that period.
3. A benchmark, which gives us an idea of the score we could expect from a “good” model.

4. A score function, which takes as its inputs our loss-function and benchmark values.

We need to specify the loss function, and a number of different loss functions have been proposed. Perhaps the most straightforward is the binary loss function proposed by Lopez (1998, p. 121), which gives exceedance observations a value of 1 and other observations a value of 0. C_t is then as follows:

$$C_t = \begin{cases} 1 & \text{if } L_t > VaR_t \\ 0 & \text{if } L_t \leq VaR_t \end{cases} \quad (14)$$

This loss function is intended for the user who is (exclusively) concerned with the frequency of exceedances. The natural benchmark for this loss function is p , the exceedance probability or expected value of $E(C_t)$. If we take our benchmark to be the expected value of C_t under the null hypothesis that the model is “good,” then Lopez (1998) suggests that a good choice of score function is the following quadratic probability score (QPS) function:

$$QPS = \frac{2}{n} \sum_{t=1}^n (C_t - p)^2 \quad (15)$$

The QPS takes a value in the range $[0,2]$, and the closer the QPS-value to zero, the better the model. We can therefore use the QPS (or some similar score function) to rank our models, with the better models having the lower scores. In addition, the QPS criterion has the attractive property that it (usually) encourages truth-telling by VaR modelers: If VaR modelers wish to minimize their QPS score, they will (usually) report their VaRs “truthfully.” This is a useful property in situations where the back-tester and the VaR modeler are different, and where the back-tester might be concerned about the VaR modeler reporting false VaR forecasts to alter the results of the back-test.

A drawback of this loss function is that it ignores the magnitude of tail losses. If we wish to remedy this defect, Lopez suggests a second,

size-adjusted, loss function:

$$C_t = \begin{cases} 1 + (L_t - VaR_t)^2 & \text{if } L_t > VaR \\ 0 & \text{if } L_t \leq VaR_t \end{cases} \quad (16)$$

This loss function allows for the sizes of tail losses in a way that (15) does not: A model that generates higher tail losses would generate higher values of (16) than one that generates lower tail losses, other things being equal. However, with this loss function, there is no longer a straightforward condition for the benchmark, so we need to estimate the benchmark by some other means (e.g., Monte Carlo simulation). The size-adjusted loss function (17) also has the drawback that it loses some of its intuition, because squared monetary returns have no ready monetary interpretation.

A way around this last problem is suggested by Blanco and Ihle (1998), who suggest the following loss function:

$$C_t = \begin{cases} (L_t - VaR_t)/VaR_t & \text{if } L_t > VaR_t \\ 0 & \text{if } L_t \leq VaR_t \end{cases} \quad (17)$$

This loss function gives each tail-loss observation a weight equal to the tail loss divided by the VaR. This has a nice intuition and ensures that higher tail losses get awarded higher C_t values without the impaired intuition introduced by squaring the tail loss. The benchmark for this forecast evaluation procedure is also easy to derive: The benchmark is equal to the difference between the Expected Shortfall (ES) and the VaR, divided by the VaR. However, the Blanco-Ihle loss function also has a problem of its own: Because (17) has the VaR as its denominator, it is not defined if the VaR is zero, and can give awkward answers if VaR gets “close” to zero or becomes negative. We should therefore only use it if we can be confident of the VaR being sufficiently large and positive.

We therefore seek a size-based loss function that avoids the squared term in the second Lopez loss function, but also avoids denominators that might be zero-valued. A promising

candidate is the tail loss itself:

$$C_t = \begin{cases} L_t & \text{if } L_t > VaR \\ 0 & \text{if } L_t \leq VaR_t \end{cases} \quad (18)$$

The expected value of the tail loss is of course the ES, so we can choose the ES as our benchmark and use a quadratic score function such as:

$$QS = \frac{2}{n} \sum_{t=1}^n (C_t - ES_t)^2 \quad (19)$$

This approach penalizes deviations of tail losses from their expected value, which makes intuitive sense. Moreover, because it is quadratic, it gives very high tail losses much greater weight than more common tail losses, and thereby comes down hard on large losses.

KEY POINTS

- In general, back-testing is the quantitative evaluation of a model. When back-testing is applied to a risk or probability density forecasting model, it involves a comparison of the model's density forecasts against subsequently realized outcomes of the random variable whose density is forecast.
- The main purposes of back-testing market risk models are to test model adequacy, to diagnose potential model problems, and to compare or rank alternative models. A good risk model should fare well by all three criteria: It should pass its statistical tests, should not generate any worrying diagnostics, and should rank well in comparison to alternative models.
- Because the typical market risk model is a model that forecasts the value-at-risk of a portfolio over one or more confidence levels for a specified horizon, back-testing of market risk models involves some comparison of VaR forecasts against subsequently realized values of profit or loss.
- Formal tests of market risk model adequacy can be applied to the frequency and inde-

pendence of exceedance observations, but can also be applied to forecasts of VaR at multiple confidence levels.

- Comparable approaches can be used for model diagnostic purposes, where the main concern is not to test model adequacy in a formal way, as such, but instead to gather evidence of possible model misspecification.
- Simple loss-scoring approaches can be used to rank the forecast performance of alternative models.

Estimating Liquidity Risks

KEVIN DOWD, PhD

Partner, Cobden Partners, London

Abstract: The measurement of liquidity risk risks is an underdeveloped area of market risk measurement and management. Liquidity issues affect the estimation of conventional market risk measures, but the measurement of liquidity risks is an important subject in its own right. Liquidity issues also figure prominently in periods of market crisis. There are various easily implementable and often complementary approaches to the estimation of liquidity-adjusted Value-at-Risk: These involve modeling the bid-ask spread or the liquidity discount incurred when liquidating a position. There are also approaches to the modelling of Liquidity-at-Risk, which deals with the riskiness of cash flows, in both noncrisis and crisis situations.

Market practitioners often assume that markets are liquid—that is, that we can liquidate or unwind positions at going market prices, usually taken to be the mean of bid and ask prices, without too much difficulty or cost. This assumption is very convenient and provides a justification for the practice of marking positions to market prices. However, it is often empirically questionable and the failure to allow for it can seriously undermine market risk measurement. In any case, liquidity risk is a major risk factor in its own right, and we will often want to measure it too.

This entry looks at liquidity issues and how they affect the estimation of market and *liquidity risk* measures. *Liquidity* issues affect market risk measurement through their impact on standard measures of market risk. In addition, because effective market risk management involves an ability to estimate and manage liquidity risk itself, we also need to be able to estimate liquidity risk—or liquidity-at-risk. Finally, since liquidity

problems are particularly prominent in market crises, we also need to address how to estimate crisis-related market risks and liquidity risks. Accordingly, the main themes of this entry are:

- The nature of market liquidity and illiquidity, and their associated costs and risks.
- The estimation of *value-at-risk (VaR)* in illiquid or partially liquid markets—*liquidity-adjusted VaR (or LVaR)*.
- Estimating *liquidity-at-risk (LaR)*.
- Estimating *crisis-related liquidity risks*.

For convenience, and to be faithful to the literature, we focus on the (discredited, but computationally convenient) VaR risk measure, but we should note that any of the approaches suggested here can be adapted to estimate superior risk measures such as coherent risk measures (see, e.g., Artzner et al., 1999) or any other quantile-based risk measures. For example, estimates of these alternative risk measures can be obtained using the “average tail VaR”

approach set out in Dowd (2005, Chapter 3): This is based on the idea that, since the VaR is a quantile, any of these other quantile-based risk measurements can be estimated as a weighted average of VaRs predicated on a suitable range of confidence levels.

LIQUIDITY AND LIQUIDITY RISKS

The notion of liquidity refers to the ability of a trader to execute a trade or liquidate a position with little or no cost, risk, or inconvenience. Liquidity is a function of the market, and depends on such factors as the number of traders in the market, the frequency and size of trades, the time it takes to carry out a trade, and the cost (and sometimes risk) of transacting. It also depends on the commodity or instrument traded, and more standardized instruments (e.g., such as FX or equities) tend to have more liquid markets than nonstandardized or tailor-made instruments (e.g., such as over-the-counter [OTC] derivatives). Markets vary greatly in their liquidity: Markets such as the FX market and the big stock markets are (generally) highly liquid; but other markets are less so, particularly those for many OTC instruments and instruments that are usually held to maturity and, hence, are rarely traded once initially bought. However, even the “big” standardized markets are not perfectly liquid—their liquidity fluctuates over time and can fall dramatically in a crisis—so we cannot take their liquidity for granted.

Imperfect liquidity also implies that there is no such thing as the going market price. Instead, there are two going market prices—an ask price, which is the price at which a trader sells, and a (lower) bid price, which is the price at which a trader buys. The “market” price often quoted is just an average of the bid and ask prices, and this price is fictional because no one actually trades at this price. The difference between the bid and ask prices is a cost of liquidity, and in principle we should allow for this cost in estimating market risk measures.

The bid-ask spread also has an associated risk, because the spread itself is a random variable. This means there is some risk associated with the price we can obtain, even if the fictional mid-spread price is given. Other things being equal, if the spread rises, the costs of closing out our position will rise, so the risk that the spread will rise should be factored into our risk measures along with the usual market price risk.

We should also take account of a further distinction. If our position is small relative to the size of the market (e.g., because we are a very small player in a very large market), then our trading should have a negligible impact on the market price. In such circumstances we can regard the bid-ask spread as exogenous to us, and we can assume that the spread is determined by the market beyond our control. However, if our position is large relative to the market, our activities will have a noticeable effect on the market itself and can affect both the market price and the bid-ask spread. For example, if we suddenly unload a large position, we should expect the market price to fall and the bid-ask spread to widen. This is partly because there is a limited market, and prices must move to induce other traders to buy. A second reason is a little more subtle: Large trades often reveal information, and the perception that they do will cause other traders to revise their views. Consequently, a large sale may encourage other traders to revise downward their assessment of the prospects for the instrument concerned, and this will further depress the price. In these circumstances the market price and the bid-ask spread are to some extent endogenous (i.e., responsive to our trading activities) and we should take account of how the market might react to us when estimating liquidity costs and risks. Other things again being equal, the bigger our trade, the bigger the impact we should expect it to have on market prices.

In sum, we are concerned with both liquidity costs and liquidity risks, and we need to take account of the difference between exogenous and endogenous liquidity. We now consider some of

the approaches available to adjust our estimates of VaR to take account of these factors.

ESTIMATING LIQUIDITY-ADJUSTED VaR

There are many ways we could estimate liquidity-adjusted VaR. These vary in their degrees of sophistication and in their ease (or otherwise) of implementation, and there is no single “best” method. However, sophisticated approaches are not necessarily more useful than more basic ones, and the best method, even if we could establish what it is, is not necessarily better than a collection of inferior ones. Instead, what we really seek are simple-to-implement (i.e., spreadsheet-executable) approaches that are transparent in terms of their underlying assumptions; in effect, we are looking for liquidity “add-ons” that allow us to modify original VaR estimates that were obtained without any consideration for liquidity. We can then easily assess the impact of our assumptions on our estimates of VaR. Moreover, there is a premium on compatibility, because different methods look at different aspects of illiquidity, and it can be helpful to combine them to get some sense of an overall liquidity adjustment. Because of this, a really good method might not always be as useful as two inferior methods that actually work well together.

Whichever models we used, we also need to check their sensitivities—how does the liquidity adjustment change as we change the confidence level, holding period, or any other parameters? A priori, we should have some idea of what these should be (e.g., that the liquidity adjustment should fall as the holding period rises, etc.), and we need to satisfy ourselves that the models we use have sensitivities of the right sign and approximate magnitude. Going further, we should also try to ensure that models are calibrated against real data (e.g., bid-ask spread parameters should be empirically plausible, etc.) and be properly stress-tested

and back-tested. In addition, we should keep in mind that different approaches are often suited to different problems, and we should not seek a best approach to the exclusion of any others. In the final analysis, liquidity issues are much more subtle than they look, and there is no established consensus on how we should deal with them. So perhaps the best advice is for risk measurers to hedge their bets, and use different approaches to highlight different liquidity concerns.

The Constant Spread Approach

Ideally, if we had actual transaction prices, we could infer the actual returns obtained by traders, in which case conventional VaR methods would take account of spread liquidity factors without the need for any further adjustment. In such cases, we would model actual returns (taking account of how they depend on market volume, etc.), infer a relevant conditional distribution (e.g., a t), and plug in the values of the parameters concerned into an appropriate parametric VaR equation. For more on how this might be done, see Giot and Grammig (2003).

However, practitioners often lack such data and have to work with market prices that are averages of bid and ask prices. They might then attempt to take account of liquidity factors by working with the bid-ask spread, and the simplest way to incorporate liquidity risk into a VaR calculation is in terms of a spread that is assumed to be constant. If we make this assumption, the liquidity cost is then equal to half the spread times the size of the position liquidated. Using obvious notation, this means that we add the following liquidity cost (LC) to a “standard” VaR:

$$LC = \frac{1}{2} \text{spread} * P \quad (1)$$

where *spread* is expressed as actual spread divided by the midpoint. For the sake of comparison and using obvious notation, let us compare

this to a benchmark conventional lognormal VaR with no adjustment for liquidity risk:

$$VaR = P [1 - \exp(\mu_R - \sigma_R z_\alpha)] \quad (2)$$

where the returns have been calculated using prices that are the midpoints of the bid-ask spread. The liquidity-adjusted VaR, $LVaR$, is then given by:

$$LVaR = VaR + LC = P[1 - \exp(\mu_R - \sigma_R z_\alpha) + \frac{1}{2}spread] \quad (3)$$

Setting $\mu_R = 0$ to clarify matters, the ratio of $LVaR$ to VaR is then

$$\frac{LVaR}{VaR} = 1 + \frac{spread}{2[1 - \exp(-\sigma_R z_\alpha)]} \quad (4)$$

It is easy to show that the liquidity adjustment (a) rises in proportion with the assumed spread, (b) falls as the confidence level increases, and (c) falls as the holding periods each increase. The first and third of these are obviously correct, but the second implication is one that may or may not be compatible with one's prior expectations.

This approach is easy to implement and requires only minimal information, but the assumption of a constant spread is highly implausible, and it takes no account of any other liquidity factors.

The Exogenous Spread Approach

A superior alternative is to assume that traders face random spreads. If our position is sufficiently small relative to the market, we can also regard our spread risk as exogenous to us (i.e., independent of our own trading), for any given holding period. We could assume any process for the spread that we believe to be empirically plausible. For example, we might believe that the spread is normally distributed:

$$spread \sim N(\mu_{spread}, \sigma_{spread}^2) \quad (5)$$

where μ_{spread} is the mean spread and σ_{spread} is the spread volatility. Alternatively, we might use some heavy-tailed distribution to accommodate excess kurtosis in the spread.

We could now estimate the $LVaR$ using Monte Carlo simulation: We could simulate both P and the spread, incorporate the spread into P to get liquidity-adjusted prices, and then infer the liquidity-adjusted VaR from the distribution of simulated liquidity-adjusted prices.

However, in practice, we might take a shortcut suggested by Bangia et al. (1999). They suggest that we specify the liquidity cost (LC) as:

$$LC = \frac{P}{2}(\mu_{spread} + k\sigma_{spread}) \quad (6)$$

where k is some parameter whose value is to be determined. The value of k could be determined by a suitably calibrated Monte Carlo exercise, but they suggest that a particular value ($k = 3$) is plausible (e.g., because it reflects the empirical facts that spreads appear to have excess kurtosis and are negatively correlated with returns, etc.). The liquidity-adjusted VaR, $LVaR$, is then equal to the conventional VaR plus the liquidity adjustment (6):

$$LVaR = VaR + LC = P[1 - \exp(\mu_R - \sigma_R z_\alpha) + \frac{P}{2}(\mu_{spread} + 3\sigma_{spread})] \quad (7)$$

Observe that this $LVaR$ incorporates (3) as a special case when $\sigma_{spread} = 0$. It therefore retains many of the properties of (3), but generalizes from (3) in allowing for the spread volatility as well. The ratio of $LVaR$ to VaR is then:

$$\frac{LVaR}{VaR} = 1 + \frac{LC}{VaR} = 1 + \frac{1}{2} \frac{(\mu_{spread} + 3\sigma_{spread})}{[1 - \exp(-\sigma_R z_\alpha)]} \quad (8)$$

This immediately tells us that the spread volatility σ_{spread} serves to increase the liquidity adjustment relative to the earlier case. The Bangia et al. framework was also further developed by Erwan (2002), who presented empirical results that are similar to the illustrative ones presented here in suggesting that the liquidity adjustment can make a big difference to our VaR estimates.

Endogenous-Price Approaches

The previous approaches assume that prices are exogenous and therefore ignore the possibility of the market price responding to our trading. However, we have also noted that this is often unreasonable, and we may wish to make a liquidity adjustment that reflects the response of the market to our own trading. If we sell, and the act of selling reduces the price, then this market-price response creates an additional loss relative to the case where the market price is exogenous, and we need to add this extra loss to our VaR. The liquidity-adjustment will also depend on the responsiveness of market prices to our trade: The more responsive the market price, the bigger the loss.

We can estimate this extra loss in various ways, but the simplest is to make use of some elementary economic theory. We begin with the notion of the price elasticity of demand, η , defined as the ratio of the proportional change in price divided by the proportional change in quantity demanded:

$$\eta = \frac{\Delta P/P}{\Delta N/N} < 0; \quad \Delta N/N > 0 \quad (9)$$

where in this context N is the size of the market and ΔN is the size of our trade. $\Delta N/N$ is therefore the size of our trade relative to the size of the market. The impact of the trade on the price is therefore

$$\frac{\Delta P}{P} = \eta \frac{\Delta N}{N} \quad (10)$$

We can therefore estimate $\Delta P/P$ on the basis of information about η and $\Delta N/N$, and both of these can be readily guessed at using a combination of economic and market judgement. The LVaR is then:

$$LVaR = VaR \left(1 - \frac{\Delta P}{P}\right) = VaR \left(1 - \eta \frac{\Delta N}{N}\right) \quad (11)$$

bearing in mind that the change in price is negative. The ratio of LVaR to VaR is therefore:

$$\frac{LVaR}{VaR} = 1 - \eta \frac{\Delta N}{N} \quad (12)$$

This gives us a very simple liquidity adjustment that depends on only two easily calibrated parameters. It is even independent of the VaR itself: The adjustment is the same regardless of whether the VaR is normal, lognormal, etc.

The ratio of LVaR to VaR thus depends entirely on the elasticity of demand η and the size of our trade relative to the size of the market ($\Delta N/N$).

This type of approach is easy to implement, and it is of considerable use in situations where we are concerned about the impact on VaR of endogenous market responses to our trading activity, as might be the case where we have large portfolios in thin markets. However, it is also narrow in focus and entirely ignores bid-ask spreads and transactions costs.

On the other hand, the fact that this approach focuses only on endogenous liquidity and the earlier ones focus on exogenous liquidity means that this last approach can easily be combined with one of the others; in effect, we can add one adjustment to the other. Thus, two very simple approaches can be added to produce an adjustment that addresses both exogenous and endogenous liquidity risk. This combined adjustment is given by

$$\frac{LVaR}{VaR} \Big|_{combined} = \frac{LVaR}{VaR} \Big|_{exogenous} + \frac{LVaR}{VaR} \Big|_{endogenous} \quad (13)$$

The Liquidity Discount Approach

A more sophisticated approach is suggested by Jarrow and Subramanian (1997). They consider a trader who faces an optimal liquidation problem—the trader must liquidate his or her position within a certain period of time to maximize expected utility, and seeks the best way to do so. Their approach is impressive, as it encompasses exogenous and endogenous market liquidity, spread cost, spread risk, an endogenous holding period, and an optimal liquidation policy.

Their analysis suggests that we should modify the traditional VaR in three ways. First, instead of using some arbitrary holding period,

we should use an optimal holding period determined by the solution to the trader's expected-utility optimization problem, which takes into account liquidity considerations and the possible impact of the trader's own trading strategy on the prices obtained. We should also add the average liquidity discount to the trader's losses (or subtract it from our prices) to take account of the expected loss from the selling process. Finally, their analysis also suggests that the volatility term should take account of the volatility of the time to liquidation and the volatility of the liquidity discount factor, as well as the volatility of the underlying market price.

To spell out their approach more formally, assume that prices between trades follow a geometric Brownian motion with parameters μ and σ . The current time is 0 and the price at time t is $p(t)$, so that geometric returns $\log(p(t)/p(0))$ are normally distributed. However, the prices actually obtained from trading are discounted from $p(t)$; more specifically, the prices obtained are $p(t)c(s)$, where $c(s)$ is a random quantity-dependent proportional discount factor, s is the amount traded, $0 \leq c(s) \leq 1$ and, other things being equal, $c(s)$ falls as s rises. Any order placed at time t will be also be subject to a random execution lag $\Delta(s)$, and therefore take place at time $t + \Delta(s)$. Other things again being equal, the execution lag $\Delta(s)$ rises with s : Bigger orders usually take longer to carry out. Our trader has S shares and wishes to maximize the present value of his or her current position, assuming that it is liquidated by the end of some horizon t , taking account of all relevant factors, including both the quantity discount $c(s)$ and the execution lag $\Delta(s)$. After solving for this problem, they produce the following expression for the liquidity-adjusted VaR:

$$\begin{aligned} LVaR &= P \left\{ E[\ln(p(\Delta(S))c(S)/p(0))] \right. \\ &\quad \left. + \text{std}[\ln(p(\Delta(S))c(S)/p(0))]z_\alpha \right\} \quad (14) \\ &= P \left\{ \left(\mu - \frac{\sigma^2}{2} \right) \mu_{\Delta(S)} + \mu_{\ln c(S)} \right. \\ &\quad \left. + \left[\sigma \sqrt{\mu_{\Delta(S)}} + \left(\mu - \frac{\sigma^2}{2} \right) \sigma_{\Delta(S)} + \sigma_{\ln c(S)} \right] z_\alpha \right\} \end{aligned}$$

where all parameters have the obvious interpretations. This expression differs from the conventional VaR in three ways. First, the liquidation horizon t in the conventional VaR is replaced by the expected execution lag $\mu_{\Delta(S)}$ in selling S shares. Clearly, the bigger is S , the longer the expected execution lag. Second, the LVaR takes account of the expected discount $\mu_{\ln c(s)}$ on the shares to be sold. And, third, the volatility σ in the conventional VaR is supplemented by additional terms related to $\sigma_{\Delta(s)}$ and $\sigma_{\ln c(s)}$, which reflect the volatilities of the execution time and the quantity discount. Note, too, that if our liquidity imperfections disappear, then $\mu_{\Delta(S)} = t$, $\sigma_{\Delta(S)} = 0$, and $c(S) = 1$ (which in turn implies $\mu_{\ln c(s)} = \sigma_{\ln c(s)} = 0$) and our LVaR (14) collapses to a conventional VaR as a special case—which is exactly as it should be.

To use this LVaR expression requires estimates of the usual Brownian motion parameters μ and σ , as well as estimates of the liquidity parameters $\mu_{\Delta(S)}$, $\sigma_{\Delta(S)}$, $\mu_{\ln c(s)}$ and $\sigma_{\ln c(s)}$, all of which are fairly easily obtained. The approach is therefore not too difficult to implement. All we have to do is then plug these parameters into (14) to obtain our LVaR.

ESTIMATING LIQUIDITY-AT-RISK (LAR)

We turn now to liquidity-at-risk (LaR), sometimes also known as cash flow-at-risk (CFaR). LaR (or CFaR) relates to the risk attached to prospective cash flows over a defined horizon period, and can be defined in terms analogous to the VaR. Thus, the LaR is the maximum likely cash outflow over the horizon period at a specified confidence level: for example, the 1-day LaR at the 95% confidence level is the maximum likely cash outflow over the next day, at the 95% confidence level, and so forth. A positive LaR means that the likely worst outcome, from a cash flow perspective, is an outflow of cash; and a negative LaR means that the likely worst outcome is an inflow of cash. The LaR is the cash flow equivalent to the VaR, but whereas

VaR deals with the risk of losses (or profits), LaR deals with the risk of cash outflows (or inflows).

These cash flow risks are quite different from the risks of liquidity-related losses. Nonetheless, they are closely related to these latter risks, and we might use LaR analysis as an input to evaluate them. Indeed, the use of LaR for such purposes is an important liquidity management tool.

An important point to appreciate about LaR is that the amounts involved can be very different from the amounts involved with VaR. Suppose for the sake of illustration that we have a large market-risk position that we hedge with a futures hedge of much the same amount. If the hedge is a good one, the basis or net risk remaining should be fairly small, and our VaR estimates should reflect that low basis risk and be relatively small themselves. However, the futures hedge leaves us exposed to the possibility of margin calls, and our exposure to margin calls will be related to the size of the futures position, which corresponds to the gross size of our original position. Thus, the VaR depends largely on the netted or hedged position, whilst the LaR depends on the larger gross position. If the hedge is a good one, the basis risk (or the VaR) will be low relative to the gross risk of the hedge position (or the LaR), and so the LaR can easily be an order of magnitude greater than the VaR. On the other hand, there are also many market risk positions that have positive VaR, but little or no cash flow risk (e.g., a portfolio of long European option positions, which generates no cash flows until the position is sold or the options expire), and in such cases the VaR will dwarf the LaR. So the LaR can be much greater than the VaR or much less than it, depending on the circumstances.

As we might expect, the LaR is potentially sensitive to any factors or activities, risky or otherwise, that might affect future cash flows. These include:

- Borrowing or lending, the impact of which on future cash flows is obvious.

- Margin requirements on market risk positions that are subject to daily marking-to-market.
- Collateral obligations, such as those on swaps, which can generate inflows or outflows of cash depending on the way the market moves. Collateral obligations can also change when counterparties like brokers alter them in response to changes in volatility, and collateral requirements on credit-sensitive positions (e.g., such as default-risky debt or credit derivatives) can change in response to credit events such as credit-downgrades.
- Unexpected cash flows can be triggered by the exercise of options, including the exercise of convertibility features on convertible debt and call features on callable debt.
- Changes in risk management policy; for instance, a switch from a futures hedge to an options hedge can have a major impact on cash flow risks, because the futures position is subject to margin requirements and marking to market whilst a (long) option position is not.

Two other points are also worth emphasizing here. The first is that obligations to make cash payments often come at bad times for the firms concerned, because they are often triggered by bad events. The standard example is where a firm suffers a credit downgrade that leads to an increase in its funding costs, and yet this same event also triggers a higher collateral requirement on some existing (e.g., swap) position and so generates an obligation to make a cash payment. It is axiomatic in many markets that firms get hit when they are most vulnerable. The second point is that positions that might be similar from a market risk perspective (e.g., such as a futures hedge and an options hedge) might have very different cash flow risks. The difference in cash flow risks arises, not so much because of differences in market risk characteristics, but because the positions have different *credit* risk characteristics, and it is the measures taken to manage the credit risk—the margin

and collateral requirements, and so on—that generate the differences in cash flow risks.

We can estimate LaR using many of the same methods used to estimate VaR and other measures of market risk. One approach, suggested by Singer (1997), is to use our existing VaR estimation tools to estimate the VaRs of marginable securities only (i.e., those where P/L translates directly into cash flows), thus allowing us to infer an LaR directly from the VaR. We could then combine this LaR estimate with comparable figures from other sources of liquidity risk within the organization (e.g., such as estimates of LaR arising from the corporate treasury) to produce an integrated measure of firm-wide liquidity risk. The beauty of this strategy is that it makes the best of the risk measurement capabilities that already exist within the firm, and effectively tweaks them to estimate liquidity risks.

However, this approach is also fairly rough and ready, and cannot be relied upon when the firm faces particularly complex liquidity risks. In such circumstances, it is often better to build a liquidity-risk measurement model from scratch, and we can start by setting out the basic types of cash flow to be considered. These might include:

- Known certain (or near certain) cash flows (e.g., income from government bonds, etc.). These are very easy to handle because we know them in advance.
- Unconditional uncertain cash flows (e.g., income from default-risky bonds, etc.). These are uncertain cash flows, which we model in terms of the probability density functions (pdfs) (i.e., we choose appropriate distributions, assign parameter values, etc.).
- Conditional uncertain cash flows. These are uncertain cash flows that depend on other variables (e.g., a cash flow might depend on whether we proceeded with a certain investment, and so we would model the cash flow in terms of a pdf, conditional on that investment); other conditioning variables that might trigger cash flows could be interest

rates, exchange rates, decisions about major projects, and so forth.

Once we specify these factors, we can then construct an appropriate engine to carry out our estimations. The choice of engine would depend on the types of cash flow risks we have to deal with. For instance, if we had fairly uncomplicated cash flows we might use an historical simulation or variance-covariance approach, or some specially designed term-structure model; however, since some cash flows are likely to be dependent on other factors such as discrete random variables (e.g., such as downgrades or defaults), it might not be easy tweaking such methods to estimate LaRs with sufficient accuracy. In such circumstances, it might be better to resort to simulation methods, which are much better suited to handling discrete variables and the potential complexities of cash flows in larger firms.

Another alternative is to use scenario analysis. We can specify liquidity scenarios, such as those arising from large changes in interest rates, default by counterparties, the redemption of puttable debt, calls for collateral on repos and derivatives, margin calls on swaps or futures positions, and so forth. We would then (as best we could) work through the likely/possible ramifications of each scenario, and so get an idea of the liquidity consequences associated with each scenario. Such exercises can be very useful, but, as with all scenario analyses, they might give us an indication of what could happen if the scenario occurs, but don't as such tell us anything about the probabilities associated with those scenarios or the LaR itself.

ESTIMATING LIQUIDITY IN CRISES

We now consider liquidity in crisis situations. As we all know, financial markets occasionally experience major crises—these include, for example, the stock market crash of 1987, the ERM crisis of 1992, the Russian default crisis of the

summer of 1998, and, of course, the many liquidity problems experienced since the onset of the financial crisis in August 2007. Typically, some event occurs that leads to a large price fall. This event triggers a huge number of sell orders, traders become reluctant to buy, and the bid-ask spread rises dramatically. At the same time, the flood of sell orders can overwhelm the market and drastically slow down the time it takes to get orders executed. Selling orders that would take minutes to execute in normal times instead take hours, and the prices eventually obtained are often much lower than sellers had anticipated. Market liquidity dries up, and does so at the very time market operators need it most. Assumptions about the market—and in particular, about market liquidity—that hold in “normal” market conditions can thus break down when markets experience crises. This means that estimating crisis liquidity is more than just a process of extrapolation from LaR under more normal market conditions: We need to estimate crisis-liquidity risks using methods that take into account the distinctive features of a crisis—large losses, high bid-ask spreads, and so forth.

One way to carry out such an exercise is by applying “crashmetrics” (Wilmott, 2000, Chapter 58). To give a simple example, we might have a position in a single derivatives instrument, and the profit/loss Π on this instrument is given by a delta-gamma approximation:

$$\Pi = \delta \Delta S + \frac{\gamma}{2} (\Delta S)^2 \quad (15)$$

where ΔS is the change in the stock price, and so forth. The maximum loss occurs when $dS = -\delta/\gamma$ and is equal to:

$$L^{\max} = -\Pi^{\min} = \frac{\delta^2}{2\gamma} \quad (16)$$

The worst-case cash outflow is therefore $m\delta^2/(2\gamma)$, where m is the margin or collateral requirement. This approach can also be extended to handle the other Greek parameters (the vegas, thetas, rhos, etc.), multi-

option portfolios, counterparty risk, and so forth. The basic idea—of identifying worst-case outcomes and then evaluating their liquidity consequences—can also be implemented in other ways as well. For example, we might identify the worst-case outcome as the expected outcome at a chosen confidence level, and we could estimate this (e.g., using extreme-value methods) as the ES at that confidence level. The cash outflow would then be m times this ES.

There are also other ways we can estimate crisis-LaR. Instead of focusing only on the high losses associated with crises, we can also take account of the high-bid ask spreads and/or the high bid-ask spread risks associated with crises. We can do so, for example, by estimating these spreads (or spread risks), and inputting these estimates into the relevant liquidity-adjusted VaR models discussed earlier.

However, these suggestions (i.e., Greek- and ES-based) are still rather simplistic, and with complicated risk factors—such as often arise with credit-related risks—we might want a more sophisticated model that was able to take account of the complications involved, such as:

- The discreteness of credit events.
- The interdependency of credit events.
- The interaction of credit and market risk factors (e.g., the ways in which credit events depend, in part, on market risk factors).
- Complications arising from the use of credit-enhancement methods such as netting arrangements, periodic settlement, credit derivatives, credit guarantees, and credit triggers (see, e.g., Wakeman, 1998).

These complicating factors are best handled using simulation methods tailor-made for the problems concerned.

The obvious alternative to probabilistic approaches to the estimation of crisis-liquidity is to use crisis-scenario analyses. We would imagine a big liquidity event—a major market crash, the default of a major financial institution or government, the outbreak of a war, or whatever—and work through the ramifications

for the liquidity of the institution concerned. One attraction of scenario analysis in this context is that we can work through scenarios in as much detail as we wish, and so take proper account of complicated interactions such as those mentioned in the last paragraph. This is harder to do using probabilistic approaches, which are by definition unable to focus on any specific scenarios. However, as with all scenario analyses, the results of these exercises are highly subjective, and the value of the results is critically dependent on the quality of the assumptions made.

KEY POINTS

- Liquidity refers to the ability to execute a trade or liquidate a position with little or no cost or inconvenience.
- Liquidity is a function of the market and depends on the type of position traded and sometimes the size and trading strategy of an individual trader.
- Liquidity risks are those associated with the prospect of imperfect or imperfect market liquidity, and can relate to risk of loss or risk to cash flows.
- There are two main aspects to liquidity risk measurement: the measurement of liquidity-adjusted measures of market risk (e.g., liquidity-adjusted value-at-risk, LVaR) and the measurement of liquidity risks per se (e.g., liquidity-at-risk, LaR).
- There are a number of easily implementable and often complementary approaches to the estimation of liquidity-adjusted measures of market risk: the *constant spread*, *exogenous spread*, and *endogenous price approaches*, and the liquidity discount approach.

- These approaches can produce risk estimates that differ substantially from the risk estimates obtained if liquidity is ignored.
- There are a number of approaches to the estimation of liquidity risks in noncrisis situations. These include both LaR approaches and scenario analyses.
- The LaR can be much greater than the VaR or much less than the VaR, depending on the circumstances.
- Crisis-related liquidity risks can be estimated using “crashmetrics” or scenario analyses hypothesized on crisis events such as a dry-up in market liquidity.

Estimate of Downside Risk with Fat-Tailed and Skewed Models

JAMES X. XIONG, PhD, CFA

Senior Research Consultant, Ibbotson Associates, A Morningstar Company

Abstract: Asset returns are often not normally distributed and exhibit several stylized empirical facts: fat tails, skewness, finite variance, time scaling, and volatility clustering. Modeling the tail distribution of asset returns plays an essential role in downside risk management. The “left tail” of the distribution is where market crashes or crises occur. Downside risk can be measured in terms of conditional value-at-risk and estimated by fat-tailed and skewed models such as Lévy stable, truncated Lévy flight, skewed Student’s t , mixture of normal distributions, and GARCH models. These fat-tailed and skewed models have different characteristics in describing the tail distribution of asset returns. The objective is to select appropriate ones that can accurately model the downside risk.

The financial crisis of 2008 has led many practitioners and academics to reassess the adequacy of the return distribution models, in particular, the left tail. This entry focuses on modeling the left fat tails since they reflect market crashes or crises and play an essential role in downside risk management.

The most common model of asset returns is assumed to be normally or Gaussian distributed (see Bachelier, 1900). In other words, the returns follow a random walk or Brownian motion. This model is natural if one assumes the return over a time interval to be the result of many small independent shocks, which leads to a Gaussian distribution by the central limit theorem. However, empirical studies have observed that the return distributions

are more leptokurtic or fat-tailed than Gaussian distributions.

A normal distribution model assumes that an asset return that is three standard deviations below its arithmetic mean (popularly referred to as a “three-sigma event”) has a probability of only approximately 0.13%; that is, once every 1,000 times. For example, from January 1926 to March 2010, the S&P 500 total return index had a monthly mean return of 0.93% and a monthly standard deviation of 5.54%. A negative three-sigma event would be a return lower than -15.69% . During this time period of 1,010 months, there were 10 monthly returns worse than -15.69% as shown in Table 1 (the three-sigma event), with the most recent loss of -16.79% in October 2008 being ranked at ninth.

Table 1 The Worst 10 Monthly Returns for the S&P 500 (from 1/1926 to 3/2010)

	S&P 500 (%)
Sep 1931	-29.73
Mar 1938	-24.87
May 1940	-22.89
May 1932	-21.96
Oct 1987	-21.52
Apr 1932	-19.97
Oct 1929	-19.73
Feb 1933	-17.72
Oct 2008	-16.79
Jun 1930	-16.25

Source: Morningstar Encorr.

This implies the probability of a three-sigma event is about 1% rather than 0.13%, or eight times greater than we would expect under a normal distribution. Hence, a normal distribution fails to describe the “fat” or “heavy” tails of the stock market.

Many statistical models have been put forth to account for the heavy tails. We discuss several standard and popular fat-tailed models, such as Mandelbrot’s *Lévy stable* hypothesis (see Mandelbrot, 1963), the *Student’s t*-distribution (see Blattberg and Gonedes, 1974), the *mixture of normal distributions* (see Clark, 1973), and *GARCH* (see Bollerslev, 1986) models. There are many other fat-tailed candidates, and this entry does not aim at being exhaustive. Instead, we select representative models and illustrate them through examples so that practitioners may have some intuition about these practically implementable models.

Along the way, we introduce a relatively new fat-tailed and skewed model: the *truncated Lévy flight* (TLF). Another name for the TLF is the tempered stable distribution. The TLF model has a few interesting properties that we will illustrate later, such as possessing *fat tails*, *skewness*, finite moments, and time scaling. Of course, these quantitative models are not the only tool, and they need to be integrated with judgmental analyses and other estimates, but

they represent a good starting point for the management of *downside risk*.

DOWNSIDE RISK MEASURE

Before we dive into the discussions of fat-tailed models, we need to specify an appropriate downside risk measure. A popular downside risk measure is value-at-risk (VaR), which is an estimate of the loss that we expect to be exceeded with a given level of probability (e.g., 5%) over a specified time period. VaR has been recommended as a way of measuring risk by regulators and various financial industry advisory committees.

Conditional value-at-risk (CVaR), a closely related measure to VaR, is derived by taking a weighted average between the VaR and losses exceeding the VaR. Other terms for CVaR include mean shortfall, tail VaR, and expected tail loss. Studies such as Rockafellar and Uryasev (2000), for example, have shown that CVaR has more attractive properties than VaR. Specifically, CVaR is a coherent measure of risk as proved by Pflug (2000) in the sense of Artzner et al. (1999). One of the coherent measures is subadditivity; that is, the risk of a combination of investments is at most as large as the sum of the individual risks. VaR is not always subadditive, which means that the VaR of a portfolio with two instruments may be greater than the sum of individual VaRs of these two instruments. In contrast, CVaR is subadditive. Therefore, CVaR is a more appropriate measure of downside risk.

LÉVY STABLE DISTRIBUTION

Lévy distributions are stable; that is, the sum of two independent random variables, characterized by the same Lévy distribution of tail index α , is itself characterized by a Lévy distribution of the same index. In other words, the functional form of the distribution is maintained, if

we sum up independent, identically distributed Lévy stable random variables. The characteristic function of the Lévy stable distribution is (Lévy, 1925):

$$\begin{aligned}\ln \varphi(q) &= i\delta q - \gamma |q|^\alpha \left[1 - i\beta \frac{q}{|q|} \tan\left(\frac{\pi}{2}\alpha\right) \right] \quad \text{for } \alpha \neq 1 \\ &= i\delta q - \gamma |q| \left[1 - i\beta \frac{q}{|q|} \frac{2}{\pi} \ln |q| \right] \quad \text{for } \alpha = 1\end{aligned}$$

The probability density function is obtained by performing the inverse Fourier transform on the characteristic function. The four parameters associated with the Lévy stable distribution are: α determines the tail weight or the distribution's kurtosis with $0 < \alpha \leq 2$; β determines the distribution's skewness; γ is a scale parameter; and δ is a location parameter. One can generate univariate stable distributed returns through a numerical software package, for example, written by John Nolan (2009).¹ (In his software, the function "stablernd()" takes four parameters, α , β , γ , and δ , and generates random returns that follow a Lévy stable distribution. For empirical analyses, these four parameters can be estimated by the software's function "stablefit().")

In 1963, Mandelbrot modeled cotton prices with a Lévy stable process (Mandelbrot, 1963). Mandelbrot observed that in addition to being fat-tailed, the returns show another interest-

ing property: time scaling. This means that the distributions of returns have similar functional forms for different time intervals, ranging from one day to one month. The time scaling property is very appealing as it allows the sum of two independent Lévy stable distributed variables to be stable distributed, with the same stability index α . The normal distribution is a special case of the Lévy stable distribution, and it is scaled in the same way that the sum of two normally distributed variables is also normally distributed.

Figure 1 shows the time scaling of the S&P 500 index returns at time intervals of 1, 2, 3, and 5 days. The scaling variable for a Lévy stable process of index α is $\tilde{Z} = \frac{Z}{(\Delta t)^{1/\alpha}}$. The best fit gives $\alpha = 1.5$, and a good data collapse can be observed in Figure 1.

Mandelbrot's finding was later supported by Fama's study on stocks (Fama, 1965). A Lévy stable distribution model has fat tails and obeys scaling properties, but it has an infinite variance, which conflicts with empirical observations that the return variance is finite. For example, extensive analyses on high-frequency data (ranging from 1 minute to 1 day) for the 1,000 largest companies provided evidence that the returns have finite variance (Gopikrishnan et al., 1998). Infinite variance complicates the

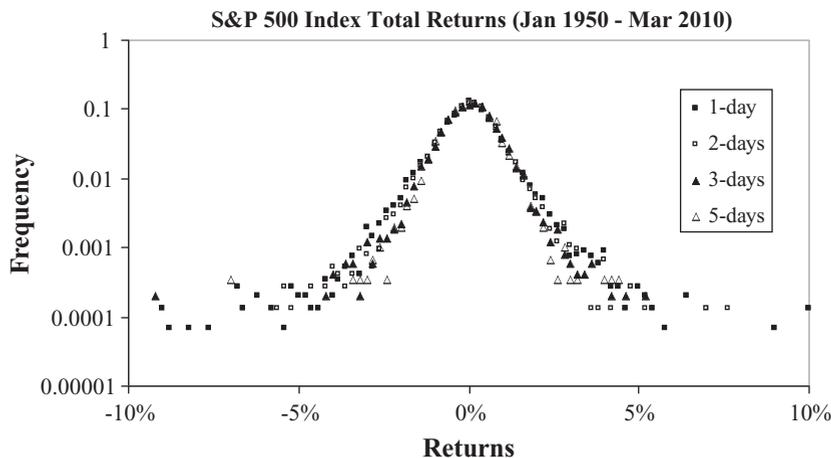

Figure 1 The Time Scaling of the S&P 500 Index with a Stability Index $\alpha = 1.5$

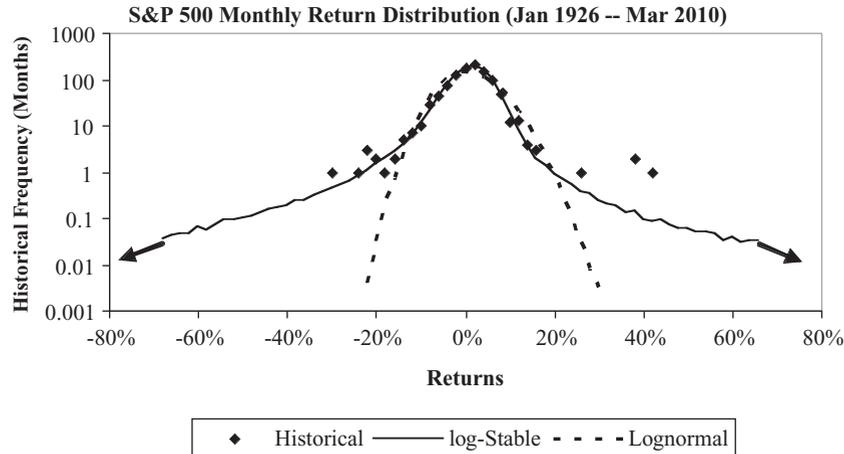

Figure 2 The Distributions of S&P 500 Monthly Returns Fitted by the Log-Stable and Lognormal Models

task of risk estimation, as well as the application of mean-variance portfolio construction.

Figure 2 illustrates the log-stable and log-normal distributions in fitting the distribution of monthly S&P 500 returns (also see Martin, Rachev, and Siboulet, 2003). Log-stable distribution applies the stable distribution to log-returns. The vertical axis of Figure 2 is in log scale with a base of 10, and this helps to view the tails of the distribution more clearly. It is clear that the lognormal distribution fails to fit the return distribution below -15% (the above-mentioned three-sigma events). The log-stable distribution fits the tail well, but it extends far beyond the historical maximum loss or gain with nonnegligible probabilities, which eventually results in an infinite variance. In other words, the tail for the log-stable distribution is perhaps too fat.

The infinite variance associated with the stable distribution induces a challenging problem in risk estimation. In practice, what is needed is a model with a distribution falling between the normal and stable distributions so that its tail is appropriately fat, but finite. By truncating the extreme tails of the stable distribution, a model named the *truncated Lévy flight* has such properties.

Truncated Lévy Flight

The TLF model was first introduced by Mantegna and Stanley (1994) in the physics literature, and it has drawn widespread attention since then. Koponen (1995) modified it in such a way as to allow an analytical calculation of the characteristic function and determination of the complete probability density distribution. Another name for the TLF is the tempered stable distribution—introduced and extended by Boyarchenko and Levendorskii (2000), Carr et al. (2002), Rosinski (2007), and Kim et al. (2008, 2010). Another application is the so-called smoothly truncated stable distribution introduced by Menn and Rachev (2009).

In this entry, we focus on the simplest TLF model by Mantegna and Stanley (1994). The probability density function (PDF) of a simple TLF process is defined as:

$$\begin{aligned} P(x) &= 0, & x < -l; \\ P(x) &= P_{Levy}(x), & -l \leq x \leq l; \\ P(x) &= 0, & x > l \end{aligned}$$

where $P_{Levy}(x)$ is the PDF of return x for a Lévy stable distribution and l is the cutoff length for the truncation. It can be seen that the truncation is abrupt. Alternative TLF models are similar

Table 2 Parameter Estimates with the Log-TLF Model for Monthly S&P 500, Weekly MSCI EM, and Weekly MSCI EAFE Returns

Log-TLF	α	β	γ	δ	Cutoff Length
S&P 500 Monthly	1.42	-0.12	0.024	0.010	6.8
MSCI EM Weekly	1.58	-0.40	0.015	0.0054	8.0
MSCI EAFE Weekly	1.79	-0.52	0.014	0.0033	10.0

and have in general smoother truncations in the form of exponential tails.

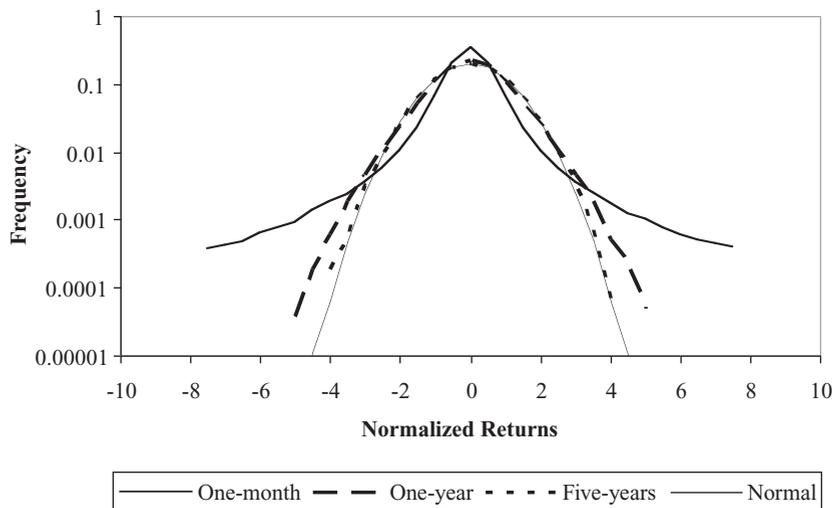

To simulate a TLF process from a Lévy stable process, we apply a truncation method on the Lévy stable distributed returns generated in the previous section so that the return series follows a TLF model. These truncated returns are then used in the distribution analyses and CVaR estimates, as well as the Monte Carlo simulations.

The truncation is simply implemented, for example, by truncating returns that are beyond 8-sigma for the MSCI Emerging Market index weekly returns or 6.8-sigma for S&P 500 monthly returns. The estimates of the five parameters are shown in Table 2. In the table, we choose the cutoff length in such a way that it is slightly larger than the historical maximum loss (in terms of standard deviation) over the entire historical period. The cutoff length shown in the table is normalized. One can think of a normalized cutoff length of 6 as a six-sigma event.

The other four parameters are estimated by the maximum likelihood method.

An interesting feature of the TLF model is its time scaling behavior. Mantegna and Stanley (1994, 1999) show that for a small time interval (e.g., a minute), the TLF distribution approximates a Lévy stable distribution with Lévy stable scaling; while for a significantly large but finite time interval (e.g., a year), the TLF distribution slowly converges to a Gaussian distribution. In other words, the TLF undergoes a crossover from a Lévy stable distribution to a Gaussian distribution as the time interval increases. This crossover is consistent with an independent empirical study of the distribution of daily, weekly and monthly returns for which a progressive convergence to a Gaussian process is deemed to be observed (Akgiray and Booth, 1988).

Figure 3 shows the convergence of the TLF from the Lévy stable distribution at a small time

**Figure 3** Time Scaling of the TLF process

interval to the Gaussian distribution at a large time interval. It shows that as the time interval increases from one month to one year and finally to five years, the normalized return distribution converges from the approximate Lévy stable distribution (one-month interval) to the normal distribution (five-year interval).

The truncation is able to mathematically solve the infinite variance problem inherent in the stable distribution. In fact, the truncation leads to the advantage that all four moments are finite. An interesting question is whether there are economic rationales for the truncation, even though the empirical evidence of finite variance is convincing. The truncation implies an upside or downside boundary for the returns. For the left tail, it is easy to see that the return is bounded by -100% due to limited liability for shareholders for unleveraged indexes or portfolios. However, the existence of the boundary for the upside tail is debatable and it may require extensive separate research. Factors that can limit an infinite positive gain for a large market index such as the S&P 500 may include competitive industries, business cycles, government intervention such as antitrust law and increasing interest rates, contrarian strategies that lead to mean reversion of returns, and so on. Fundamental "intrinsic valuation" indicates that the asset prices should be commensurate with the overall economic growth, which is limited by population growth, labor resources, productivity, and so on.

On the drawback side, like the normal or Lévy stable distribution model, the TLF model assumes an independent and identically distributed process and therefore it cannot describe the time-dependent volatility or volatility clustering observed in market data. Volatility clustering means that a period of high volatility tends to be followed by high volatility and a period of low volatility is likely followed by low volatility.

An attempt to address this drawback is to assume TLF innovations instead of Gaussian innovations in GARCH models. A few stud-

ies have investigated the option pricing problem with GARCH dynamics and non-Gaussian innovations. For example, Menn and Rachev (2009) considered smoothly truncated stable innovations in order to provide a practical framework to extend option pricing theory to the Lévy stable model. Kim et al. (2010) studied parametric models based on tempered stable innovations, and they showed that the GARCH model with tempered stable innovations explains both asset price behavior and European option prices better than the normal GARCH model.

STUDENT'S *t*-DISTRIBUTION

The Student's *t*-distribution is well documented in the literature. Its probability density function is given by:

$$P(x) = \frac{\Gamma\left(\frac{\nu+1}{2}\right)}{\sqrt{\pi\nu}\Gamma\left(\frac{\nu}{2}\right)} \left(1 + \frac{x^2}{\nu}\right)^{-\frac{\nu+1}{2}}$$

where ν is the degrees of freedom. The Student's *t*-distribution coincides with the Cauchy distribution for $\nu = 1$, and approaches Gaussian for $\nu \rightarrow \infty$. Finite variance only exists for $\nu > 2$.

Blattberg and Gonedes (1974) proposed that the returns are distributed with a Student's *t*-distribution. Markowitz and Usmen (1996) found that the daily log-return data of the S&P 500 index can be fitted by the Student's *t*-distribution with about 4.5 degrees of freedom. Hurst and Platen (1997) reached a similar conclusion. Platen and Sidorowicz (2007) investigated the log-returns of a variety of diversified world stock indexes in different currency denominations by applying the maximum likelihood ratio test to the large class of generalized hyperbolic distributions, and showed that the Student's *t*-distribution with about four degrees of freedom was the best fit among the models they tested.

The Student's t -distribution is symmetric, thus it cannot model skewness. In order to model negative skewness, Hansen (1994) introduced the skewed Student's t -distribution, which is able to model skewness, but it requires one more parameter to be estimated.

The Student's t -distribution has fat tails but does not obey time scaling, which indicates that the sum of two independent Student's t -distributed variables is not a Student's t -variable with the same degrees of freedom. It cannot model volatility clustering.

The kurtosis of the Student's t distribution is given by $\frac{6}{4-\nu}$, and it is only defined for $\nu > 4$. In other words, the kurtosis is infinite when ν is less than or equal to 4, and the skewness tends to be unstable for $\nu \leq 4$. In order to avoid an infinite kurtosis, we set the minimum ν as 4.1 when the maximum likelihood estimate gives a value of ν less than 4 (shown as MLE- ν in Table 3). Our numerical simulations show that the CVaR estimate is not sensitive to this small change of ν .

For the symmetric Student's t -distribution, ν is the only parameter that needs to be estimated for normalized returns. For the skewed Student's t -distribution, we need to add a parameter, λ , to capture the skewness (see Hansen, 1994). These estimated parameters are shown in Table 3.

Table 3 Parameter Estimates with the Log Student's t and Log Skewed Student's t Distributions for Monthly S&P 500, Weekly MSCI EM, and Weekly MSCI EAFE Returns

Log Student's t		
	ν	MLE- ν
S&P 500 Monthly	4.1	3.6
MSCI EM Weekly	4.1	4.0
MSCI EAFE Weekly	4.4	4.4
Log Skewed t		
	ν	λ
S&P 500 Monthly	4.1	-0.13
MSCI EM Weekly	4.1	-0.25
MSCI EAFE Weekly	4.4	-0.09

MIXTURE OF NORMAL DISTRIBUTIONS

In the mixture of normal distributions model, the fat tails are obtained through subordination. The model considered for the log-returns is:

$$d \log S(t) = \mu dt + \sigma g(t) dW$$

where μ and σ are associated with the normal process of an individual trade. W is a standard Brownian motion. This model becomes the standard geometric Brownian motion when $g(t)$ is constant. $g(t)$ is a subordinator and positive increasing random process that characterizes the market trading activity time.

If $g(t)$ is assumed to be lognormally distributed with mean μ_s and standard deviation σ_s , this mixture process is also referred to as the normal-lognormal mixture. The probability density function for the normal-lognormal mixture is given in Clark (1973).

Other kinds of mixtures exist in the literature, such as a normal-gamma mixture, also referred to as a variance gamma process (Madan and Seneta, 1990). In this entry, we only illustrate the normal-lognormal mixture, one of the simplest mixture models. The estimated parameters for the normal-lognormal mixture are shown in Table 4.

The mixture of normal distributions utilizes the concept of a subordinated process. Clark (1973) assumes that trading volume is a plausible measure of the evolution of price dynamics. Indeed, a sizeable literature has demonstrated a strong positive contemporaneous correlation between trading volume and return volatility (see, for example, Andersen, 1996). More specifically, the distribution of log-returns occurring

Table 4 Parameter Estimates with the Mixture Distribution for Monthly S&P 500, Weekly MSCI EM, and Weekly MSCI EAFE Returns

	μ	σ	μ_s	σ_s
S&P 500 Monthly	0.0075	0.0382	0.0006	1.193
MSCI EM Weekly	0.0019	0.0206	0.0002	1.241
MSCI EAFE Weekly	0.0013	0.0152	0.0003	1.280

from a given level of trading volume is subordinate to the distribution of an individual trade and directed by the distribution of the trading volume. By assuming the normal distribution for the individual trade and finite moments for the distribution of the trading volume, Clark (1973) proves that the mixed distribution has fat tails with all moments finite.

The mixture of normal distributions is intuitively appealing because it is directly linked to market microstructure such as information flow, trading volume, and number of transactions. The subordinated process premise has also evolved into stochastic volatility that now receives vigorous attention in the finance literature (see Andersen, 1996). In general, mixture of normal distributions has fat tails but does not obey time scaling. A generalized mixture of normal distributions, however, can describe volatility clustering.

GARCH Models

General autoregressive conditional heteroscedasticity (GARCH) models, first introduced by Bollerslev (1986), are now widely employed in financial time-series analyses. In particular, they are used to predict short horizon volatilities (ranging from one day to one month).

The return generating process is based on geometric Brownian motion but with the variance being a time-dependent GARCH(1,1) process, which is defined by the relation:

$$\sigma_t^2 = \alpha_0 + \alpha_1 r_{t-1}^2 + \beta_1 \sigma_{t-1}^2$$

where α_0 , α_1 , and β_1 are the control parameters of the GARCH(1,1) stochastic process. r_t is a random variable with zero mean and variance σ_t^2 , and is characterized by a conditional probability density function $f_t(x)$, which is arbitrary but is often chosen to be Gaussian. In this entry, the innovation σ_t^2 is assumed to be Gaussian. These three control parameters are estimated by the maximum likelihood method and shown in Table 5.

Table 5 Parameter Estimates with the GARCH(1,1) Model for Monthly S&P 500, Weekly MSCI EM, and Weekly MSCI EAFE Returns

	α_0	α_1	β_1
S&P 500 Monthly	0.00006	0.1291	0.8474
MSCI EM Weekly	0.00002	0.1431	0.8309
MSCI EAFE Weekly	0.00002	0.0897	0.8815

GARCH models assume that volatility changes with time and with past information. Because of the time-dependent volatility, the unconditional distribution of returns exhibit fat tails. GARCH models allow for volatility clustering or autocorrelation in the volatility.

The most popular GARCH model is GARCH(1,1). The scaling properties of GARCH(1,1) are not clear from the theory; however, numerical simulations of GARCH(1,1) with Gaussian innovations show that it fails to describe the scaling properties of high-frequency data (see Mantegna and Stanley, 1999).

GARCH(1,1) processes are unconditionally stationary with finite variance if $1 - \alpha_1 - \beta_1 > 0$, and have finite kurtosis if $1 - \beta_1^2 - 2\alpha_1\beta_1 - 3\alpha_1^2 > 0$.

MODELING RETURN DISTRIBUTIONS FOR MAJOR INDEXES

Applications of the Lévy stable, Student's t , and mixture of normal distribution models in modeling market indexes are well documented (see, for example, Mandelbrot [1963], Clark [1973], Blattberg and Gonedes [1974], Markowitz and Usmen [1996], Hurst and Platen [1997], Martin, Rachev and Siboulet [2003], Platen and Sidorowicz [2007], etc.). The literature offered detailed methodology on how the model parameters are estimated. In some cases, they performed comparisons for these models.

Mantegna and Stanley (1999) studied the TLF model and GARCH(1,1) with Gaussian innovations processes. They found that the TLF model well describes the time scaling, while it is not

able to properly describe the volatility clustering. The GARCH(1,1) model seems to be complementary to the TLF: It is able to describe the volatility clustering, but it fails to describe the time scaling. As mentioned earlier, however, the GARCH model with TLF innovations might offer a better solution to the TLF model or GARCH with Gaussian innovations.

Many previous studies have focused on high-frequency data such as daily return data. Here, we are interested in weekly or monthly data because investors typically have a relatively long investment horizon and portfolios are often rebalanced monthly. We apply these fat-tailed models to some well-known weekly or monthly returns of equity indexes. Our test assets include the monthly S&P 500 total return index, the weekly MSCI Emerging Market index, and the weekly MSCI EAFE index. One reason to use weekly data is to have more data points in the tails given that the MSCI indexes

have relatively short histories. A few other equity and fixed income indexes, such as the MSCI UK, U.S. Long-Term Government Bond, Muni bonds, and some individual stocks were tested with the same methodologies and the results are similar, so they are not reported (e.g., Xiong, 2010).

We apply the maximum likelihood method to calibrate model parameters as previous studies did. The estimated parameters for the TLF, Student's t , normal-lognormal mixture, and GARCH(1,1) are shown in Tables 2, 3, 4, and 5, respectively. Since we are more interested in modeling downside risk, our goal is to fit the model's tail distribution to the empirical tail distribution in terms of CVaR through Monte Carlo simulations.

Table 6 focuses on nonstable distribution models and presents the empirical statistics as well as the Monte Carlo simulation results for the six models. The statistics for each model

Table 6 Statistics Summary for Historical Returns, as Well as Simulated Returns for Lognormal, Log-TLF, Log Student's t , Log Skewed Student's t , Normal-Lognormal Mixture, and GARCH(1,1) Models

GARCH(1,1)	0.16%	2.29%	0.10	4.20	-4.73%

are based on 1,000,000 simulated random returns that follow the corresponding distribution models. It can be seen that the lognormal model underestimates the *monthly* CVaR by 2.04% for the S&P 500, the *weekly* CVaR by 1.57% for the MSCI EM, and the *weekly* CVaR by 0.8% for the MSCI EAFE, respectively. The log Student's *t*-distribution, normal-lognormal mixture, and GARCH(1,1) have similar CVaR estimates, and all of them are better than the lognormal model but appear to underestimate the tail risk. On the other hand, both the log-TLF model and the log skewed Student's *t*-model provide a good fit for CVaR for all three indexes: S&P 500, MCSI EM, and MSCI EAFE.

Note that the log Student's *t*, normal-lognormal mixture, and GARCH(1,1) are positively skewed by design in a way similar to the lognormal distribution because we are working with the log-returns. The positive skewness resulted from taking the exponential function on the log-returns. None of these three models can account for negative skewness without modifications.

Therefore there are two reasons why the log-TLF and the log skewed Student's *t*-models do well in fitting the CVaR. First, their tails are appropriately fat, and second, both of them are able to capture negative skewness. For the TLF model, the fatness of the tail is controlled by α and the cutoff length and the skewness is controlled by β as shown in Table 2. For the skewed Student's *t*-distribution, the fatness of the tail is controlled by the degrees of freedom ν and the skewness is controlled by λ as shown in Table 3.

Figures 4, 5, and 6 compare the log-TLF model with other models in fitting the historical return distributions for monthly S&P 500 returns, weekly MSCI EM returns, and weekly MSCI EAFE returns, respectively. The figures confirm the results shown in Table 6. It can be seen that the log-TLF provides a good fit for the three indexes. The log skewed Student's *t* is almost as effective as the log-TLF model in fitting CVaRs. Compared to the log skewed Student's *t*-distribution, the log-TLF has a fatter but shorter tail because of the truncation. On the other hand, the normal-lognormal mixture

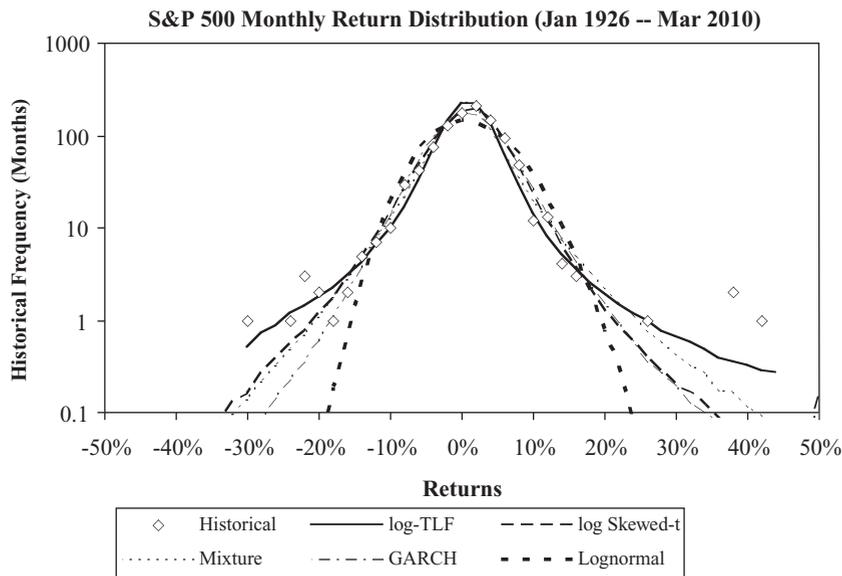

Figure 4 The Historical Distributions of S&P 500 Monthly Returns Fitted by the Log-TLF, Log Skewed Student's *t*, Normal-Lognormal Mixture, GARCH(1,1), and Lognormal Models

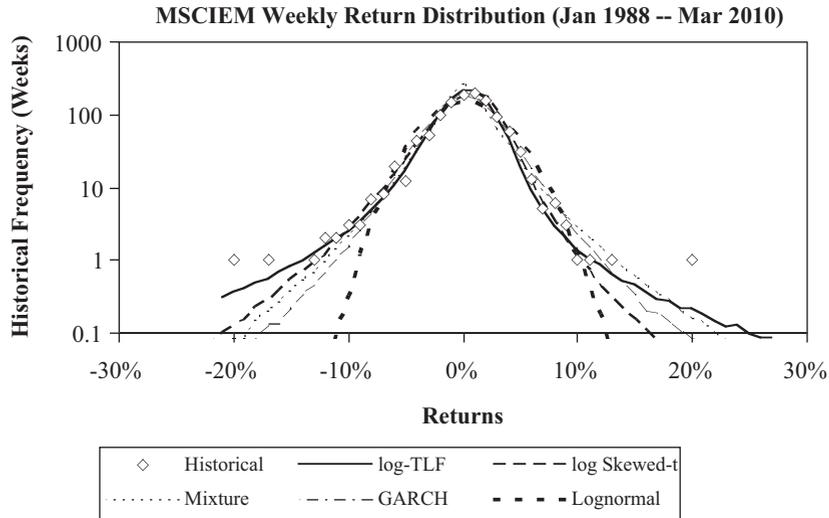

Figure 5 The Historical Distributions of MSCI EM Weekly Returns Fitted by the Log-TLF, Log Skewed Student's t , Normal-Lognormal Mixture, GARCH(1,1), and Lognormal Models

and GARCH(1,1) model have CVaRs that fall between those of the log-TLF and lognormal models. The finding for the log symmetric Student's t -distribution, not plotted due to space limitations, is similar to the normal-lognormal mixture and GARCH(1,1) model.

Table 7 summarizes the underestimated CVaRs for the six models that have been applied to the three indexes. The underestimated

tails are reported on a relative basis based on CVaR estimates shown in Table 6. For example, the lognormal model underestimates the monthly CVaR by a relative percentage of 18% ($= \frac{12.2 - 9.96}{12.2}$) for the S&P 500 index.

Averaging over the three indexes, the lognormal model underestimates the CVaR by about 18% on a relative basis. The normal-lognormal mixture, the log Student's t -distribution, and

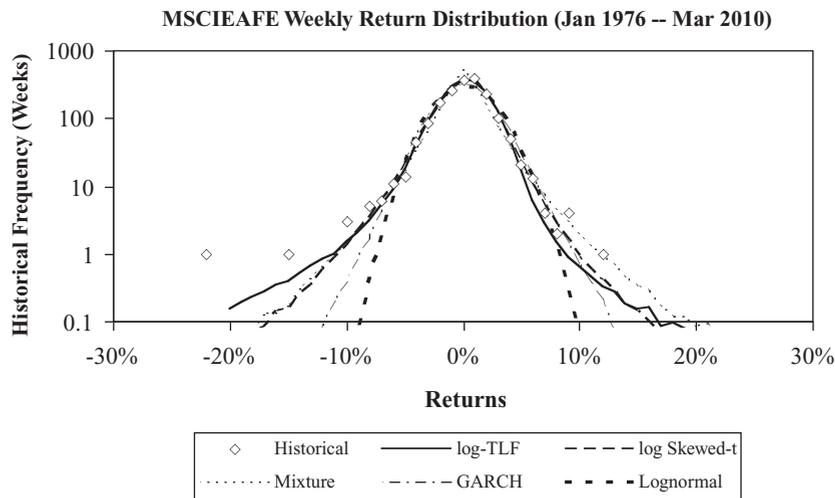

Figure 6 The Historical Distributions of MSCI EAFE Weekly Returns Fitted by the Log-TLF, Log Skewed Student's t , Normal-Lognormal Mixture, GARCH(1,1), and Lognormal Models

Table 7 Underestimated CVaRs in Relative Percentage for the Six Models

Index	S&P 500	MSCI EM	MSCI EAFE
Data Range	1926.1–2010.3	1988.1–2010.4	1976.1–2010.4
Number of Periods	1011 Monthly	1164 Weekly	1792 Weekly
Lognormal	18%	21%	15%
Log-TLF	0%	0%	0%
Log Student's t	11%	13%	6%
Log Student's Skewed t	2%	0%	0%
Normal-Lognormal Mixture	7%	9%	2%
GARCH(1,1)	12%	13%	10%

GARCH(1,1) with Gaussian innovations perform better than the lognormal model but appear to underestimate the CVaR by about 6%, 10%, and 12%, respectively. In contrast, both the log-TLF and log skewed t -distribution did a better job in modeling the CVaR.

KEY POINTS

- It is well known that asset returns often exhibit fat tails, negative skewness, time scaling, and volatility clustering. Fat-tailed and skewed models can be used to estimate the downside risk of assets. It is important that the selected models are able to capture fat tails and skewness, among others.
- The lognormal distribution is the fundamental assumption of many important financial models, but it has thin tails and thus can significantly underestimate the downside risk. On the other side, the Lévy stable distribution exhibits time scaling and fat tails, but it tends to overestimate the downside risk due to its infinite variance.
- The Student's t -distribution can model fat tails but not negative skewness. A modification results in the skewed Student's t -distribution, which can model both fat tails and negative skewness. However, both of them do not possess time scaling properties and cannot model volatility clustering.
- The normal-lognormal mixture is intuitive as it is directly linked to market microstructure such as information flow and trading volume. It has fat tails but cannot model negative

skewness. In general, it does not possess time scaling.

- The truncated Lévy flight model can describe the asymptotic return distributions measured at all frequencies and the scaling properties (self-similarities). More specifically, for a small time interval (e.g., a minute), this distribution approximates a Lévy stable distribution with Lévy stable scaling; while for a significantly large but finite time interval (e.g., a year), the truncated Lévy flight distribution slowly converges to a Gaussian distribution. It has finite four moments and can model both fat tails and negative skewness.
- The truncated Lévy flight or tempered stable distribution model cannot describe volatility clustering. In contrast, GARCH with Gaussian innovations can model volatility clustering but it is often found that the tail is not fat enough. Recent studies show that a GARCH with truncated Lévy flight innovations appears to be able to describe most of the stylized empirical facts: fat tails, skewness, and volatility clustering.

Moving Average Models for Volatility and Correlation, and Covariance Matrices

CAROL ALEXANDER, PhD

Professor of Finance, University of Sussex

Abstract: The volatilities and correlations of the returns on a set of assets, risk factors, or interest rates are summarized in a covariance matrix. This matrix lies at the heart of risk and return analysis. It contains all the information necessary to estimate the volatility of a portfolio, to simulate correlated values for its risk factors, to diversify investments, and to obtain efficient portfolios that have the optimal trade-off between risk and return. Both risk managers and asset managers require covariance matrices that may include very many assets or risk factors. For instance, in a global risk management system of a large international bank all the major yield curves, equity indexes, foreign exchange rates, and commodity prices will be encompassed in one very large dimensional covariance matrix.

Variances and *covariances* are parameters of the joint distribution of asset (or risk factor) returns. It is important to understand that they are unobservable. They can only be estimated or forecast within the context of a model. Continuous-time models, used for option pricing, are often based on stochastic processes for the variance and covariance. Discrete-time models, used for measuring portfolio risk, are based on time series models for variance and covariance. In each case, we can only ever estimate or forecast variance and covariance within the context of an assumed model.

It must be emphasized that there is no absolute “true” variance or covariance. What is “true” depends only on the statistical model.

Even if we knew for certain that our model was a correct representation of the data generation process, we could never measure the true variance and covariance parameters exactly because pure variance and covariance are not traded in the market. An exception to this is the futures on *volatility* indexes such as the Chicago Board Options Exchange Volatility Index (VIX). Hence, some risk-neutral volatility is observed. However, this entry deals with covariance matrices in the physical measure.

Estimating a variance according to the formulas given by a model, using historical data, gives an observed variance that is “realized” by the process assumed in our model. But this “realized variance” is still only ever an

estimate. Sample estimates are always subject to sampling error, which means that their value depends on the sample data used.

In summary, different statistical models can give different estimates of variance and covariance for two reasons:

- A true variance (or covariance) is different between models. As a result, there is a considerable degree of model risk inherent in the construction of a covariance or *correlation matrix*. That is, very different results can be obtained using two different statistical models even when they are based on exactly the same data.
- The estimates of the true variances (and covariances) are subject to sampling error. That is, even when we use the same model to estimate a variance, our estimates will differ depending on the data used. Both changing the sample period and changing the frequency of the observations will affect the covariance matrix estimate.

This entry covers moving average discrete-time series models for variance and covariance, focusing on the practical implementation of the approach and providing an explanation for their advantages and limitations. Other statistical tools are described in Alexander (2008a, Chapter 9).

BASIC PROPERTIES OF COVARIANCE AND CORRELATION MATRICES

The covariance matrix is a square, symmetric matrix of variance and covariances of a set of m returns on assets, or on risk factors, given by:

$$\mathbf{V} = \begin{pmatrix} \sigma_1^2 & \sigma_{12} & \dots & \dots & \sigma_{1m} \\ \sigma_{21} & \sigma_2^2 & \dots & \dots & \sigma_{2m} \\ \sigma_{31} & \sigma_{32} & \sigma_3^2 & \dots & \sigma_{3m} \\ \dots & \dots & \dots & \dots & \dots \\ \sigma_{m1} & \dots & \dots & \dots & \sigma_m^2 \end{pmatrix} \quad (1)$$

Since

$$\begin{pmatrix} \sigma_1^2 & \sigma_{12} & \dots & \dots & \sigma_{1m} \\ \sigma_{21} & \sigma_2^2 & \dots & \dots & \sigma_{2m} \\ \sigma_{31} & \sigma_{32} & \sigma_3^2 & \dots & \sigma_{3m} \\ \dots & \dots & \dots & \dots & \dots \\ \sigma_{m1} & \dots & \dots & \dots & \sigma_m^2 \end{pmatrix} = \begin{pmatrix} \sigma_1^2 & \varrho_{12}\sigma_1\sigma_2 & \dots & \dots & \varrho_{1m}\sigma_1\sigma_m \\ \varrho_{21}\sigma_2\sigma_1 & \sigma_2^2 & \dots & \dots & \varrho_{2m}\sigma_2\sigma_m \\ \varrho_{31}\sigma_3\sigma_1 & \varrho_{32}\sigma_3\sigma_2 & \sigma_3^2 & \dots & \varrho_{3m}\sigma_3\sigma_m \\ \dots & \dots & \dots & \dots & \dots \\ \varrho_{m1}\sigma_m\sigma_1 & \dots & \dots & \dots & \sigma_m^2 \end{pmatrix}$$

a covariance matrix can also be expressed as

$$\mathbf{V} = \mathbf{D}\mathbf{C}\mathbf{D} \quad (2)$$

where \mathbf{D} is a diagonal matrix with elements equal to the standard deviations of the returns and \mathbf{C} is the correlation matrix of the returns. That is:

$$\begin{pmatrix} \sigma_1^2 & \sigma_{12} & \dots & \dots & \sigma_{1m} \\ \sigma_{12} & \sigma_2^2 & \dots & \dots & \sigma_{2m} \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \sigma_{1m} & \sigma_{2m} & \dots & \dots & \sigma_m^2 \end{pmatrix} = \begin{pmatrix} \sigma_1 & 0 & \dots & \dots & 0 \\ 0 & \sigma_2 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & 0 \\ 0 & \dots & \dots & 0 & \sigma_m \end{pmatrix} \times \begin{pmatrix} 1 & \varrho_{12} & \dots & \dots & \varrho_{1m} \\ \varrho_{12} & 1 & \dots & \dots & \varrho_{2m} \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \varrho_{1m} & \varrho_{2m} & \dots & \dots & 1 \end{pmatrix} \begin{pmatrix} \sigma_1 & 0 & \dots & \dots & 0 \\ 0 & \sigma_2 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & 0 \\ 0 & \dots & \dots & 0 & \sigma_m \end{pmatrix}$$

Hence, the covariance matrix is simply a mathematically convenient way to express the asset volatilities and their *correlations*.

To illustrate how to estimate an annual covariance matrix and a 10-day covariance matrix, assume three assets that have the following volatilities and correlations:

Asset 1 volatility	20%	Asset 1–Asset 2 correlation	0.8
Asset 2 volatility	10%	Asset 1–Asset 3 correlation	0.5
Asset 3 volatility	15%	Asset 3–Asset 2 correlation	0.3

Then,

$$\mathbf{D} = \begin{pmatrix} 0.2 & 0 & 0 \\ 0 & 0.1 & 0 \\ 0 & 0 & 0.15 \end{pmatrix} \quad \mathbf{C} = \begin{pmatrix} 1 & 0.8 & 0.5 \\ 0.8 & 1 & 0.3 \\ 0.5 & 0.3 & 1 \end{pmatrix}$$

So the annual covariance matrix \mathbf{DCD} is:

$$\begin{pmatrix} 0.2 & 0 & 0 \\ 0 & 0.1 & 0 \\ 0 & 0 & 0.15 \end{pmatrix} \begin{pmatrix} 1 & 0.8 & 0.5 \\ 0.8 & 1 & 0.3 \\ 0.5 & 0.3 & 1 \end{pmatrix} \begin{pmatrix} 0.2 & 0 & 0 \\ 0 & 0.1 & 0 \\ 0 & 0 & 0.15 \end{pmatrix} \\ = \begin{pmatrix} 0.04 & 0.016 & 0.015 \\ 0.016 & 0.01 & 0.0045 \\ 0.015 & 0.0045 & 0.0225 \end{pmatrix}$$

To find a 10-day covariance matrix in this simple case, one is forced to assume the returns are independent and identically distributed in order to use the square root of time rule: that is, that the h -day covariance matrix is h times the 1 day covariance matrix. Put another way, the 10-day covariance matrix is obtained from the annual matrix by dividing each element by 25, assuming there are 250 trading days per year.

Alternatively, we can obtain the 10-day matrix using the 10-day volatilities in \mathbf{D} . Note that under the independent and identically distributed returns assumption \mathbf{C} should not be affected by the holding period. That is,

$$\mathbf{D} = \begin{pmatrix} 0.04 & 0 & 0 \\ 0 & 0.02 & 0 \\ 0 & 0 & 0.03 \end{pmatrix} \mathbf{C} = \begin{pmatrix} 1 & 0.8 & 0.5 \\ 0.8 & 1 & 0.3 \\ 0.5 & 0.3 & 1 \end{pmatrix}$$

because each volatility is divided by 5 (that is, the square root of 25). Then we get the same result as above, that is

$$\begin{pmatrix} 0.04 & 0 & 0 \\ 0 & 0.02 & 0 \\ 0 & 0 & 0.03 \end{pmatrix} \begin{pmatrix} 1 & 0.8 & 0.5 \\ 0.8 & 1 & 0.3 \\ 0.5 & 0.3 & 1 \end{pmatrix} \\ \times \begin{pmatrix} 0.04 & 0 & 0 \\ 0 & 0.02 & 0 \\ 0 & 0 & 0.03 \end{pmatrix} = \begin{pmatrix} 0.16 & 0.064 & 0.06 \\ 0.064 & 0.04 & 0.018 \\ 0.06 & 0.018 & 0.09 \end{pmatrix} \\ \times 10^{-2}$$

Note that \mathbf{V} is positive semidefinite if and only if \mathbf{C} is positive semidefinite. \mathbf{D} is always positive definite. Hence, the positive semidefiniteness of \mathbf{V} only depends on the way we construct the correlation matrix. It is quite a challenge to generate meaningful, positive semidefinite correlation matrices that are large enough for managers to be able to net the risks across all positions in a firm. Simplifying assumptions are necessary. For example, *RiskMetrics* (1996) uses a very simple methodology based on moving

averages in order to estimate extremely large positive definite matrices covering hundreds of risk factors for global financial markets. (This is discussed further below.)

EQUALLY WEIGHTED AVERAGES

This section describes how volatility and correlation are estimated and forecast by applying equal weights to certain historical time series data. We outline a number of pitfalls and limitations of this approach and as a result recommend that these models be used as an indication of the possible range for long-term volatility and correlation. As we shall see, these models are of dubious validity for short-term volatility and correlation forecasting.

In the following, for simplicity, we assume that the mean return is zero and that returns are measured at the daily frequency, unless specifically stated otherwise. A zero mean return is a standard assumption for risk assessments based on time series of daily data, but if returns are measured over longer intervals it may not be very realistic. Then the equally weighted estimate of the variance of returns is the average of the squared returns and the corresponding volatility estimate is the square root of this expressed as an annual percentage. The equally weighted estimate of the covariance of two returns is the average of the cross products of returns and the equally weighted estimate of their correlation is the ratio of the covariance to the square root of the product of the two variances.

Equal weighting of historical data was the first widely accepted statistical method for forecasting volatility and correlation of financial asset returns. For many years, it was the market standard to forecast average volatility over the next h days by taking an equally weighted average of squared returns over the previous h days. This method was called the historical volatility forecast. Nowadays, many different statistical forecasting techniques can be applied to

historical time series data so it is confusing to call this equally weighted method the historical method. However, this rather confusing terminology remains standard.

Perceived changes in volatility and correlation have important consequences for all types of risk management decisions, whether to do with capitalization, resource allocation, or hedging strategies. Indeed it is these parameters of the returns distributions that are the fundamental building blocks of market risk assessment models. It is therefore essential to understand what type of variability in returns the model has measured. The model assumes that an independently and identically distributed process generates returns. That is, both volatility and correlation are constant and the “square root of time rule” applies. This assumption has important ramifications and we shall take care to explain these very carefully.

Statistical Methodology

The methodology for constructing a covariance matrix based on equally weighted averages can be described in very simple terms. Consider a set of time series $\{r_{i,t}\}$ $i = 1, \dots, m$; $t = 1, \dots, T$. Here the subscript i denotes the asset or risk factor, and t denotes the time at which each return is measured. We shall assume that each return has a zero mean. Then an unbiased estimate of the unconditional variance of the i th returns variable at time t , based on the T most recent daily returns as:

$$\hat{\sigma}_{i,t}^2 = \frac{\sum_{l=1}^T r_{i,t-l}^2}{T} \quad (3)$$

The term “unbiased estimator” means the expected value of the estimator is equal to the true value.

Note that (3) gives an unbiased estimate of the variance but this is not the same as the square of an unbiased estimate of the standard deviation. That is, $\sqrt{E(\hat{\sigma}^2)} = \sigma$ but $E(\hat{\sigma}) \neq \sigma$. So really the hat ‘^’ should be written over the whole of σ^2 .

But it is generally understood that the notation $\hat{\sigma}^2$ is used to denote the estimate or forecast of a variance, and not the square of an estimate of the standard deviation. So, in the case that the mean return is zero, we have

$$E(\hat{\sigma}^2) = \sigma^2$$

If the mean return is not assumed to be zero we need to estimate this from the sample, and this places a (linear) constraint on the variance estimated from sample data. In that case, to obtain an unbiased estimate we should use

$$s_{i,t}^2 = \frac{\sum_{l=1}^T (r_{i,t-l} - \bar{r}_i)^2}{T-1} \quad (4)$$

where \bar{r}_i is the average return on the i th series, taken over the whole sample of T data points. The mean-deviation form above may be useful for estimating variance using monthly or even weekly data over a period for which average returns are significantly different from zero. However with daily data the average return is usually very small and since, as we shall see below, the errors induced by other assumptions are huge relative to the error induced by assuming the mean is zero, we normally use the form (3).

Similarly, an unbiased estimate of the unconditional covariance of two zero mean returns at time t , based on the T most recent daily returns is:

$$\hat{\sigma}_{i,j,t} = \frac{\sum_{l=1}^n r_{i,t-l} r_{j,t-l}}{T} \quad (5)$$

As mentioned above, we would normally ignore the mean deviation adjustment with daily data.

The equally weighted unconditional covariance matrix estimate at time t for a set of k returns is thus $\hat{\mathbf{V}}_t = (\hat{\sigma}_{i,j,t})$ for $i, j = 1, \dots, k$. Loosely speaking, the term “unconditional” refers to the fact that it is the overall or long-run or average variance that we are estimating, as opposed to a conditional variance that can

change from day to day and is sensitive to recent events.

As mentioned in the introduction, we use the term “volatility” to refer to the annualized standard deviation. The equally weighted estimates of volatility and correlation are obtained in two stages. First, one obtains an unbiased estimate of the unconditional covariance matrix using equally weighted averages of squared returns and cross products of returns and the same number n of data points each time. Then these are converted into volatility and correlation estimates by applying the usual formulas. For instance, if the returns are measured at the daily frequency and there are 250 trading days per year:

$$\text{Equally weighted volatility} = \hat{\sigma}_t \sqrt{250} \quad (6)$$

$$\text{Equally weighted correlation} = \hat{\varrho}_{ij,t} = \frac{\hat{\sigma}_{ij,t}}{\hat{\sigma}_{i,t} \hat{\sigma}_{j,t}}$$

In the equally weighted methodology the forecasted covariance matrix is simply taken to be the current estimate, there being nothing else in the model to distinguish an estimate from a forecast. The original risk horizon for the covariance matrix is given by the frequency of the data—daily returns will give the 1-day covariance matrix forecast, weekly returns will give the 1-week covariance matrix forecast, and so forth. Then, since the model assumes that returns are independently and identically distributed we can use the square root of time rule to convert a 1-day forecast into an h -day covariance matrix forecast, simply by multiplying each element of the 1-day matrix by h . Similarly, a monthly forecast can be obtained for the weekly forecast by multiplying each element by 4, and so forth.

Having obtained a forecast of variance, volatility, covariance, and correlation we should ask: How accurate is this forecast? For this we could provide either a confidence interval, that is, a range within which we are fairly certain that the true parameter will lie, or a standard error for our parameter estimate. *The stan-*

dard error gives a measure of precision of the estimate and can be used to test whether the true parameter can take a certain value, or lie in a given range. The next few sections show how such confidence intervals and standard errors can be constructed.

Confidence Intervals for Variance and Volatility

A confidence interval for the true variance σ^2 when it is estimated by an equally weighted average can be derived using a straightforward application of sampling theory. Assuming the variance estimate is based on n normally distributed returns with an assumed mean of zero, then $T\hat{\sigma}^2/\sigma^2$ will have a chi-squared distribution with T degrees of freedom (see Freund, 1998). A $100(1 - \alpha)\%$ two-sided confidence interval for $T\hat{\sigma}^2/\sigma^2$ would therefore take the form $(\chi_{1-\alpha/2,T}^2, \chi_{\alpha/2,T}^2)$ and a straightforward calculation gives the associated confidence interval for the variance σ^2 as:

$$\left(\frac{T\hat{\sigma}^2}{\chi_{\alpha/2,T}^2}, \frac{T\hat{\sigma}^2}{\chi_{1-\alpha/2,T}^2} \right) \quad (7)$$

For example, a 95% confidence interval for an equally weighted variance forecast based on 30 observations is obtained using the upper and lower chi-squared critical values:

$$\chi_{0.975,30}^2 = 16.791 \quad \text{and} \quad \chi_{0.025,30}^2 = 46.979$$

So the confidence interval is $(0.6386\hat{\sigma}^2, 1.7867\hat{\sigma}^2)$ and exact values are obtained by substituting in the value of the variance estimate.

Figure 1 illustrates the upper and lower bounds for a confidence interval for a variance forecast when the equally weighted variance estimate is one. We see that as the sample size T increases, the width of the confidence interval decreases, markedly so as T increases from low values.

We can turn now to the confidence intervals that would apply to an estimate of volatility. Recall that volatility, being the square root of the variance, is simply a monotonic decreasing

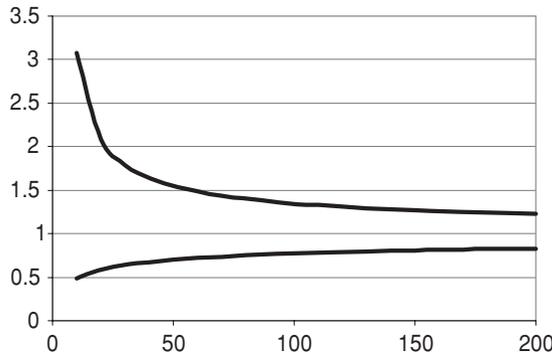

Figure 1 Confidence Interval for Variance Forecasts

transformation of the variance. Percentiles are invariant under any strictly monotonic increasing transformation. That is, if f is any monotonic increasing function of a random variable X , then:

$$P(c_l < X < c_u) = P(f(c_l) < f(X) < f(c_u)) \quad (8)$$

Property (8) provides a confidence interval for a historical volatility based on the confidence interval (7). Since \sqrt{x} is a monotonic increasing function of x , one simply takes the square root of the lower and upper bounds for the equally weighted variance. For instance if a 95% confidence interval for the variance is [16%, 64%] then a 95% for the associated volatility is [4%, 8%]. And, since x^2 is also monotonic increasing for $x > 0$, the converse also applies. Thus if a 95% confidence interval for the volatility is [4%, 8%] then a 95% for the associated variance is [16%, 64%].

Standard Errors for Equally Weighted Average Estimators

An estimator of any parameter has a distribution and a point estimate of volatility is just the expectation of the distribution of the volatility estimator. The distribution function of the equally weighted average volatility estimator is not just square root of the distribution function of the corresponding variance estimate. In-

stead, it may be derived from the distribution of the variance estimator via a simple transformation. Since volatility is the square root of the variance, the density function of the volatility estimator is

$$g(\hat{\sigma}) = 2\hat{\sigma}h(\hat{\sigma}^2) \quad \text{for } \hat{\sigma} > 0 \quad (9)$$

where $h(\hat{\sigma}^2)$ is the density function of the variance estimator. This follows from the fact that if y is a monotonic and differentiable function of x , then their probability densities $g(\cdot)$ and $h(\cdot)$ are related as $g(y) = |dx/dy|h(x)$ (see Freund, 1998). Note that when $y = \sqrt{x}$, $|dx/dy| = 2y$ and so $g(y) = 2yh(x)$.

In addition to the point estimate or expectation, one might also estimate the standard deviation of the distribution of the estimator. This is called the "standard error" of the estimate. The standard error determines the width of a confidence interval for a forecast and it indicates how reliable a forecast is considered to be. The wider the confidence interval, the more uncertainty there is in the forecast.

Standard errors for equally weighted average variance estimates are based on a normality assumption for the returns. Moving average models assume that returns are independent and identically distributed. Now assuming normality also, so that the returns are normally and independently distributed, denoted by $NID(0, \sigma^2)$, we apply the variance operator to (3). Note that if X_i are independent random variables ($i = 1, \dots, T$), then $f(X_i)$ are also independent for any monotonic differentiable function f . Hence, the squared returns are independent, and we have:

$$V(\hat{\sigma}_t^2) = \sum_{i=1}^T V(r_{t-i}^2)/T^2 \quad (10)$$

Since $V(X) = E(X^2) - E(X)^2$ for any random variable X , $V(r_t^2) = E(r_t^4) - E(r_t^2)^2$. By the zero mean assumption $E(r_t^2) = \sigma^2$ and assuming normality, $E(r_t^4) = 3\sigma^4$. Hence for every t :

$$V(r_t^2) = 3\sigma^4 - \sigma^4 = 2\sigma^4$$

and substituting this into (10) gives

$$V(\hat{\sigma}_t^2) = \frac{2\sigma^4}{T} \quad (11)$$

Hence, the standard error of an equally weighted average variance estimate based on T zero mean squared returns is $\sigma^2\sqrt{\frac{2}{T}}$ or simply $\sqrt{\frac{2}{T}}$, when expressed as a percentage of the variance. For instance, the standard error of the variance estimate is 20% when 50 observations are used in the estimate, and 10% when 200 observations are used in the estimate.

What about the standard error of the volatility estimator? To derive this, we first prove that for any continuously differentiable function f and random variable X :

$$V(f(X)) \approx f'(E(X))^2 V(X) \quad (12)$$

To show this, we take a second order Taylor expansion of f about the mean of X and then take expectations. See Alexander (2008a), Chapter 1. This gives:

$$E(f(X)) \approx f(E(X)) + \frac{1}{2}f''(E(X))V(X) \quad (13)$$

Similarly,

$$E(f(X)^2) \approx f(E(X))^2 + (f'(E(X)))^2 + f(E(X))f''(E(X))V(X) \quad (14)$$

again ignoring higher-order terms. The result (12) follows on noting that:

$$V(f(X)) = E(f(X)^2) - E(f(X))^2$$

We can now use (11) and (12) to derive the standard error of a historical volatility estimate. From (12) we have $V(\hat{\sigma}^2) \approx (2\hat{\sigma})^2 V(\hat{\sigma})$ and so:

$$V(\hat{\sigma}) \approx \frac{V(\hat{\sigma}^2)}{(2\hat{\sigma})^2} \quad (15)$$

Now using (11) in (15) we obtain the variance of the volatility estimator as:

$$V(\hat{\sigma}) = \left(\frac{1}{2\sigma^2}\right) \left(\frac{2\sigma^4}{T}\right) = \frac{\sigma^2}{2T} \quad (16)$$

so the standard error of the volatility estimator as a percentage of volatility is $(2T)^{-1/2}$. This result tells us that the standard error of the volatility estimator (as a percentage of volatility) is approximately one-half the size of the standard error of the variance (as a percentage of the variance).

Thus, as a percentage of the volatility, the standard error of the historical volatility estimator is approximately 10% when 50 observations are used in the estimate, and 5% when 200 observations are used in the estimate. The standard errors on *equally weighted moving average* volatility estimates become very large when only a few observations are used. This is one reason why it is advisable to use a long averaging period in historical volatility estimates.

It is harder to derive the standard error of an equally weighted average correlation estimate. However, it can be shown that

$$V(\hat{\rho}_{ij}) = \frac{1 - \rho^2}{T - 2} \quad (17)$$

and so we have the following t -distribution for the correlation estimate divided by its standard error:

$$\frac{\hat{\rho}_{ij}\sqrt{T-2}}{\sqrt{1-\hat{\rho}_{ij}^2}} \sim t_{T-2} \quad (18)$$

In particular, the significance of a correlation estimate depends on the number of observations that are used in the sample.

To illustrate testing for the significance of historical correlation, suppose that a historical correlation estimate of 0.2 is obtained using 38 observations. Is this significantly greater than zero? The null hypothesis is $H_0 : \rho = 0$, the alternative hypothesis is $H_1 : \rho > 0$, and the test statistic is (18). Computing the value of this statistic given our data gives

$$t = \frac{0.2 \times 6}{\sqrt{1 - 0.04}} = \frac{12}{\sqrt{96}} = \frac{3}{\sqrt{6}} = \sqrt{1.5} = 1.225$$

Even the 10% upper critical value of the t -distribution with 36 degrees of freedom is greater than this value (it is in fact 1.3). Hence

we cannot reject the null hypothesis: 0.2 is not significantly greater than zero when estimated from 38 observations. However, if the same value of 0.2 had been obtained from a sample with, say, 100 observations our t -value would have been 2.02, which is significantly positive at the 2.5% level because the upper 2.5% critical value of the t -distribution with 98 degrees of freedom is 1.98.

Equally Weighted Moving Average Covariance Matrices

An equally weighted “moving” average is calculated on a fixed size data “window” that is rolled through time, each day adding the new return and taking off the oldest return. The length of this window of data, also called the “look-back” period or averaging period, is the time interval over which we compute the average of the squared returns (for variance) or the average cross products of returns (for covariance). In the past, several large financial institutions have lost a lot of money because they used the equally weighted moving average model inappropriately. I would not be surprised if much more money was lost because of the inexperienced use of this model in the future. The problem is not the model itself—after all, it is a perfectly respectable statistical formula for an unbiased estimator—the problems arise from its inappropriate application within a time series context.

A (fallacious) argument goes as follows: Long-term predictions should be unaffected by short-term phenomena such as “volatility clustering” so it will be appropriate to take the average over a very long historic period. But short-term predictions should reflect current market conditions, which means that only the immediate past returns should be used. Some people use an historical averaging period of T days in order to forecast forward T days; others use slightly longer historical periods than the forecast period. For example, for a 10-day fore-

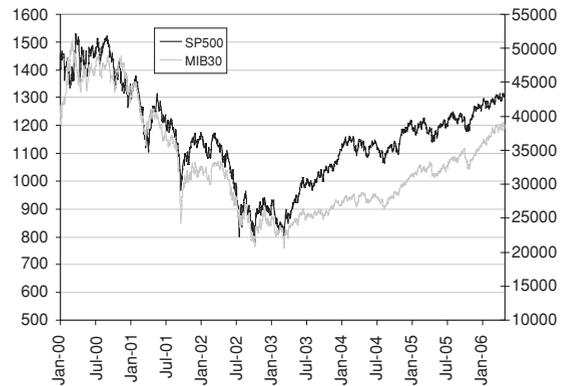

Figure 2 MIB 30 and S&P 100 Daily Close

cast, some practitioners might look back 30 days or more. But this apparently sensible approach actually induces a major problem. If one or more extreme returns is included in the averaging period, the volatility (or correlation) forecast can suddenly jump downward to a completely different level on a day when absolutely nothing happened in the markets. And prior to mysteriously jumping down, a historical forecast will be much larger than it should be.

Figure 2 illustrates the daily closing prices of the Italian MIB 30 stock index between the beginning of January 2000 and the end of April 2006 and compares these with the S&P 100 index prices over the same period. The prices were downloaded from Yahoo! Finance. We will show how to calculate the 30-day, 60-day, and 90-day historical volatilities of these two stock indexes and compare them graphically.

We construct three different equally weighted moving average volatility estimates for the MIB 30 index, with $T = 30$ days, 60 days and 90 days, respectively. The result is shown in Figure 3. Let us first focus on the early part of the data period and on the period after the September 11, 2001 (9/11), terrorist attack in particular. The Italian index reacted to the news far more than most other indexes. The volatility estimate based on 30 days of data jumped from 15% to nearly 50% in one day, and then continued to rise further, up to 55%. Then, suddenly, exactly 30 days after the event, 30-day volatility jumped down again

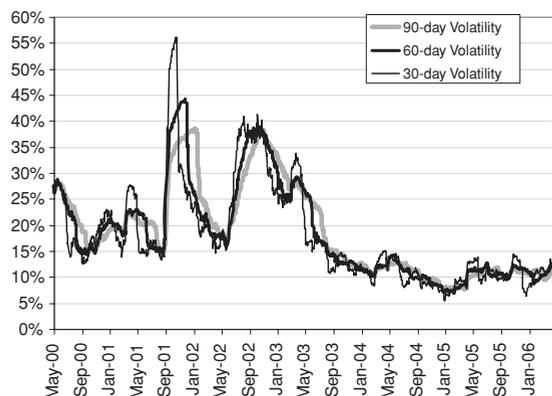

Figure 3 Equally Weighted Moving Average Volatility Estimates of the MIB 30 Index

to 30%. But nothing particular happened in the Italian markets on that day. The drastic fall in volatility was just a “ghost” of the 9/11 terrorist attack: It was no reflection at all of the real market conditions at that time.

Similar features are apparent in the 60-day and 90-day volatility series. Each series jumps up immediately after the 9/11 event, and then, either 60 or 90 days afterward, jumps down again. On November 9, 2001, the three different look-back periods gave volatility estimates of 30%, 43%, and 36%, but they are all based on the same underlying data and the same independent and identically distributed assumption for the returns! Other such ghost features are evident later in the period, for instance, in March 2001 and March 2003. Later on in the period, the choice of look-back period does not make so much difference: The three volatility estimates are all around the 10% level.

Case Study: Measuring the Volatility and Correlation of U.S. Treasuries

The interest rate covariance matrix is an important determinant of the value at risk (VaR) of a cash flow. In this section, we show how to estimate the volatilities and correlations of different maturity U.S. zero-coupon interest rates using the equal weighted moving average

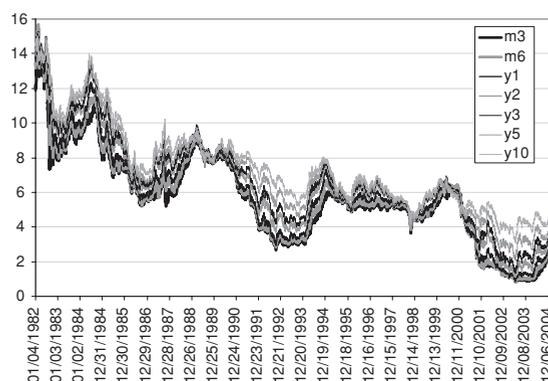

Figure 4 U.S. Treasury Rates

Source: <http://www.federalreserve.gov/releases/h15/data.htm>.

method. Consider daily data on constant maturity U.S. Treasury rates between January 4, 1982 and March 11, 2005. The rates are graphed in Figure 4.

It is evident that rates followed marked trends over the period. From a high of about 15% in 1982, by the end of the same period the short-term rates were below 3%. Also, periods where the term structure of interest rates is relatively flat are interspersed with periods when the term structure is upward sloping, sometimes with the long-term rates being several percent higher than the short-term rates. During the upward sloping yield curve regimes, especially the latter one from 2000 to 2005, the medium- to long-term interest rates are more volatile than the short-term rates, in absolute terms. However, it is not clear which rates are the most volatile in relative terms, as the short rates are much lower than the medium to long-term rates. There are three decisions that must be made:

Decision 1: How long an historical data period should be used?

Decision 2: Which frequency of observations should be used?

Decision 3: Should the volatilities and correlations be measured directly on absolute changes in interest rates, or should they be measured on relative changes and then the result converted into absolute terms?

Decision 1: How Long a Historical Data Period Should Be Used?

The equally weighted historical method gives an average volatility, or correlation, over the sample period chosen. The longer the data period, the less relevant that average may be today (that is, at the end of the sample). Looking at Figure 4, it may be thought that data from 2000 onward, and possibly also data during the first half of the 1990s, are relevant today. However, we may not wish to include data from the latter half of the 1990s, when the yield curve was flat.

Decision 2: Which Frequency of Observations Should Be Used?

This is an important decision, which depends on the end use of the covariance matrix. We can always use the square root of time rule to convert the holding period of a covariance matrix. For instance, a 10-day covariance matrix can be converted into a 1-day matrix by dividing each element by 10; and it can be converted into an annual covariance matrix by multiplying each element by 25. However, this conversion is based on the assumption that variations in interest rates are independent and identically distributed. Moreover, the data become more noisy when we use high-frequency data. For instance, daily variations may not be relevant if we only ever want to measure covariances over a 10-day period. The extra variation in the daily data is not useful, and the crudeness of the square root of time rule will introduce an error. To avoid the use of crude assumptions it is best to use a data frequency that corresponds to the holding period of the covariance matrix.

However, the two decisions above are linked. For instance, if data are quarterly, we need a data period of five or more years; otherwise, the standard error of the estimates will be very large. But then our quarterly covariance matrix represents an average over many years that may not be thought of as relevant today. If data are daily, then just one year of data provides plenty of observations to measure the historical model

volatilities and correlations accurately. Also, a history of one year is a better representation of today's markets than a history of five or more years. However, if it is a quarterly covariance matrix that we seek, we have to apply the square root of time rule to the daily matrix. Moreover, the daily variations that are captured by the matrix may not be relevant information at the quarterly frequency.

In summary, there may be a trade-off between using data at the relevant frequency and using data that are relevant today. It should be noted that such a trade-off between Decisions 1 and 2 above applies to the measurement of risk in all asset classes and not only to interest rates.

In interest rates, there is another decision to make before we can measure risk. Since the price value of a basis point (PV01) sensitivity vector is usually measured in basis points, an interest rate covariance matrix is also usually expressed in basis points. Hence, we have Decision 3.

Decision 3: Absolute versus Relative Measures

Should the volatilities and correlations be measured directly on absolute changes in interest rates, or should they be measured on relative changes and then the result converted into absolute terms?

If rates have been trending over the data period the two approaches are likely to give very different results. One has to make a decision about whether relative changes or absolute changes are the more stable. In these data, for example, an absolute change of 50 basis points in 1982 was relatively small, but in 2005 it would have represented a very large change. Hence, to estimate an average daily covariance matrix over the entire data sample, it may be more reasonable to suppose that the volatilities and correlations should be measured on relative changes and then converted to absolute terms.

Note, however, that a daily matrix based on the entire sample would capture a very long-term average of volatilities and correlations between daily U.S. Treasury rates, indeed it

is a 22-year average that includes several periods of different regimes in interest rates. Such a long-term average, which is useful for long-term forecasts, may be better based on lower frequency data (e.g., monthly). For a 1-day forecast horizon, we shall use only the data since January 1, 2000.

To make the choice for Decision 3, we take both the relative daily changes (the difference in the log rates) and the absolute daily changes (the differences in the rates, in basis-point terms). Then we obtain the standard deviation, correlation, and covariance in each case, and in the case of relative changes we translate the results into absolute terms. We now compare results based on relative changes with results based on absolute changes. The correlation matrix estimates based on the period January 1, 2000, to March 11, 2005, are shown in Table 1.

The matrices are similar. Both matrices display the usual characteristics of an interest rate term structure: Correlations are higher at the long end than the short end, and they decrease as the difference between the two maturities increases.

Table 1 Correlation of U.S. Treasuries

(a) Based on Relative Changes							
	m3	m6	y1	y2	y3	y5	y10
m3	1.00						
m6	0.77	1.00					
y1	0.53	0.84	1.00				
y2	0.44	0.69	0.88	1.00			
y3	0.42	0.66	0.84	0.97	1.00		
y5	0.39	0.62	0.79	0.91	0.96	1.00	
y10	0.32	0.54	0.71	0.82	0.88	0.95	1.00
(b) Based on Absolute Changes							
	m3	m6	y1	y2	y3	y5	y10
m3	1.00						
m6	0.79	1.00					
y1	0.54	0.81	1.00				
y2	0.40	0.67	0.87	1.00			
y3	0.37	0.62	0.83	0.97	1.00		
y5	0.33	0.57	0.77	0.92	0.95	1.00	
y10	0.26	0.48	0.69	0.84	0.88	0.95	1.00

Table 2 compares the volatilities of the interest rates obtained using the two methods. The figures in the last row of each table represent an average absolute volatility for each rate over the period January 1, 2000 to March 11, 2005. Basing this first on relative changes in interest rates, Table 2(a) gives the standard deviation of relative returns volatility in the first row. The long-term rates have the lowest standard deviations, and the medium-term rates have the highest standard deviations. These standard deviations are then annualized (by multiplying by $\sqrt{250}$, assuming each rate is independent and identically distributed) and multiplied by the level of the interest rate on March 11, 2005. There was a very marked upward sloping yield curve on March 11, 2005. Hence the long-term rates are more volatile than the short-term rates: For instance, the 3-month rate has an absolute volatility of about 76 basis points, but the absolute volatility of the 10-year rates is about 98 basis points.

Table 2(b) measures the standard deviation of absolute changes in interest rates over the period January 1, 2000 to March 11, 2005, and then converts this into volatility by multiplying by $\sqrt{250}$. We again find that the long-term rates are more volatile than the short-term rates; for instance, the six-month rate has an absolute volatility of about 62 basis points, but the absolute volatility of the five-year rates is about 106 bps. (It should be noted that it is quite unusual for long-term rates to be more volatile than short-term rates. But from 2000 to 2004 the U.S. Fed was exerting a lot of control on short-term rates, to bring down the general level of interest rates. However, the market expected interest rates to rise, because the yield curve was upward sloping during most of the period.) We find that correlations were similar, whether based on relative or absolute changes. But Table 2 shows there is a substantial difference between the volatilities obtained using the two methods. When volatilities are based directly on the absolute changes, they are slightly lower at the short end and substantially lower for the medium-term rates.

Table 2 Volatility of U.S. Treasuries

(a) Based on Relative Changes							
	m3	m6	y1	y2	y3	y5	y10
Standard deviation	0.0174	0.0172	0.0224	0.0267	0.0239	0.0187	0.0136
Yield curve on March 11, 2005	2.76	3.06	3.28	3.73	3.94	4.22	4.56
Absolute volatility (in basis points)	75.89	83.08	116.23	157.61	148.71	124.88	98.21
(b) Based on Absolute Changes							
	m3	m6	y1	y2	y3	y5	y10
Standard deviation	4.4735	3.9459	4.7796	6.4626	6.7964	6.7615	6.1738
Absolute volatility (in basis points)	70.73	62.39	75.57	102.18	107.46	106.91	97.62

Finally, we obtain the annual covariance matrix of absolute changes (in basis point terms) by multiplying the correlation matrix by the appropriate absolute volatilities and to obtain the one-day covariance matrix we divide by 250. The results are shown in Table 3. Depending on whether we base estimates of volatility and correlation on relative or absolute changes in interest rates, the covariance matrix can be very different. In this case, it is short-term and medium-term volatility estimates that are the most affected by the choice. Given that we have used the equally weighted average method-

Table 3 One-Day Covariance Matrix of U.S. Treasuries, in Basis Points

(a) Based on Relative Changes							
	m3	m6	y1	y2	y3	y5	y10
m3	23.04						
m6	19.46	27.61					
y1	18.85	32.26	54.04				
y2	20.87	36.29	64.50	99.36			
y3	18.98	32.86	58.28	91.14	88.46		
y5	14.75	25.84	45.95	71.94	71.01	62.38	
y10	9.67	17.70	32.45	51.07	51.29	46.47	38.58
(b) Based on Absolute Changes							
	m3	m6	y1	y2	y3	y5	y10
m3	20.01						
m6	13.96	15.57					
y1	11.65	15.30	22.84				
y2	11.69	17.01	26.86	41.77			
y3	11.17	16.76	26.96	42.73	46.19		
y5	9.89	15.21	25.03	40.09	43.81	45.72	
y10	7.17	11.71	20.25	33.34	36.92	39.55	38.12

ology to construct the covariance matrix, the underlying assumption is that volatilities and correlations are constant. Hence, the choice between relative or absolute changes depends on which are the more stable. In countries with very high interest rates, or when interest rates have been trending during the sample period, relative changes tend to be more stable than absolute changes.

In summary, there are four crucial decisions to be made when estimating a covariance matrix for interest rates:

1. Which statistical model should we employ?
2. Which historical data period should be used?
3. Should the data frequency be daily, weekly, monthly, or quarterly?
4. Should we base the matrix on relative or absolute changes in interest rates?

The first three decisions must also be made when estimating covariance matrices in other asset classes such as equities, commodities, and foreign exchange rates. There is a huge amount of model risk involved with the construction of covariance matrices; very different results may be obtained depending on the choice made.

Pitfalls of the Equally Weighted Moving Average Method

The problems encountered when applying this model stem not from the small jumps that are often encountered in financial asset prices, but

from the large jumps that are only rarely encountered. When a long averaging period is used, the importance of a single extreme event is averaged out within a large sample of returns. Hence, a moving average volatility estimate may not respond enough to a short, sharp shock in the market. This effect is clearly visible in 2002, where only the 30-day volatility rose significantly over a matter of a few weeks. The longer-term volatilities did rise, but it took several months for them to respond to the market falls in the MIB during mid-2002. At this point in time there was actually a cluster of volatility, which often happens in financial markets. The effect of the cluster was to make the longer-term volatilities rise, eventually, but then they took too long to return to normal levels. It was not until markets returned to normal in late 2003 that the three volatility series in Figure 2 are in line with each other.

When there is an extreme event in the market, even just one very large return will influence the T -day moving average estimate for exactly T days until that very large squared return falls out of the data window. Hence volatility will jump up, for exactly T days, and then fall dramatically on day $T + 1$, even though nothing happened in the market on that day. This type of ghost feature is simply an artifact of the use of equal weighting. The problem is that extreme events are just as important to current estimates, whether they occurred yesterday or a very long time ago. A single large, squared return remains just as important $T - 1$ days ago as it was yesterday. It will affect the T -day volatility or correlation estimate for exactly T days after that return was experienced, and to exactly the same extent. However, with other models we would find that volatility or correlation had long ago returned to normal levels. Exactly $T + 1$ days after the extreme event, the equally weighted moving average volatility estimate mysteriously drops back down to about the correct level—that is, provided that we have not had another extreme return in the interim!

Note that the smaller is T , the number of data points used in the data window, the more variable the historical volatility series will be. When any estimates are based on a small sample size they will not be very precise. The larger the sample size the more accurate the estimate, because sampling errors are proportional to $1/\sqrt{T}$. For this reason alone a short moving average will be more variable than a long moving average. Hence, a 30-day historic volatility (or correlation) will always be more variable than a 60-day historic volatility (or correlation) that is based on the same daily return data. Of course, if one really believes in the assumption of constant volatility that underlies this method, one should always use as long a history as possible, so that sampling errors are reduced.

It is important to realize that whatever the length of the historical averaging period and whenever the estimate is made, the equally weighted method is always estimating the same parameter: the unconditional volatility (or correlation) of the returns. But this is a constant—it does not change over the process. Thus, the variation in T -day historic estimates can only be attributed to sampling error: There is nothing else in the model to explain this variation. It is not a time-varying volatility model, even though some users try to force it into that framework.

The problem with the equally weighted moving average model is that it tries to make an estimate of a constant volatility into a forecast of a time-varying volatility. Similarly, it tries to make an estimate of a constant correlation into a forecast of a time-varying correlation. No wonder financial firms have lost a lot of money with this model! It is really only suitable for long-term forecasts of average volatility, or correlation, for instance over a period of between six months to several years. In this case, the look-back period should be long enough to include a variety of price jumps, with a relative frequency that represents the modeler expectations of the probability of future price jumps of that magnitude during the forecast horizon.

Using Equally Weighted Moving Averages

To forecast a long-term average for volatility using the equally weighted model, it is standard to use a large sample size T in the variance estimate. The confidence intervals for historical volatility estimators given earlier in this entry provide a useful indication of the accuracy of these long-term volatility forecasts and the approximate standard errors that we have derived earlier in this entry give an indication of variability in long-term volatility. Here, we saw that the variability in estimates decreased as the sample size increased. Hence, long-term volatility that is forecast from this model may prove useful.

When pricing options, it is the long-term volatility that is most difficult to forecast. Options trading often focuses on short-maturity options and long-term options are much less liquid. Hence, it is not easy to forecast a long-term implied volatility. Long-term volatility holds the greatest uncertainty, yet it is the most important determinant of long-term option prices.

We conclude this section with an interesting conundrum, considering two hypothetical historical volatility modelers, whom we shall call Tom and Dick, both forecasting volatility over a 12-month risk horizon based on equally weighted average of squared returns over the past 12 months of daily data. Imagine that it is January 2006 and that on October 15, 2005, the market crashed, returning -50% in the space of a few days. So some very large jumps occurred during the current data window, albeit three months ago.

Tom includes these extremely large returns in his data window, so his ex-post average of squared returns, which is also his volatility forecast in this model, will be very high. Because of this, Tom has an implicit belief that another jump of equal magnitude will occur during the forecast horizon. This implicit belief will continue until one year after the crash, when those

large negative returns fall out of his moving data window. Consider Tom's position in October 2006. Up to the middle of October he includes the crash period in his forecast but after that the crash period drops out of the data window and his forecast of volatility in the future suddenly decreases—as if he suddenly decided that another crash was very unlikely. That is, he drastically changes his belief about the possibility of an extreme return. So, to be consistent with his previous beliefs, should Tom now “bootstrap” the extreme returns experienced during October 2005 back into his data set?

And what about Dick, who in January 2006 does not believe that another market crash could occur in his 12-month forecast horizon? So, in January 2006, he should somehow filter out those extreme returns from his data. Of course, it is dangerous to embrace the possibility of bootstrapping in and filtering out extreme returns in data in an ad hoc way, before it is used in the model. However, if one does not do this, the historical model can imply a very strange behavior of the beliefs of the modeler.

In the Bayesian framework of uncertain volatility the equally weighted model has an important role to play. Equally weighted moving averages can be used to set the bounds for long-term volatility; that is, we can use the model to find a range $[\sigma_{min}, \sigma_{max}]$ for the long-term average volatility forecast. The lower bound σ_{min} can be estimated using a long period of historical data with all the very extreme returns removed and the upper bound σ_{max} can be estimated using the historical data where the very extreme returns are retained—and even adding some!

A modeler's beliefs about long-term volatility can be formalized by a probability distribution over the range $[\sigma_{min}, \sigma_{max}]$. This distribution would then be carried through for the rest of the analysis. For instance, upper and lower price bounds might be obtained for long-term exposures with option-like structures, such as warrants on a firm's equity or convertibles bonds.

This type of Bayesian method, which provides a price distribution rather than a single price, will be increasingly used in market risk management in the future.

EXPONENTIALLY WEIGHTED MOVING AVERAGES

An *exponentially weighted moving average* (EWMA) avoids the pitfalls explained in the previous section because it puts more weight on the more recent observations. Thus as extreme returns move further into the past as the data window slides along, they become less important in the average.

Statistical Methodology

An exponentially weighted moving average can be defined on any time series of data. Say that on date t we have recorded data up to time $t - 1$, so we have observations (x_{t-1}, \dots, x_1) . The exponentially weighted average of these observations is defined as:

$$\begin{aligned} \text{EWMA}(x_{t-1}, \dots, x_1) \\ = \frac{x_{t-1} + \lambda x_{t-2} + \lambda^2 x_{t-3} + \dots + \lambda^{t-2} x_1}{1 + \lambda + \lambda^2 + \dots + \lambda^{t-2}} \end{aligned}$$

where λ is a constant, $0 < \lambda < 1$, called the smoothing or the decay constant. Since $\lambda^T \rightarrow 0$ as $T \rightarrow \infty$ the exponentially weighted average places negligible weight on observations far in the past. And since $1 + \lambda + \lambda^2 + \dots = (1 - \lambda)^{-1}$ we have, for large t ,

$$\begin{aligned} \text{EWMA}(x_{t-1}, \dots, x_1) &\approx \frac{x_{t-1} + \lambda x_{t-2} + \lambda^2 x_{t-3} + \dots}{1 + \lambda + \lambda^2 + \dots} \\ &= (1 - \lambda) \sum_{i=1}^{\infty} \lambda^{i-1} x_{t-i} \end{aligned}$$

This is the formula that is used to calculate exponentially weighted moving average (EWMA) estimates of variance (with x being the squared return) and covariance (with x being the cross product of the two returns). As with equally weighted moving averages, it is

standard to use squared daily returns and cross products of daily returns, not in mean deviation form. That is:

$$\hat{\sigma}_t^2 = (1 - \lambda) \sum_{i=1}^{\infty} \lambda^{i-1} r_{t-i}^2 \quad (19)$$

and

$$\hat{\sigma}_{12,t} = (1 - \lambda) \sum_{i=1}^{\infty} \lambda^{i-1} r_{1,t-i} r_{2,t-i} \quad (20)$$

The above formulas may be rewritten in the form of recursions, more easily used in calculations:

$$\hat{\sigma}_t^2 = (1 - \lambda) r_{t-1}^2 + \lambda \hat{\sigma}_{t-1}^2 \quad (21)$$

and

$$\hat{\sigma}_{12,t} = (1 - \lambda) r_{1,t-1} r_{2,t-1} + \lambda \hat{\sigma}_{12,t-1} \quad (22)$$

An alternative notation used for the above is $V_\lambda(r_t)$, for $\hat{\sigma}_t^2$ and $\text{COV}_\lambda(r_{1,t}, r_{2,t})$ for $\hat{\sigma}_{12,t}$ when we want to make explicit the dependence on the *smoothing constant*.

One converts the variance to volatility by taking the annualized square root, the annualizing constant being determined by the data frequency as usual. Note that for the EWMA correlation the covariance is divided by the square root of the product of the two EWMA variance estimates, all with the same value of λ . Similarly for the EWMA beta the covariance between the stock (or portfolio) returns and the market returns is divided by the EWMA estimate for the market variance, both with the same value of λ . That is:

$$\hat{\rho}_{t,\lambda} = \frac{\text{COV}_\lambda(r_{1,t}, r_{2,t})}{\sqrt{V_\lambda(r_{1,t}) V_\lambda(r_{2,t})}} \quad (23)$$

and

$$\hat{\beta}_{t,\lambda} = \frac{\text{COV}_\lambda(X_t, Y_t)}{V_\lambda(X_t)} \quad (24)$$

Interpretation of λ

There are two terms on the right-hand side of (21). The first term $(1 - \lambda) r_{t-1}^2$ determines the intensity of reaction of volatility to market

events: The smaller is λ the more the volatility reacts to the market information in yesterday's return. The second term $\lambda\hat{\sigma}_{t-1}^2$ determines the persistence in volatility: Irrespective of what happens in the market, if volatility was high yesterday it will be still be high today. The closer that λ is to 1, the more persistent is volatility following a market shock.

Thus, a high λ gives little reaction to actual market events but great persistence in volatility, and a low λ gives highly reactive volatilities that quickly die away. An unfortunate restriction of exponentially weighted moving average models is that the reaction and persistence parameters are not independent: The strength of reaction to market events is determined by $1 - \lambda$, while the persistence of shocks is determined by λ . But this assumption is not empirically justified except perhaps in a few markets (e.g., major U.S. dollar exchange rates).

The effect of using a different value of λ in EWMA volatility forecasts can be quite substantial. Figure 5 compares two EWMA volatility estimates/forecasts of the S&P 100 index, with $\lambda = 0.90$ and $\lambda = 0.975$. It is not unusual for these two EWMA estimates to differ by as much as 10%.

So which is the best value to use for the smoothing constant? How should we choose λ ? This is not an easy question. (By contrast, in generalized autoregressive conditional het-

eroskedasticity (GARCH) models there is no question of how we should estimate parameters, because maximum likelihood estimation is an optimal method that always gives consistent estimators.) Statistical methods may be considered: For example, λ could be chosen to minimize the root mean square error between the EWMA estimate of variance and the squared return. But, in practice, λ is often chosen subjectively because the same value of λ has to be used for all elements in an EWMA covariance matrix. As a rule of thumb, we might take values of λ between about 0.75 (volatility is highly reactive but has little persistence) and 0.98 (volatility is very persistent but not highly reactive).

Properties of the Estimates

An EWMA volatility estimate will react immediately following an unusually large return, then the effect of this return on the EWMA volatility estimate gradually diminishes over time. The reaction of EWMA volatility estimates to market events therefore persists over time, and with a strength that is determined by the smoothing constant λ . The larger the value of λ , the more weight is placed on observations in the past and so the smoother the series becomes.

Figure 6 compares the EWMA volatility of the MIB index with $\lambda = 0.95$ and the 60-day equally

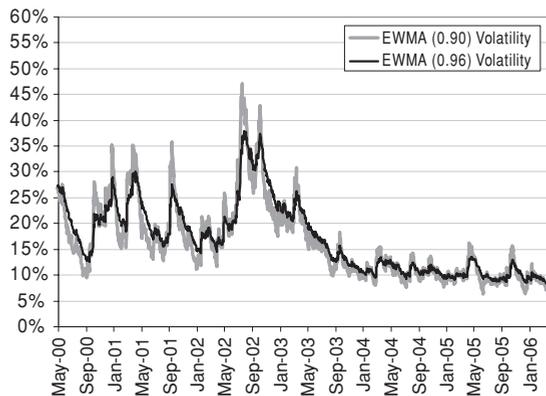

Figure 5 EWMA Volatility Estimates for SP100 with Different λ s

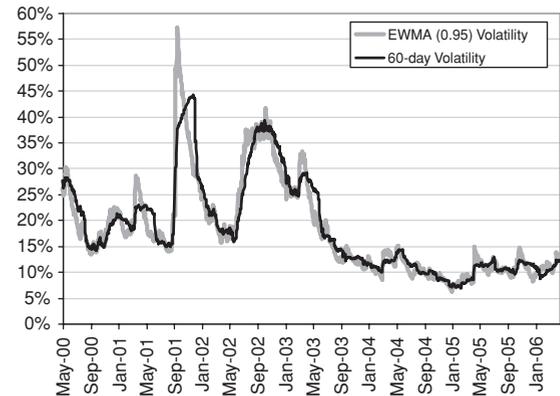

Figure 6 EWMA versus Equally Weighted Volatility

weighted volatility estimate. The difference between the two estimators is marked following an extreme market return. The EWMA estimate gives a higher volatility than the equally weighted estimate, but it returns to normal levels faster than the equally weighted estimate because it does not suffer from the ghost features discussed above.

One of the disadvantages of using EWMA to estimate and forecast covariance matrices is that the same value of λ is used for all the variances and covariances in the matrix. For instance, in a large matrix covering several asset classes, the same λ applies to all equity indexes, foreign exchange rates, interest rates, and/or commodities in the matrix. But why should all these risk factors have similar reaction and persistence to shocks? This constraint is commonly applied merely because it guarantees that the matrix will be positive semidefinite.

The EWMA Forecasting Model

The exponentially weighted average variance estimate (19), or in its equivalent form (21), is just a methodology for calculating $\hat{\sigma}_t^2$. That is, it gives a variance estimate at any point in time but there is no model as such that explains the behavior of the variance of returns, σ_t^2 at each time t . In this sense, we have to distinguish EWMA from a GARCH model, which starts with a proper specification of the dynamics of σ_t^2 and then proceeds to estimate the parameters of this model.

Without a proper model, it is not clear how we should turn our current estimate of variance into a forecast of variance over some future horizon. One possibility is to augment (21) by assuming it is the estimate associated with the model

$$\sigma_t^2 = (1 - \lambda) r_{t-1}^2 + \lambda \sigma_{t-1}^2 \quad r_t | I_{t-1} \sim N(0, \sigma_t^2) \quad (25)$$

An alternative is to assume a constant volatility, so the fact that our estimates are time vary-

ing is merely due to sampling error. In that case any EWMA variance forecast must be constant and equal to the current EWMA estimate. Similar remarks apply to the EWMA covariance, this time regarding EWMA as a simplistic version of bivariate normal GARCH. Similarly, the EWMA volatility (or correlation) forecast for all risk horizons is simply set at the current EWMA estimate of volatility (or correlation). The base horizon for the forecast is given by the frequency of the data—daily returns will give the one-day covariance matrix forecast, weekly returns will give the one-week covariance matrix forecast, and so forth. Then, since the returns are independent and identically distributed, the square root of time rule applies. So we can convert a one-day forecast into an h -day covariance matrix forecast by multiplying each element of the one-day EWMA covariance matrix by h .

Since the choice of λ itself is quite ad hoc, as discussed above, some users choose different values of λ for forecasting over different horizons. For instance, as discussed later in this entry, in the RiskMetrics™ methodology a relatively low value of λ is used for short-term forecasts and a higher value of λ is used for long-term forecasts. However, this is purely an ad hoc rule.

Standard Errors for EWMA Forecasts

In the previous section, we justified the assumption that the underlying returns are normally and independently distributed with mean zero and variance σ^2 . That is, for all t

$$E(r_t) = 0 \quad \text{and} \quad V(r_t) = E(r_t^2) = \sigma^2$$

In this section, we use this assumption to obtain standard errors for EWMA forecasts. From the above, and further from the normality assumption, we have:

$$V(r_t^2) = E(r_t^4) - E(r_t^2)^2 = 3\sigma^4 - \sigma^4 = 2\sigma^4$$

Now we can apply the variance operator to (21) and calculate the variance of the EWMA

variance estimator as:

$$V(\hat{\sigma}_t^2) = \frac{(1-\lambda)^2}{(1-\lambda^2)} V(r_t^2) = 2 \frac{1-\lambda}{1+\lambda} \sigma^4 \quad (26)$$

For instance, as a percentage of the variance, the standard error of the EWMA variance estimator is about 5% when $\lambda = 0.95$, 10.5% when $\lambda = 0.9$, and 16.2% when $\lambda = 0.85$.

A single point forecast of volatility can be very misleading. A forecast is always a distribution. It represents our uncertainty over the quantity that is being forecast. The standard error of a volatility forecast is useful because it can be translated into a standard error for a VaR estimate, for instance, or an option price. In any VaR model one should be aware of the uncertainty that is introduced by possible errors in the forecast of the covariance matrix. Similarly, in any mark-to-model value of an option, one should be aware of the uncertainty that is introduced by possible errors in the volatility forecast.

The RiskMetrics™ Methodology

Three very large covariance matrices, each based on a different moving average methodology, are available from www.riskmetrics.com. These matrices cover all types of assets including government bonds, money markets, swaps, foreign exchange, and equity indexes for 31 currencies and commodities. Subscribers have access to all of these matrices updated on a daily basis—and end-of-year matrices are also available to subscribers wishing to use them in scenario analysis. After a few days, the datasets are also made available free for educational use.

The RiskMetrics™ group is the market leader in market and credit risk data and modeling for banks, corporate asset managers, and financial intermediaries. It is highly recommended that readers visit the Web site (www.riskmetrics.com), where they will find a surprisingly large amount of information in the form of free publications and data. See the References at the end of this entry for details.

The three covariance matrices provided by the RiskMetrics group are each based on a history of daily returns in all the asset classes mentioned above. They are:

1. **Regulatory matrix:** This takes its name from the (unfortunate) requirement that banks must use at least 250 days of historical data for VaR estimation. Hence this metric is an equally weighted average matrix with $n = 250$. The volatilities and correlations constructed from this matrix represent forecasts of average volatility (or correlation) over the next 250 days.
2. **Daily matrix:** This is an EWMA covariance matrix with $\lambda = 0.94$ for all elements. It is not dissimilar to an equally weighted average with $n = 25$, except that it does not suffer from the ghost features caused by very extreme market events. The volatilities and correlations constructed from this matrix represent forecasts of average volatility (or correlation) over the next day.
3. **Monthly matrix:** This is an EWMA covariance matrix with $\lambda = 0.97$ for all elements and then multiplied by 25 (that is, using the square root of time rule and assuming 25 days per month). The volatilities and correlations constructed from this matrix represent forecasts of average volatility (or correlation) over the next 25 days.

The main difference between the three different methods is evidenced following major market movements: The regulatory forecast will produce a ghost effect of this event, and does not react as much as the daily or monthly forecasts. The most reactive is the daily forecast, but it also has less persistence than the monthly forecast.

Figure 7 compares the estimates for the FTSE 100 volatility based on each of the three RiskMetrics methodologies and using daily data from January 2, 1995, to June 23, 2006. As mentioned earlier in this entry, these estimates are assumed to be the forecasts over, respectively, one day, one month, and one year. In volatile

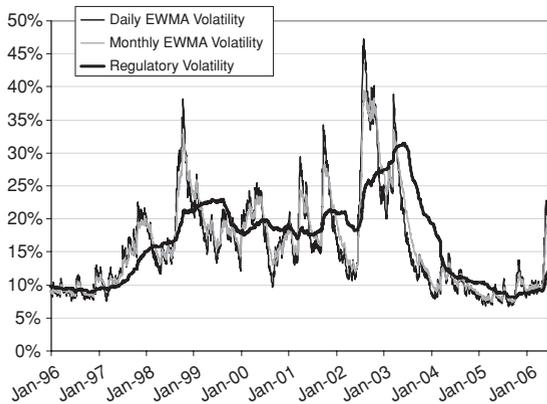

Figure 7 Comparison of the RiskMetrics “Forecasts” for FTSE100 Volatility

times, the daily and monthly estimates lie well above the regulatory forecast and the converse is true in more tranquil periods. For instance, during most of 2003, the regulatory estimate of average volatility over the next year was about 10% higher than both of the shorter-term estimates. However, it was falling dramatically during this period, and indeed the regulatory forecast of more than 20% volatility on average between June 2003 and June 2004 was entirely wrong. However, at the end of the period, in June 2006, the daily forecasts were above 20%, and the monthly forecasts were only just below this. However, the regulatory forecast over the next year was only slightly more than 10%.

During periods when the markets have been tranquil for some time, for instance during the whole of 2005, the three forecasts tend to agree more. But during and directly after a volatile period there are large differences between the regulatory forecasts and the two EWMA forecasts, and these differences are very difficult to justify. Neither the equally weighted average nor the EWMA methodology is based on a proper forecasting model. One simply assumes the current estimate is the volatility forecast. But the current estimate is a backward-looking measure based on recent historical data. So both of these moving average models make the assumption that the behavior of future volatility

is the same as its past behavior and this is a very simplistic view.

KEY POINTS

- The equally weighted moving average, or historical approach to estimating/forecasting volatilities and correlations, was the only statistical method used by practitioners until the mid-1990s.
- The historical method may provide a useful indication of the possible range for a long-term average, such as the average volatility or correlation over the next several years. However, its application to short-term forecasting suffers from at least four drawbacks: (1) The forecast of volatility/correlation over all future horizons is simply taken to be the current estimate of volatility, because the underlying assumption in the model is that returns are independent and identically distributed; (2) the only choice facing the user is on the data points to use in the data window; (3) following an extreme market move the forecasts of volatility and correlation will exhibit a so-called “ghost” feature of that extreme move, which will severely bias the volatility and correlation forecasts upward; and (4) the extent of this bias depends very much on the size of the data window.
- The bias issue associated with the historical approach was addressed by the RiskMetrics™ data and software suite. The choice of methodology helped to popularize the use of exponentially weighted moving averages (EWMA) by financial analysts.
- The EWMA approach provides useful forecasts for volatility and correlation over the very short term, such as over the new day or week. However, its use for longer-term forecasting is limited, and this methodology has two major problems: (1) The forecast of volatility/correlation over all future horizons is simply taken to be the current estimate of volatility, because the underlying assumption

in the model is that returns are independent and identically distributed, and (2) the only choice facing the user is about the value of the smoothing constant. With the EWMA approach, the forecasts produced depend crucially on this decision, yet there is no statistical procedure to choose for the value of the smoothing constant.

- Moving average models assume returns are independent and identically distributed, and the further assumption that they are normally distributed allows one to derive standard errors and confidence intervals for moving average forecasts. But empirical observations suggest that returns to financial assets are hardly ever independent and identically, let alone normally, distributed. For these reasons more and more practitioners are basing their forecasts on generalized autoregressive conditional heteroskedasticity (GARCH) models.
- There is no doubt that GARCH models produce superior volatility forecasts. It is only in GARCH models that the term structure volatility forecasts converge to the long-run average volatility—the other models produce constant volatility term structures. Moreover, the value of the EWMA smoothing constant is

chosen subjectively and the same smoothing constant must be used for all the returns, otherwise the covariance matrix need not be positive semidefinite. But GARCH parameters are estimated optimally and GARCH covariance matrices truly reflect the time-varying volatilities and correlations of the multivariate returns distributions.

Software for Financial Modeling

Introduction to Financial Model Building with MATLAB

DESSISLAVA A. PACHAMANOVA, PhD

Associate Professor of Operations Research, Babson College

Abstract: MATLAB is a modeling environment that allows for input and output processing, statistical analysis, simulation, and other types of model building for the purpose of analysis of a situation. MATLAB uses a number-array-oriented programming language; that is, a programming language in which vectors and matrices are the basic data structures. Reliable built-in functions, a wide range of specialized toolboxes, easy interface with widespread software like Microsoft Excel, and beautiful graphing capabilities for data visualization make implementation with MATLAB efficient and useful for the financial modeler.

MATLAB is an interactive computing environment for model development that also enables data visualization, data analysis, and numerical simulation. The core of the MATLAB environment was created as a number-array-oriented programming language; that is, as a programming language in which vectors and matrices are the basic data structures. (MATLAB stands for Matrix Laboratory.) Operations involving matrices and vectors can be performed efficiently within the core MATLAB *software* product. More specialized operations, such as statistical data analysis, optimization, and simulation, can be accessed by purchasing some of MATLAB's specialized toolboxes. Once a toolbox is installed, functions from the toolbox can be called in the same way as standard MATLAB functions, without any special additional syntax. MATLAB toolboxes that are useful for quantitative analysis in financial applications include:

- Statistics Toolbox
- Optimization Toolbox
- Global Optimization Toolbox
- Curve Fitting Toolbox
- Neural Network Toolbox
- Partial Differential Equation Toolbox

For example, the Statistics Toolbox contains data analysis tools (for multivariate analysis, statistical tests, statistical plots), random number generation tools, and quasi-random number generation tools, which are useful for implementing risk management and derivative pricing routines. The Optimization Toolbox contains solvers for linear, quadratic, nonlinear, and binary optimization, which can aid quantitative portfolio allocation schemes. The Global Optimization Toolbox contains randomized search optimization subroutines that can be used for solving complex (e.g., mixed-integer) optimization problems to near

optimality. It is useful, for example, for creating more complex portfolio allocation or trading routines. For more details and information about the other toolboxes, see the Mathworks website, <http://www.mathworks.com>.

MATLAB also has toolboxes that are specifically targeted at financial applications. These toolboxes include:

- Financial Toolbox
- Econometrics Toolbox
- Datafeed Toolbox
- Fixed-Income Toolbox
- Financial Derivatives Toolbox

For example, the Financial Toolbox contains specialized routines for computing frequently used financial quantities, such as present and future value, basic portfolio optimization, term structure of interest rates, bond prices, and derivative prices. It also contains functions that help with the manipulation of typical financial data sets, such as multivariate regression with missing data. Many of these routines can be implemented by using standard MATLAB functions, but the Financial Toolbox puts them together in a convenient package.

It is worth noting that most of the financial toolboxes require installation of one or more of the mathematics toolboxes listed earlier. For example, the Financial Toolbox requires the Statistics Toolbox and the Optimization Toolbox. The Financial Derivatives Toolbox requires the Statistics, Optimization, and Finance Toolboxes.

Another tool of interest to those who use Windows and Microsoft Excel extensively as the platform for their applications is Spreadsheet Link EX. Spreadsheet Link EX enables the manipulation of Microsoft Excel worksheets from within MATLAB and using MATLAB functions from within Excel. This is a useful toolbox that allows powerful MATLAB capabilities to be accessed through a familiar interface.

This entry provides brief pointers to important aspects of *modeling* in MATLAB. We discuss basic array construction and operations, func-

tions and scripts, as well as graphs. We also provide examples of MATLAB code for portfolio optimization schemes and for pricing a European call option by simulation.

When readers try to implement such routines themselves, they may find it useful to know that the MATLAB manual and online help contain abundant information and examples. Detailed documentation is also provided in MATLAB itself. For example, typing `help` at the prompt in MATLAB lists all major topics. Type `help name of function` at the prompt or in the box in the Help dialog box to access the documentation on that function in MATLAB. If unsure of which help topic is relevant, click on the button with question mark () in MATLAB's top menu. It provides richer search options.

THE MATLAB DESKTOP AND EDITOR

The standard MATLAB desktop window contains a **Workspace** window, a **Command History** window, and a **Command** window (see Figure 1). Depending on how you customize the MATLAB desktop window, however, you may see more or fewer windows. To check which windows are currently displayed and view other options, click on **Desktop** in the top MATLAB desktop window menu.

MATLAB commands are entered in the **Command** window. When a series of commands need to be given, it is more convenient to list them in an *M-file*, which is basically a file with instructions that MATLAB executes sequentially. Such files (*scripts*) are saved with the suffix “.m” and can be called from the prompt in the **Command** window typing their name (without the suffix “.m”). For example, if you create a file **OptimizePortfolio.m** with instructions on how to perform optimal portfolio allocation, you can call that file from the MATLAB command prompt by typing

```
>> OptimizePortfolio
```

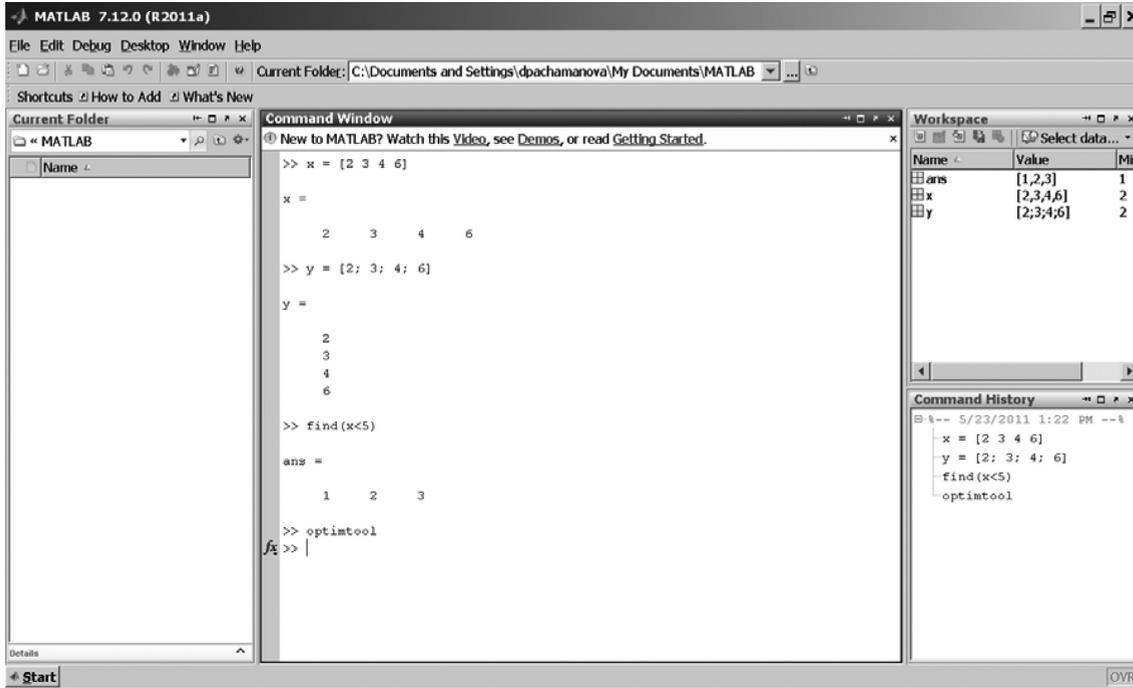

Figure 1 The Standard MATLAB Desktop

(If the file is saved in a directory other than the default MATLAB directory, you will need to make sure that MATLAB can find the file. Select **Desktop > Current Directory** from the top menu and navigate to the correct directory before typing the command at the prompt.)

To create an M-file, you can use any text editing program, such as WordPad, NotePad, and the open source editor Emacs. In general, it is convenient to use an editor that recognizes the MATLAB file type and provides helpful highlighting for parts of the code that have different characteristics. (For example, comments in the code appear in different colors than commands.) MATLAB's own editor can do that, and Emacs can be set up to recognize the MATLAB file format as well.

To call MATLAB's editor in order to create or edit M-files, select **Desktop > Editor** from the top menu. Alternatively, you can use the shortcut buttons at the top of the MATLAB desktop window: the button  to open the MATLAB

editor to write a new file, or the button  to open a file that has already been created.

BASIC OPERATIONS AND MATRIX ARRAY CONSTRUCTION

Basic Mathematical Operations

MATLAB can perform many kinds of different mathematical operations, such as addition (+), multiplication (* or .*), square root (sqrt or sqrtm), and power (^). These commands can be entered at the command prompt. For example, typing

```
>> 3*sqrt(4) + 15
```

and pressing Enter produces the output

```
ans =
    21
```

To suppress output, use the semicolon (;). For example, entering

```
>> 3*sqrt(4) + 15;
```

does not result in any visible output in the command window. However, MATLAB still performs the calculation. To see this, let us assign the value of the above expression to a variable, `ExpressionValue`:

```
>> ExpressionValue = 3*sqrt(4) + 15;
```

Then, typing `ExpressionValue` at the command prompt, you get

```
>> ExpressionValue
ExpressionValue =
    21
```

Constructing Vectors and Matrices

As mentioned earlier, MATLAB's core data structures are vectors and matrices. For example, the command

```
>> x = [2 3 4 6]
```

produces a horizontal vector array (one row) `x` that contains the numbers 2, 3, 4, and 6.

The semicolon (;) is used to create new rows. To create a vertical vector array `y` with the same entries, you can enter

```
>> y = [2; 3; 4; 6]
```

or press **Enter** after entering each number. (MATLAB treats semicolons and carriage returns in array declarations as new lines.) The different syntax is useful depending on the source for downloading the data that populate the *arrays*.

Matrices are declared similarly. For example, a 2-by-2 matrix `X` can be specified as

```
>> X = [1 2 3 4; 5 6 7 8]
X =
     1     2     3     4
     5     6     7     8
```

MATLAB is case-sensitive; that is, it will treat the matrix `X` and the vector `x` defined earlier as separate variables.

Special commands exist for declaring types of matrices that are used often. For example,

```
>> I = eye(3,3)
I =
     1     0     0
     0     1     0
     0     0     1
```

produces a 3×3 identity matrix.

Similarly, the commands `ones(n,m)` and `zeros(n,m)` can be used to declare matrices that contain only 0s or 1s of the desired dimension (`n × m`), and `diag(x)` can be used to create a matrix that has a vector `x` as its diagonal elements, and 0s everywhere else.

You can also “stack” matrices and vectors. For example,

```
>> Y = [x; X]
Y =
     2     3     4     6
     1     2     3     4
     5     6     7     8
```

Basic Array Operations

To transpose an array `A`, use the command `transpose(A)` or `A'`. This operation converts a horizontal vector into a vertical one and vice versa, and flips the elements of a matrix that contains real numbers in its entries around the diagonal, keeping the diagonal entries the same.

For example,

```
>> x'
ans =
     1     5
     2     6
     3     7
     4     8
```

To multiply two arrays, you can simply use the multiplication command `*`. Since the operation `*` performs a matrix multiplication, you

need to make sure that the matrix dimensions agree. For example, an error results in the case when the 1×4 array x is multiplied by the 2×4 array X :

```
>> x*X
???) Error using ==> mtimes
Inner matrix dimensions must agree.
```

To multiply x and X correctly, you can instead type

```
>> x*X'
ans =
    44    104
```

If you need to perform an element-by-element multiplication of two arrays (of equal sizes), use the `.*` operator. For example,

```
>> X.*X
ans =
     1     4     9    16
    25    36    49    64
```

Note that this is different from the matrix product. The matrix product would produce the following result:

```
>> X'*X
ans =
    26    32    38    44
    32    40    48    56
    38    48    58    68
    44    56    68    80
```

When a matrix array is multiplied by a number, all of the array's entries are multiplied by that number. Similarly, if a number is added to a matrix array, the number will be added to all of the elements of the matrix. For example,

```
>> 10+X
ans =
    11    12    13    14
    15    16    17    18
```

Extracting Information from Arrays

Suppose you have a matrix array `Data` with financial data on annual stock returns over

10 years for 1,000 companies traded on the New York Stock Exchange, and you would like to check the entry for the return on stock 253 in year 7. You are dealing with a 10×1000 matrix array in which each row is a time period and each column contains the returns on a particular stock. You are looking for the element in row 7, column 253 of this array. This can be requested with the command `Data(7,253)`.

Suppose now that you would like to extract information on all of stock 253's returns over the 10 years. This means that you are looking for the elements of column 253 of the matrix array. This can be requested with the command `Data(:,253)`. The colon operator replaces the row index to specify that elements with all indexes in the 253rd column should be produced. Similarly, if you would like to request all elements in the same row (e.g., the returns on all stocks in year 7), you can use the colon operator again: `Data(7,:)`.

To illustrate the output, let us use the matrix array X . To find out what the value of the element in row 1, column 3 is, enter

```
>> X(1,3)
ans =
     3
```

The third column of X is

```
>> X(:,3)
ans =
     3
     7
```

Similarly, the second row of X can be obtained as

```
>> X(2,:)
ans =
     5     6     7     8
```

IMPORTANT MATLAB FUNCTIONS

MATLAB supports a number of built-in functions. A function is written as a command and

takes arguments as inputs in parentheses. It processes the inputs by using operations hidden from the user and passes the final results back to the user. While we cannot cover many of the MATLAB functions in this brief introduction, we illustrate how functions work with an example of the function `find`, which can be useful in many situations.

`find` takes in an array and a condition as arguments and returns the indexes of elements within the array that satisfy the condition. In addition to traditional applications, `find` can be very helpful when dealing with missing data, which happens often with financial time series.

Suppose you want to find the indexes of the elements that are less than 5 of the 1×4 array `x` from the previous section. At the prompt, type

```
>> find(x<5)
```

The result is

```
ans =
     1     2     3
```

Now let us see how `find` works when the array is a matrix rather than a vector. Recall that `Y` was the matrix array obtained by stacking `x` and `X`. Suppose you want to find the indexes of the elements in the array that are less than 5. At the prompt, type

```
>> ind = find(Y<5)
```

MATLAB creates the following array:

```
ind =
     1
     2
     4
     5
     7
     8
    11
```

MATLAB treated the matrix array as a stacked-up collection of column vectors. The elements of the array `ind` correspond to the indexes of the elements in that long column vector. Obtaining the actual elements of `Y` that cor-

respond to these indexes can be accomplished by typing

```
>> Y(ind)
```

This produces the answer

```
ans =
     2
     1
     3
     2
     4
     3
     4
```

The indexing of an array as a sequence of stacked columns works well if the array is a vector, but it can get confusing if the array is a matrix. In the latter case, it is more intuitive to obtain the indexes as a row and column index. For example,

```
>> [indRow,indCol] = find(Y<5)
```

produces

```
indRow =
     1
     2
     1
     2
     1
     2
     2
indCol =
     1
     1
     2
     2
     3
     3
     4
```

This means that the following elements of `Y` have values less than 5: (row 1, column 1), (row 2, column 1), (row 1, column 2), and so on. Unfortunately, looking up the actual values of the elements of `Y` as `Y(indRow,indCol)` does not work.

CREATING USER-DEFINED FUNCTIONS

The compactness of the function syntax makes functions desirable when a user needs to call a certain sequence of commands often. For example, the Black-Scholes formula for pricing European options takes a number of steps to compute. It is convenient to have a function that returns one value—the option price—to the user after the user inputs values of factors that determine that price, such as the strike price, the time to maturity, the volatility, and so on.

Functions need to be written in M-files. Although general script M-files can contain any sequence of instructions that will be completed

when the name of the file is typed at the MATLAB prompt, function M-files need to start with a specific first line. That line contains the word “function” and a declaration of the function name, inputs, and outputs. The function name and the name of the M-file should be the same.

The Black-Scholes formula already exists in the Financial Toolbox, so it is convenient to see how the price is computed and discuss important aspects of writing user-defined functions. (We have skipped some lines in the code for the sake of brevity.) Users can view the source code for some of the advanced MATLAB functions in the toolboxes by entering *type function name* at the prompt.

```
>> type blsprice
function [call,put] = blsprice(S, X, r, T, sig, q)
% BLSPRICE Black-Scholes put and call option pricing.
% Compute European put and call option prices using a Black-Scholes model.
%
% [Call,Put] = blsprice(Price, Strike, Rate, Time, Volatility)
% [Call,Put] = blsprice(Price, Strike, Rate, Time, Volatility, % Yield)
%
% Optional Input: Yield
%
% Inputs:
% Price - Current price of the underlying asset.
% Strike - Strike (i.e., exercise) price of the option.
% Rate - Annualized continuously compounded risk-free rate of
% return over the life of the option, expressed as a positive decimal number.
% Time - Time to expiration of the option, expressed in years.
% Volatility - Annualized asset price volatility (i.e., annualized
% standard deviation of the continuously compounded asset return),
% expressed as a positive decimal number.
% Optional Input: Yield - Annualized continuously compounded yield of the
% underlying asset over the life of the option, expressed as a decimal
% number. If Yield is empty or missing. the default value is zero. For
% example, this could represent the dividend yield (annual dividend rate
% expressed as a percentage of the price of the security) or foreign
% risk-free interest rate for options written on stock indices and
% currencies, respectively.
%
```

```

% Outputs:
% Call      - Price (i.e., value) of a European call option.
% Put      - Price (i.e., value) of a European put option.
...
%

d2(isnan(d2)) = 0;

call(i) = S(i) .* exp(-q(i).*T(i)) .* normcdf( d1) - ...
    X(i) .* exp(-r(i).*T(i)) .* normcdf( d2);
put (i) = X(i) .* exp(-r(i).*T(i)) .* normcdf(-d2) - ...
    S(i) .* exp(-q(i).*T(i)) .* normcdf(-d1);

warning(state) % Restore the state.

%
% Reshape the outputs for the user.
%

call = reshape(call, nRows, nCols);
put = reshape(put , nRows, nCols);
% [EOF]

```

Some aspects of this function are very complicated for a beginner, but a review of the function syntax helps create a list of useful pointers to which you can refer when creating your own functions:

- The first line contains the word `function` followed by a specification of the outputs of the function `call` (in this case, `[call,put]`).

Note that a function can have more than one output. After calling the function, MATLAB computes the values for the outputs, and the variable `call` will contain the price of a European call option, while the variable `put` will contain the price of a European put option. Next, we have an equal sign followed by the name of the function (`blsprice`) and the arguments for the function (`S` for current stock

price, X for strike price, r for rate of return, T for time to maturity, sig for volatility, as well as the optional argument `yield` for continuous dividend yield).

- When the function is called with specific input values, you can assign the output to variables. For example,

```
>> [callOutput,putOutput]
= blsprice(110,100,0.10,2,0.40)
callOutput =
38.1757
putOutput =
10.0488
```

- The names of the input variables need to participate in calculations in the function. For example, S appears as the current stock price in the first line (`function [call,put] = blsprice(S, X, r, T, sig, q)`), and this is the same variable that is used to store the value of the stock price in the computations. Similarly, the names of the output variables (`call` and `put`) should appear somewhere in the text of the function and be assigned an expression, which can then be returned to the user.
- Note the abundance of the percentage sign (%) in the function code. This sign is used for writing comments that are ignored by MATLAB when executing the code. It is always a good idea to comment abundantly in order to be able to retrace your reasoning later. The first comment line is called “the H1 line,” and it is the line that is searched by the MATLAB built-in function `lookfor`. `lookfor` searches all MATLAB files containing a keyword in their first line. (This is useful if you are not sure which function to use for a specific purpose, and you would like to find the names of all functions that may be relevant.) Therefore, it is important to provide a meaningful description of your function in the first commented line. After the first line, you can continue with a more detailed description of the function and list references.

CONTROL FLOW STATEMENTS

M-files, whether of a generic or function kind, can contain more advanced operations than matrix manipulation. Next, we briefly review a couple of control flow statements that are often used in such files: the `for` loop and the `if` statement.

The general format of a `for` loop is

```
for n = array
commands
end
```

The commands inside the `for` loop are executed once for every value in the column in the array. (Typically, the array is a vector of numbers, so the loop is executed once for every number.) For example,

```
for n = 1:5
v(n) = sqrt(n);
end
```

results in

```
v =
1.0000 1.4142 1.7321 2.0000 2.2361
```

The array `1:5` is equivalent to `[1 2 3 4 5]`. MATLAB starts out with $n = 1$, computes its square root, and assigns it to `v(1)`. Then, it keeps repeating the process until it has computed `v(5)` for $n = 5$.

Loops in MATLAB are often necessary, but as a general rule MATLAB is more efficient in array operations than in loops. For example, the same effect (adding 10 to each element of the vector x) can be achieved in two ways:

```
for n = 1:4
x(n) = x(n) + 10;
end
```

and

```
>> x = x+10
```

Both of them result in

```
x =
12 13 14 16
```

The second command would typically be completed faster. Loops are not as inefficient as they used to be in older versions of MATLAB, however—the difference in speed between the two approaches has been greatly reduced in the latest versions of the software.

The `if` statement has the following general format:

```
if expression
commands
end
```

The commands are completed only if all elements in the expression are true. A somewhat more complex `if` statement is

```
if expression1
commands1
elseif expression2
commands2
else expression3
commands3
end
```

Commands1 are completed if `expression1` is true. If `expression1` is not true, MATLAB moves on and checks if `expression2` is true. If `expression2` is true, `commands2` are completed. If `expression2` is not true either, MATLAB moves to `expression3`. If `expression3` is true, `commands3` are completed; otherwise MATLAB exits. The `elseif` or `else` commands are optional in `if` statements.

There are several other useful control flow statements, such as the `while` loop, `switch-case` constructions, and `try-catch` blocks. See the MATLAB manual and help for more detail.

GRAPHS

MATLAB is well known for its beautiful graphing capabilities. The most common function for plotting two-dimensional (2-D) graphs is `plot`.

To illustrate how `plot` works, suppose we would like to plot the standard normal prob-

ability distribution. We will use the function `normpdf` (available from the Statistics Toolbox), which computes the probability density function (PDF) of a normal random variable.

The command

```
>> x = linspace(-6,6,100)
```

creates a vector `x` with 100 values, equally spaced between the minimum value -6 and the maximum value $+6$. (In reality, the normal distribution stretches from negative infinity to positive infinity, but it is highly unlikely that we will obtain realizations that are greater than 6 standard deviations away from the mean of 0, so we focus on plotting the center of the distribution.)

The command

```
>> y = normpdf(x)
```

computes the values of the normal probability distribution function for every value in the array for `x`.

To plot `x` versus `y`, use

```
>> plot(x,y)
```

The result is the graph in Figure 2.

You can play with the options for the graph. For example,

```
>> plot(x,y,'r:p'); title('Normal PDF');
xlabel('x'); ylabel('pdf')
```

plots the same graph as a red dotted line with a pentagram symbol, labels the horizontal (`x`) and the vertical (`y`) axes, and creates a title for the graph (see Figure 3).

To plot multiple graphs on the same picture, use the command `hold on` before you start and `hold off` when you are done with the instructions. For example, suppose we would like to plot the standard normal distribution and a standard `t`-distribution with 5 degrees of freedom on the same graph in order to compare them. The following sequence of commands accomplishes this.

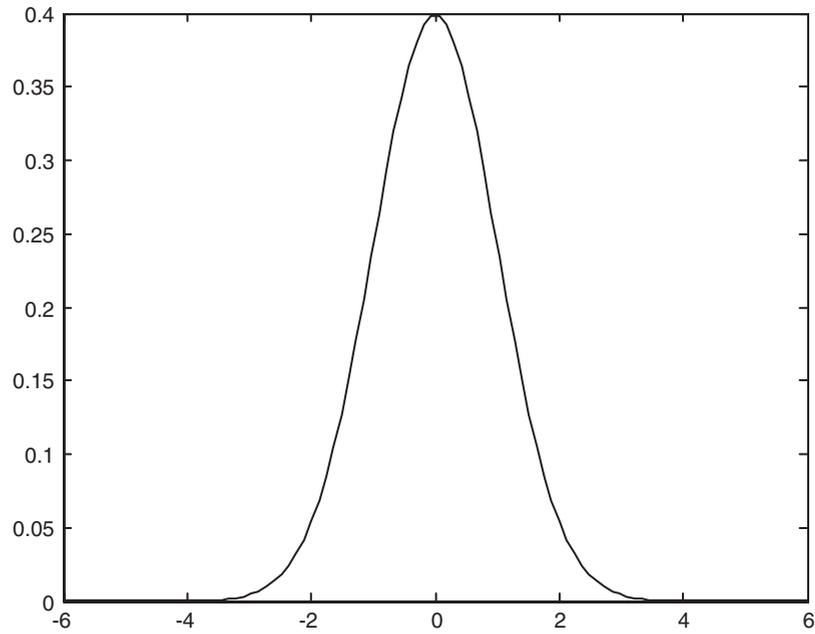

Figure 2 A Plot of the PDF of the Normal Distribution

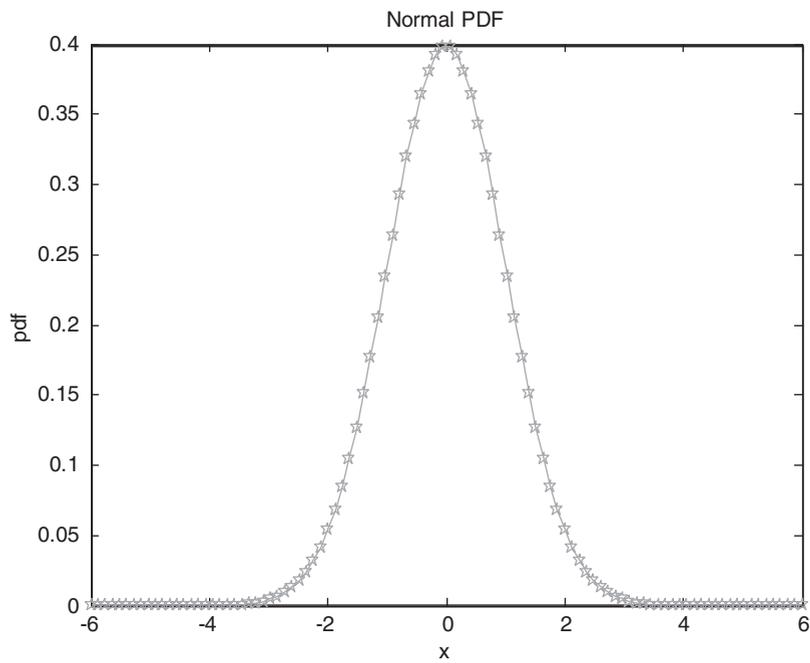

Figure 3 A Plot of the PDF of the Normal Distribution (with Modified Options)

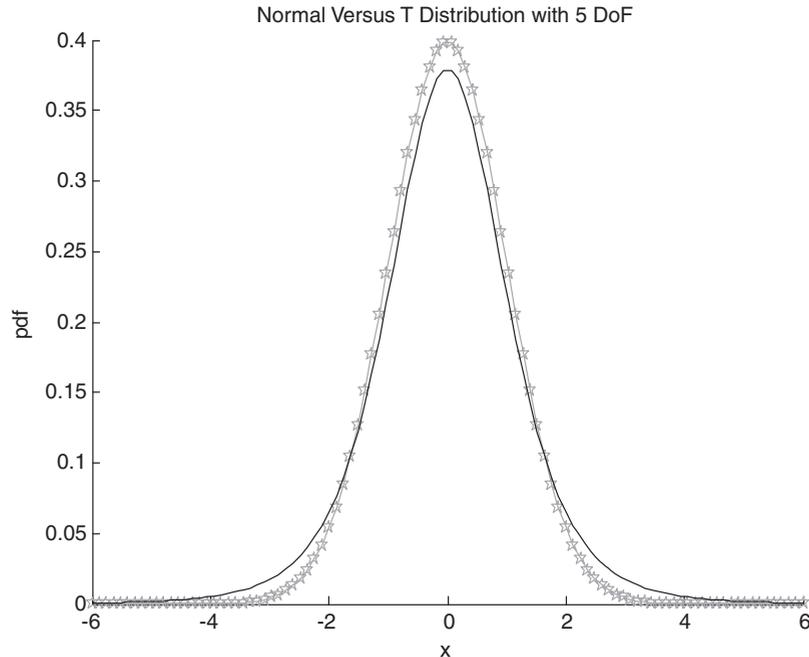

Figure 4 Illustration of hold on / hold off Effect

First, we declare a variable that follows a t-distribution with 5 degrees of freedom:

```
>> t=tpdf(x,5);
```

Then, we plot the graph:

```
>> hold on
>> plot(x,y,'r:p'); xlabel('x');
    ylabel('pdf')
>> plot(x,t);
>> title('Normal Versus T Distribution');
>> hold off
```

The results are displayed in Figure 4.

Alternatively, you can list several pairs of variables inside the plot function. For example,

```
>> plot(x,y,'r:p',x,t); xlabel('x');
    ylabel('pdf')
>> legend('Normal PDF','T PDF')
>> title('Normal Versus T Distribution
    with 5 DoF');
```

This script also creates a legend (Figure 5).

Legend, titles, and other graph attributes can be added and modified also after the basic plot command has been given and a graph window has popped up. To modify an existing graph's options, click on the corresponding items in the top menu of the graph window.

Suppose now that we would like to plot the two PDFs side by side in the same figure. To graph several separate graphs in the same figure, use the command subplot(number of rows, number of columns, index of graph within the graph array).

For example, the code

```
>> subplot(1,2,1), plot(x,y,'r:p');
    xlabel('x'); ylabel('pdf')
>> title('(a) Normal PDF')
>> subplot(1,2,2), plot(x,t);
    xlabel('x'); ylabel('pdf')
>> title('(b) T PDF')
```

produces the graph in Figure 6.

Finally, we briefly discuss three-dimensional (3-D) graphs. They can be created with

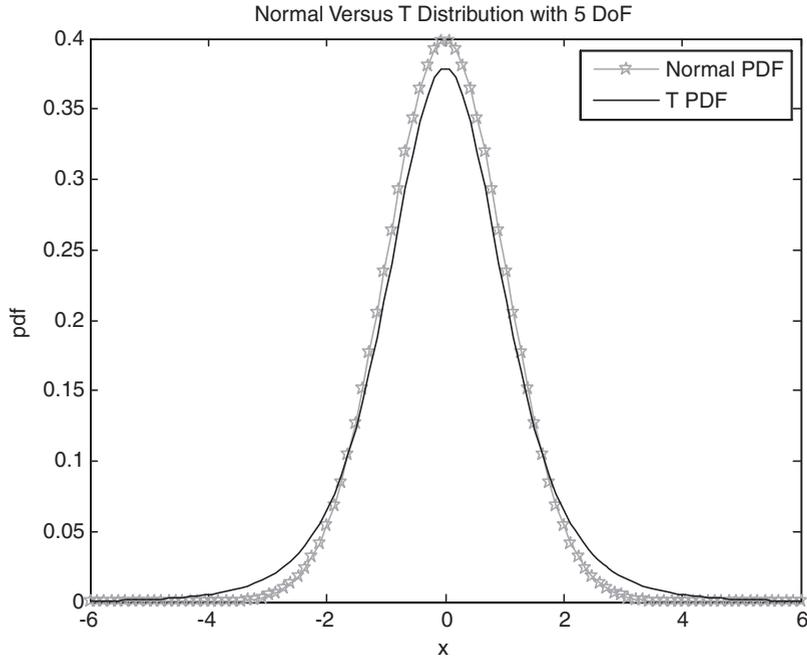

Figure 5 Changing Defaults and Plotting Multiple Graphs with the plot Function

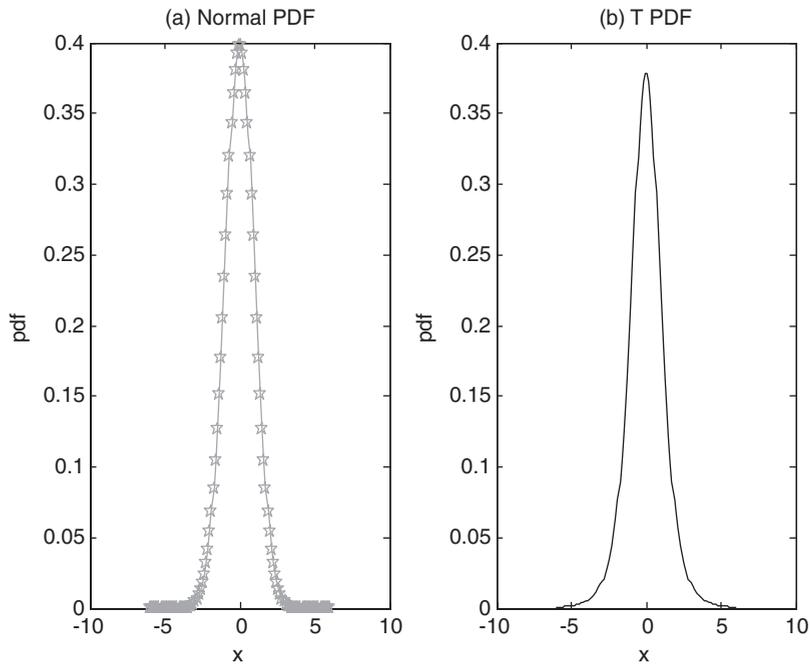

Figure 6 Multiple Plots within the Same Figure

commands like `plot3` and `surf`, and as a general matter are more complex.

The command `plot3`(first variable x , second variable y , third variable z) plots points in 3-D space whose three coordinates are given by the vectors or matrices (x, y, z) in the three arguments of the function. The arguments need to be arrays of equal sizes.

The command `surf`(x, y, z) plots a shaded surface using z as the height and (x, y) as the vectors or matrices that define the other two dimensions of the surface. When x and y are vector arrays, as is the case in most financial applications, the number of rows for z should be the length of the vector array y , and the number of columns for z should be the length of the vector array x .

For example, suppose we would like to plot a multivariate normal distribution function for two normal variables, x_1 and x_2 , that have means of 0 and are correlated with covariance matrix $[0.25 \ 0.3; 0.3 \ 1]$. (Note that this notation means that the variance of x_1 is 0.25 (the standard deviation of x_1 is 0.5), the variance of x_2 is 1 (the standard deviation of x_2 is 1), and the covariance of x_1 and x_2 is 0.3.

The multivariate normal distribution function can be computed with the MATLAB function `mvnpdf`(X, μ, Σ). The arguments μ and Σ are the vector array of average (expected) values for the normal random variables and their covariance matrix, respectively. In this case, we have two normal random variables, so $\mu = [0 \ 0]$ and $\Sigma = [0.25 \ 0.3; 0.3 \ 1]$. The first argument in the function (matrix X) provides the points at which the function should be evaluated. The function is evaluated for every row of X , taking the elements in that row as the coordinates of the point at which the function should be evaluated. Therefore, since in our example we are looking at two normal random variables, there should be two columns of the matrix X . We cannot simply provide two columns with, say, equally spaced values for x_1 and x_2 . If we do,

MATLAB would pair each entry of x_1 with the corresponding entry of x_2 , and will only use those combinations of coordinates, so the plot will look two-dimensional. The columns of X should provide a grid. In other words, we cannot simply provide possible coordinates along each axis and expect that MATLAB will know to take every combination of possible coordinates to obtain the points at which to plot the function. To create this grid of points, we need to go through a couple of steps.

First, we would use the function `[X1, X2] = meshgrid(x1, x2)`. It creates two matrices. The number of rows in the first matrix, X_1 , is the same as the number of elements in the vector y (i.e., the number of rows equals `length(y)`, another useful MATLAB command). Each row of the column X_1 contains identical entries: the entries of the vector x . The matrix X_2 contains the same number of columns as the number of elements in the vector x , and each column contains an identical copy of the vector y . While perhaps difficult to imagine at first, $X_1(i, j)$ and $X_2(i, j)$ cover all possible combinations of the elements of the original vectors, x and y .

The second step is to create the array `[X1(:), X2(:)]`. The colon operator `(:)` has multiple uses, but in the context of being used as an argument for a matrix, it takes all entries of a matrix, column by column, and lists them as a vector array. Therefore, the array `[X1(:), X2(:)]` would contain two columns with every possible combination of coordinates generated by the original list in the vector arrays x and y .

To summarize, here are the commands used to generate 30 points between -4 and 4 along each coordinate x_1 and x_2 , then to evaluate the multivariate normal PDF at each combination of coordinates:

```
>> x1 = linspace(-4,4,30);
    x2 = linspace(-4,4,30);
>> Sigma = [0.25 0.3; 0.3 1]; mu = [0 0];
>> [X1,X2] = meshgrid(x1,x2);
>> z = mvnpdf([X1(:),X2(:)],mu,Sigma);
```

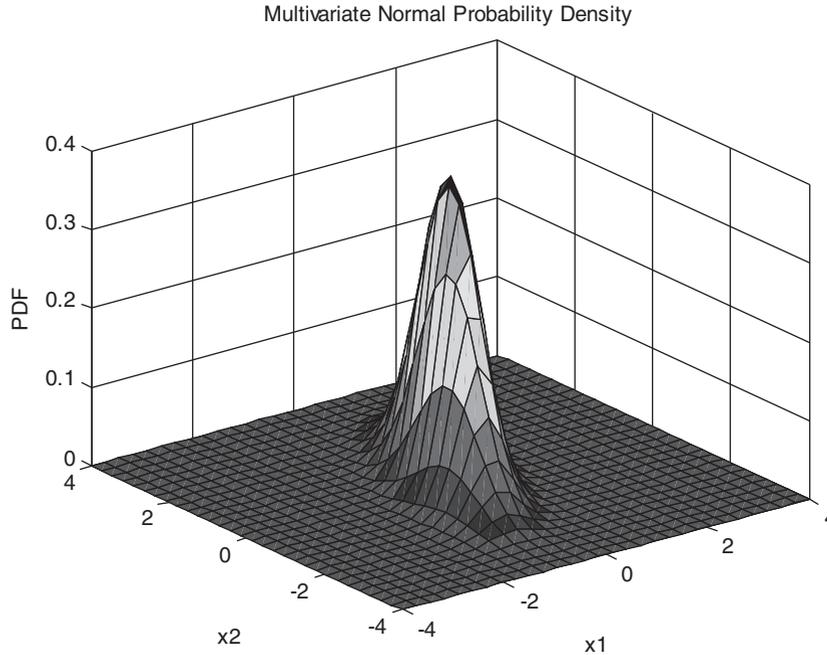

Figure 7 Three-Dimensional Plot of a Multivariate Normal Distribution

The output of this sequence of commands is a vertical array of values that represent the multivariate normal PDF evaluated at each combination of coordinates. (If you skip the semicolon at the end of the last row with the function `mvnpdf`, you can see what the output looks like. You can also use the command `size(z)` to check the dimensions of `z`.) Now we would like to plot these values. We will use the `surf` function.

The `surf` function's third argument, `z`, needs to be a matrix whose entries represent the values of the function to be plotted at each combination of coordinates. However, we obtained a vector of values for the PDF. We need to "reshape" that vector back into a matrix. This can be done with the command `Z = reshape(z, m, n)`. The function `reshape` takes the array `z` and goes through the elements of `z` columnwise. The first `m` elements of `z` become the first column of the new matrix `Z`, the next `m` elements of `z` become the second column of the matrix `Z`, and so forth until `n` columns for `Z` are created. In this example, we would like to create

`length(x1)` columns and `length(x2)` rows. (This may be a bit confusing, but, as we mentioned earlier, the function `surf` expects the third argument to be a matrix with the number of columns equal to the size of the first argument, and the number of rows equal to the size of the second argument.)

```
>> Z = reshape(z, length(x2), length(x1));
>> surf(x1, x2, Z);
>> title('Multivariate Normal
    Probability Density');
>> axis([-4 4 -4 4 0 0.4]);
>> xlabel('x1'); ylabel('x2');
    zlabel('PDF');
```

The resulting graph is in Figure 7.

IMPORTING DATA AND INTERACTING WITH SPREADSHEETS

MATLAB recognizes files with the extension `.dat` as data files. Such files should contain text structured in rows and columns. For example,

suppose that the file `returns.dat` contains daily annual returns on the stocks traded in the NYSE for 10 years. The command

```
>> load returns.dat
```

imports the data in the file into a data structure—a matrix array with rows and columns that can then be referenced using some of the commands we described earlier.

Many financial companies build their infrastructure around Microsoft Excel. The MATLAB core product contains some useful functions for importing Excel data and exporting MATLAB results to spreadsheets. The function

```
>> xlsread('fileName', 'sheetName',
           'range')
```

allows the user to read into MATLAB the data stored in file `fileName`, worksheet `sheetName`, cells in range `range`. Instead of a range in the spreadsheet, you can state an array name if you had named the array of cells in advance. Variations of this command exist; for instance

```
>> xlsread('fileName', -1)
```

allows the user to select the range in `fileName` directly, through interactive selection in Excel. Type `help xlsread` at the MATLAB command prompt for further information.

The function

```
>> xlswrite('fileName', output, 'sheetName',
           'cell')
```

allows the user to export MATLAB results (`output`) to a worksheet (`sheetName`) in an Excel file (`fileName`). MATLAB preserves the dimensions of the `output` and writes it to the spreadsheet starting at cell reference `cell`. For example, if `output` is a horizontal array of numbers, MATLAB will write the data in a row in the Excel file, starting at `cell`.

MATLAB operations work within the `xlswrite` command. For example, you can switch the array dimensions (transpose) the

output by using `output'` inside the parentheses of the `xlswrite` command if you desire different output formatting in the Excel spreadsheet.

More sophisticated capabilities exist through MATLAB's Excel Link. With Excel Link, you can call MATLAB's functions directly from within Excel, thus ensuring access to MATLAB's superior computational and graphical capabilities. Excel Link is purchased as a separate toolbox. It can then be made visible from within Excel by selecting it as one of Excel's Add-Ins. There are 11 commands (they all start with "ML") that allow for communicating data back and forth between Excel and MATLAB. For example, `=MLAppendMatrix()` creates or appends a matrix in MATLAB with data from an Excel spreadsheet.

A word of caution: Excel Link formulas are not case sensitive. For example, `MLAppendMatrix` and `mlappendmatrix` are the same. However, MATLAB functions and variables called through these links are case sensitive. For example, `x` and `X` would still be treated as two separate variables.

EXAMPLES

This section discusses several *scripts* and *functions* in MATLAB that can be used in financial applications. The goal is to illustrate the use of toolboxes in MATLAB and to provide concrete examples of some of the tools introduced earlier in the entry.

Optimization in MATLAB

Optimization is an area in applied mathematics that, most generally, deals with efficient algorithms for finding an optimal solution among a set of solutions that satisfy given constraints. The first application of optimization in finance was suggested by Harry Markowitz in 1952, in a seminal paper that outlined his mean-variance optimization framework for optimal asset allocation. Some other classical problems in finance

Table 1 MATLAB Optimization Toolbox Functions/Solvers Appropriate for Specific Types of Optimization Problems

	Discrete	bintprog				

Note: Asterisk (*) is used to denote solvers that are available only through the Global Optimization Toolbox. Blank entries mean that there is currently no solver available. Technically, the Global Optimization Toolbox can be used for solving discrete problems as well; however, it requires additional programming.

that can be solved by optimization algorithms include:

1. Is there a possibility to make riskless profit given market prices of related securities?
2. How should trades be executed so as to reach a target allocation with minimum transaction costs?
3. Given a limited capital budget, which capital budgeting projects should be selected?
4. Given estimates for the costs and benefits of a multistage capital budgeting project, at what stage should the project be expanded/abandoned?

MATLAB’s Optimization Toolbox contains solvers for a range of optimization problems. MATLAB expects optimization formulations to be passed to its solvers in an array form and has functions that call specific solvers for specific types of optimization problems. (See Table 1 for a quick overview. See also MATLAB’s help for a complete listing.) If the Global Optimization Toolbox is available, the range of solvers is expanded to include randomized search algorithms.

The most often used solver in MATLAB is `fmincon`, which is the solver for general nonlinear optimization. However, if you know the type of problem you are trying to solve, you are always better off giving the optimization soft-

ware as much information as you can in order to make the optimization process more accurate and efficient. In financial applications, you are most likely to encounter situations in which you need `linprog` (a linear programming solver), `quadprog` (a quadratic programming solver), `bintprog` (a binary programming solver), and randomized search algorithms, such as `simulannealbnd` and `ga`.

We will use `linprog` and `quadprog` to solve two examples of portfolio allocation problems. Before we show the actual implementation, we need to explain how solvers are actually called in MATLAB. There are two ways to call the solvers: as functions directly from the command prompt (equivalently, from within M-files), or through the optimization tool.

The MATLAB optimization tool provides an interface between the solvers and the user. While using such an interface may not be optimal when solving sequences of optimization problems, as in the case of dynamic programming or stochastic programming, it is quite convenient when solving a single optimization problem, because it lists all available solvers, prompts the user for the different inputs that the optimization solvers expect, and allows for easy manipulation of the options. Options can be specified directly when a solver is called from the command prompt as well, but that is more difficult for MATLAB beginners.

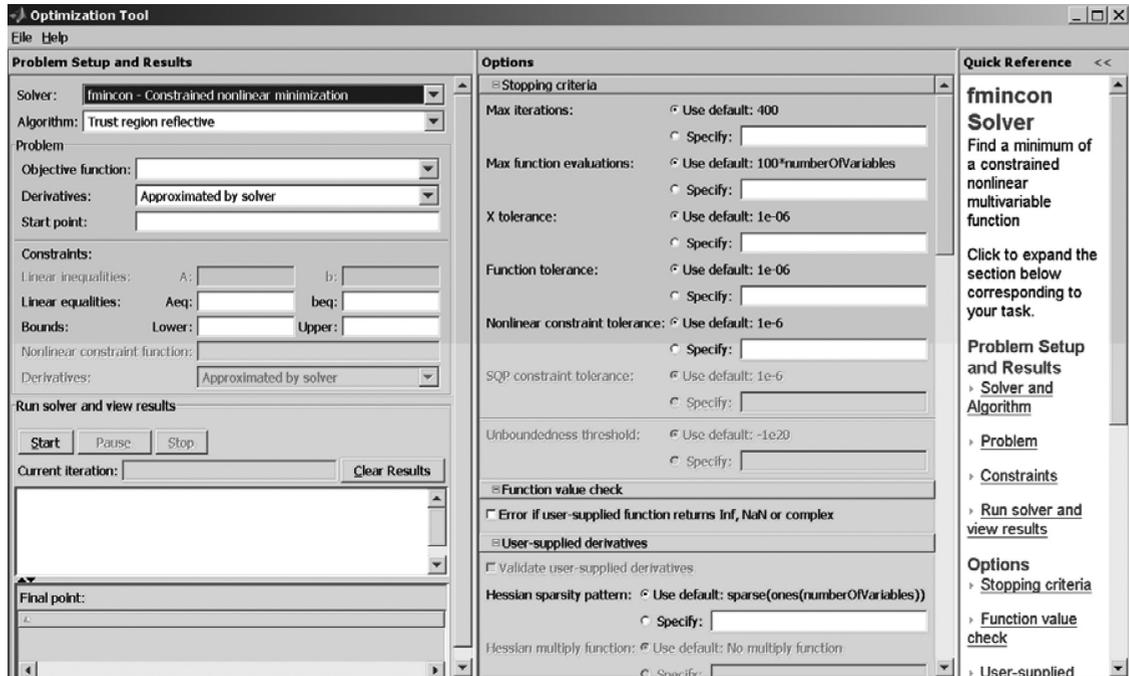

Figure 8 The Optimization Tool Interface in MATLAB

The optimization tool is called by typing `optimtool` at the MATLAB command prompt. The optimization tool dialog box is shown in Figure 8. The panel on the left-hand side is dedicated to the specification of the inputs: the type of solver that needs to be called, the arrays with the problem data, the starting point, and so on. The panel in the middle allows for changing the level of tolerance in the search for the optimal solution. For example, the Function tolerance is currently set at the default value of $1e-06$, which is 10^{-6} . This means that the selected algorithm will continue to iterate through solutions until the improvement in successive objective function values becomes smaller than 10^{-6} . Sometimes, such level of accuracy is unnecessary. For example, if our objective function is measured in dollars and cents (e.g., we are maximizing dollar return as in the simple portfolio allocation example we will discuss next), then technically we do not need precision beyond 2–3 digits after the decimal point. Therefore, we can speed up the algorithm by relaxing the re-

quirements on tolerance. Other useful options include level of display (whether to show iterations of the optimization algorithm or not) and function plots at intermediate stages.

Linear Optimization: Simple Portfolio Allocation

Let us consider a specific example to illustrate the use of the optimization function `linprog`. (For more details, see section 5.3.1 in Pachamanova and Fabozzi, 2010.)

The portfolio manager at a large university in the United States is tasked with investing a \$10 million donation to the university endowment. He has decided to invest these funds only in mutual funds and is considering the following four: an aggressive growth fund (Fund 1), an index fund (Fund 2), a corporate bond fund (Fund 3), and a money market fund (Fund 4), each with a different expected annual return and risk level. (The risk level measurement is deliberately simplified for the sake of this example.) The investment guidelines established

Table 2 Data for the Portfolio Manager’s Problem

Fund type	Growth	Index	Bond	Money market
Fund #	1	2	3	4
Expected return	20.69%	5.87%	10.52%	2.43%
Risk level	4	2	2	1
Max investment	40%	40%	40%	40%

by the Board of Trustees limit the percentage of the money that can be allocated to any single type of investment to 40% of the total amount. The data for the portfolio manager’s task are provided in Table 2. In addition, in order to contain the risk of the investment to an acceptable level, the amount of money allocated to the aggressive growth and the corporate bond funds cannot exceed 60% of the portfolio, and the aggregate average risk level of the portfolio cannot exceed 2. What is the optimal portfolio allocation for achieving the maximum expected return at the end of the year, if no short selling is allowed?

The vector of decision variables for this optimization problem can be defined as $x = (x_1, x_2, x_3, x_4)$: amounts (in \$) invested in Fund 1, 2, 3, and 4, respectively.

Let the vector of expected returns be $\mu = (20.69\%, 5.87\%, 10.52\%, 2.43\%)$. Then, the objective function can be written as

$$f(x) = \mu'x = (20.69\%) \cdot x_1 + (5.87\%) \cdot x_2 + (10.52\%) \cdot x_3 + (2.43\%) \cdot x_4$$

It represents the optimal expected dollar amount at the end of the year.

There are also several constraints.

1. The total amount invested should be \$10 million. This can be formulated as $x_1 + x_2 + x_3 + x_4 = 10,000,000$.
2. The total amount invested in Fund 1 and Fund 3 cannot be more than 60% of the total investment (\$6 million). This can be written as

$$x_1 + x_3 \leq 6,000,000$$

3. The average risk level of the portfolio cannot be more than 2. This constraint can be expressed as

$$4 \cdot (\text{proportion of investment with risk level 4}) + 2 \cdot (\text{proportion of investment with risk level 2}) + 1 \cdot (\text{proportion of investment with risk level 1}) \leq 2$$

or, mathematically,

$$\frac{4 \cdot x_1 + 2 \cdot x_2 + 2 \cdot x_3 + 1 \cdot x_4}{x_1 + x_2 + x_3 + x_4} \leq 2$$

In this particular example we know that the total amount $x_1 + x_2 + x_3 + x_4 = 10,000,000$, so the constraint can be formulated as

$$4 \cdot x_1 + 2 \cdot x_2 + 2 \cdot x_3 + 1 \cdot x_4 \leq 2 \cdot 10,000,000$$

1. The maximum investment in each fund cannot be more than 40% of the total amount (\$4,000,000). These constraints can be written as

$$x_1 \leq 4,000,000, x_2 \leq 4,000,000, x_3 \leq 4,000,000, x_4 \leq 4,000,000.$$

2. Given the no short selling requirement, the amounts invested in each fund cannot be negative. These are nonnegativity constraints: $x_1 \geq 0, x_2 \geq 0, x_3 \geq 0, x_4 \geq 0$.

The final optimization formulation can be written in matrix form. The objective function is

$$\max_{x_1, x_2, x_3, x_4} [0.2069 \quad 0.0587 \quad 0.1052 \quad 0.0243] \cdot \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix}$$

Let us organize the constraints into groups according to their signs. This will be useful when we input the constraints into MATLAB.

$$\text{Equality(=)} : [1 \quad 1 \quad 1 \quad 1] \cdot \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = 10,000,000$$

$$\text{Inequality(≤)} : \begin{bmatrix} 1 & 0 & 1 & 0 \\ 4 & 2 & 2 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} \leq \begin{bmatrix} 6,000,000 \\ 20,000,000 \\ 4,000,000 \\ 4,000,000 \\ 4,000,000 \\ 4,000,000 \end{bmatrix}$$

$$\text{Nonnegativity}(\geq): \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} \geq \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

This is a linear optimization problem because all constraints and the objective function are linear. To solve linear optimization problems with MATLAB, use `linprog (f,A,b,Aeq,beq,lb,ub)`. The function arguments `f,A,b,Aeq,beq,lb,ub` correspond to the following

LP formulation:

$$\begin{array}{ll} \min_x & f'x \\ \text{s.t.} & Ax \leq b \\ & Aeq \cdot x = beq \\ & lb \leq x \leq ub \end{array}$$

Therefore, before calling `linprog`, you need to write the problem formulation in this particular form. We include the complete MATLAB script below.

```

1  numAssets = 4;
2  expReturnsVec = [0.2069 0.0587 0.1052 0.0243]';
3  %create placeholders for an array of decision variables
4  %(amounts to invest in
5  %each fund) and the optimal portfolio expected return (to be filled out
6  %after the optimization)
7
8  amountsVec = zeros(numAssets,1);
9  optReturn = [];
10
11 %vector of coefficients of objective function f since MATLAB expects
12 %minimization (and we are maximizing), take the negative of the function
13 %we are trying to maximize
14 f = -expReturnsVec;
15
16 %A, matrix of coefficients in constraints with inequalities so that
17 %Ax<=b
18 A = [1 0 1 0;
19      4 2 2 1;
20      1 0 0 0;
21      0 1 0 0;
22      0 0 1 0;
23      0 0 0 1];
24
25 %b
26 b = [6000000 20000000 4000000 4000000 4000000 4000000]';
27
28 %Aeq, matrix of coefficients in constraints with equalities so that
29 %Aeq*x=beq
30 Aeq = ones(1,numAssets);
31
32 %beq
33 beq = 10000000;
34
35 %lower bounds: nonnegativity requires that all decision variables are >= 0

```

```

36 lb = zeros(numAssets,1);
37
38 %upper bounds can be left infinite (although, technically, we cannot invest
39 %more than the $10m we have available)
40 ub = inf*ones(numAssets,1);
41
42 [amountsVec,optReturn] = linprog(f,A,b,Aeq,beq,lb,ub);
43
44 format('bank');
45
46 amountsVec
47 %revert to correct number for maximum return (reverse sign)
48 optReturn = -optReturn

```

The process for formulating the optimization problem is as follows. First, we ask ourselves what corresponds to the vector of decision variables x in the `linprog` formulation. In our example, x maps directly to the vector of amounts to invest in each asset. We then enter problem data, such as the expected returns vector `expReturnsVec`. We allocate empty arrays to store the values of the optimal solution `amountsVec` and the optimal value of the objective function `optReturn` after collecting the information from the solver.

Next, we create the input data for the `linprog` solver. The solver expects a vector of objective function coefficients f , which in our case is the vector of expected returns on the different assets. Note, however (line 14), that we specify f as `-expReturnsVec`. This is because MATLAB expects a minimization problem, and our objective function is to maximize expected revenue, so we need to convert our problem to the required form by minimizing the negative of the expression for the maximization objective. At the end (line 48), we take the negative of the optimal value for expected return found by the solver, so that we arrive at the actual optimal value for the maximization problem. The optimal values of the decision variables, which in this case are the amounts to invest, `amountsVec`, do not need to be modified af-

ter the optimization results are returned by the solver.

Lines 14–40 contain the specification of the other inputs in the problem. Note that we are in fact using the matrices of coefficients for the groups of constraints (inequality, equality, and nonnegativity) that we defined earlier. Namely, A (lines 18–23) is the matrix of left-hand-side inequality constraint coefficients; A_{eq} (line 30) is the matrix of left-hand-side equality constraint coefficients; b (line 26) is the vector of right-hand-side coefficients of the inequality constraints; and beq (line 33) is the vector of right-hand-side coefficients of the equality constraints (in our example, we have only one equality constraint). The lower bounds, lb (line 36), are the zeros from the right-hand-side of the nonnegativity constraints on the decision variables, so we create a vector array with size equal to the number of decision variables that contains only zeros. We have explicit upper bounds of \$4,000,000 on each decision variable since we cannot invest more than that amount in each individual fund, so we could have stated those bounds as the input vector ub . However, these bounds have already been included in the matrix A , so we do not need to state them again. Instead, we state the individual upper bounds as infinity, that is, as the product of the number `inf` (in MATLAB, that denotes

infinity) and a vector of ones. (See line 40 of the code.)

An equivalent formulation of the constraints from MATLAB's perspective would have been to specify the arrays *A*, *beq*, and *ub* as

```
A = [1 0 1 0;
     4 2 2 1]
b = [6000000 20000000]'
ub = 4000000*ones(numAssets,1)
```

with all other input arrays remaining the same.

After all inputs have been specified, the `linprog` solver is called (line 42). The syntax in line 42 outputs requests that the output from the optimization be stored in the arrays we specified at the beginning, `amountsVec` and `optReturn`. The results are then printed to the screen and are formatted according to `format('bank')` (line 44), which basically rounds numbers to two decimal places.

After running the M-file, we obtain the following output:

```
amountsVec =
    2000000.00
         0.00
    4000000.00
    4000000.00
optReturn =
    931800.00
```

If you prefer to solve the problem by using the optimization tool for solving this problem, you need to fill out the dialog box as shown in Figure 9. Select `linprog` as the solver from the drop-down menu at the top. Under **Algorithm**, you can either leave the default (**Large Scale**), or select **Medium scale – simplex**, which is appropriate because our problem is quite small. We entered the names of the arrays that correspond to the objective function coefficients and the constraint coefficients in the corresponding fields in the left panel of the dialog box.

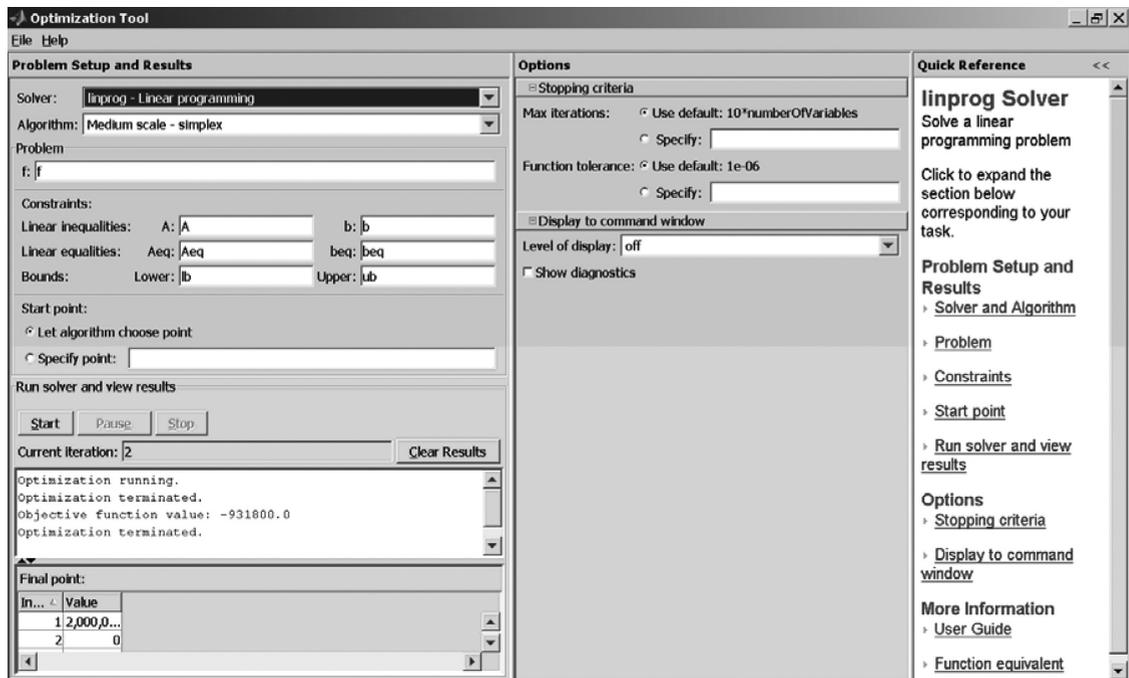

Figure 9 The Optimization Tool Dialog Box for the Portfolio Allocation Problem

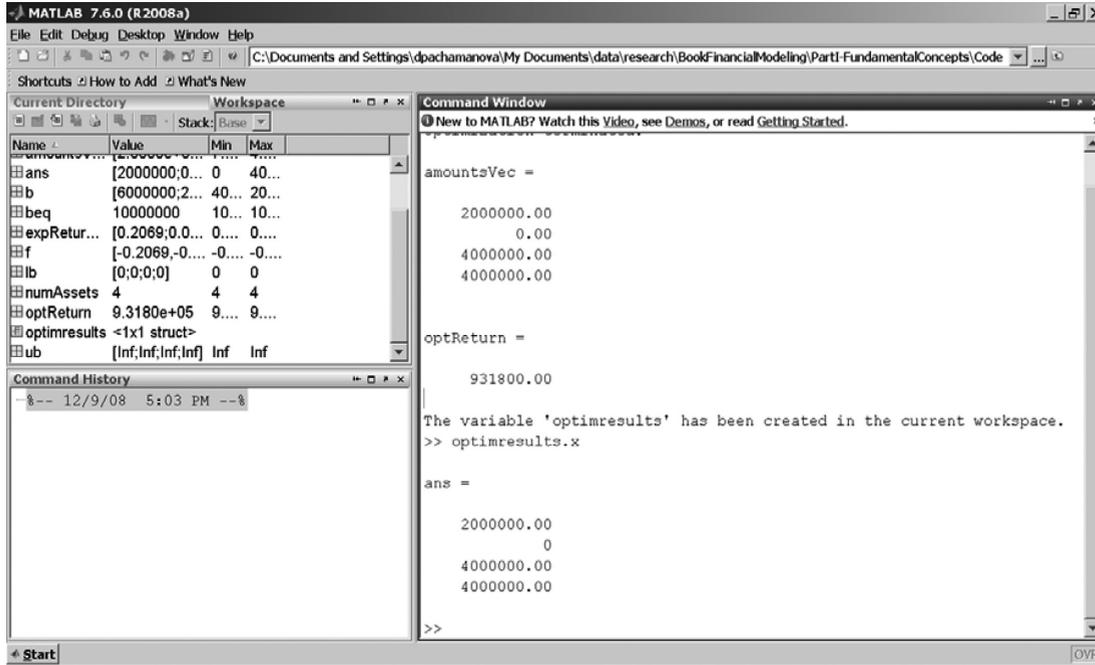

Figure 10 Handling the Structure of Optimization Results Exported from MATLAB's Optimization Tool

Note that these arrays must be prefilled; that is, they must be entered from the command prompt or read from a file before the problem is solved through the optimization tool; otherwise the solver will complain that these arrays are empty. You can make sure that the arrays f , A , b , A_{eq} , b_{eq} , lb , ub are filled in by checking first whether they are listed in the **Workspace** window at the upper left corner of the MATLAB desktop. Once all the input data are specified, click on the **Start** button in the left panel to solve the problem. The solution appears in the field below the **Start** button.

The optimization model can be saved as a script in an M-file by selecting **File | Generate M-file** from the main menu in the optimization tool. In addition, the optimization results can be exported to the workspace and further manipulated by selecting **File | Export to Workspace**. To export only the results, as opposed to the entire model, check **Export results to a MATLAB structure named: optimresults**. This creates a structure of results, `optimresults`, that

shows up in the **Workspace**. So, for example, the optimal solution (the portfolio allocation) can be read by typing `optimresults.x` at the command prompt. (See Figure 10.) Similarly, the optimal value of the objective function can be retrieved by typing `optimresults.fval` at the command prompt.

Quadratic Optimization: Mean-Variance Portfolio Allocation

The classical mean-variance portfolio optimization problem as introduced by Harry Markowitz (1952) is to minimize the variance of portfolio return subject to the constraint that the expected portfolio return is at a certain level. Let us consider a slight variation of the problem, in which we require that the expected return is at least at a certain level r_{target} . The mathematical formulation is

$$\begin{aligned}
 \min_w \quad & \mathbf{w}'\Sigma\mathbf{w} \\
 \text{s.t.} \quad & \mathbf{w}'\boldsymbol{\mu} \geq r_{\text{target}} \\
 & \mathbf{w}'\mathbf{1} = 1
 \end{aligned}$$

where \mathbf{w} is the vector of portfolio weights (to be determined), $\boldsymbol{\mu}$ is the vector of expected returns, $\boldsymbol{\Sigma}$ is the covariance matrix of returns, and $\mathbf{1}$ is a vector of ones of appropriate dimension.

The minimum variance portfolio allocation problem is a quadratic optimization problem with linear constraints. The `quadprog` function in MATLAB solves exactly problems of this kind:

$$\begin{aligned} \min_{\mathbf{x}} \quad & \frac{1}{2} \mathbf{x}' \mathbf{H} \mathbf{x} + \mathbf{f}' \mathbf{x} \\ \text{s.t.} \quad & \mathbf{A} \mathbf{x} \leq \mathbf{b} \\ & \mathbf{A} \mathbf{e} \mathbf{q} \cdot \mathbf{x} = \mathbf{b} \mathbf{e} \mathbf{q} \\ & \mathbf{l} \mathbf{b} \leq \mathbf{x} \leq \mathbf{u} \mathbf{b} \end{aligned}$$

and is called with the command `quadprog(H, f, A, b, Aeq, beq, lb, ub)`.

It is easy to see how to match the two formulations:

- $\mathbf{x} = \mathbf{w}$
- $\mathbf{f} = \mathbf{0}$
- $\mathbf{H} = 2 \boldsymbol{\Sigma}$
- $\mathbf{A} = -\boldsymbol{\mu}'$
- $\mathbf{b} = -r_{\text{target}}$
- $\mathbf{A} \mathbf{e} \mathbf{q} = \mathbf{1}'$
- $\mathbf{b} \mathbf{e} \mathbf{q} = 1$
- $\mathbf{l} \mathbf{b} = -\text{infinity}$
- $\mathbf{u} \mathbf{b} = \text{infinity}$

```
numAssets = 2;
muVec = [9.1; 12.1];
SigmaMx = [272.25, -57.35;
           -57.35, 249.64];
```

```
targetReturn = 11;
```

```
%SINGLE OPTIMIZATION
```

```
%create the matrix X
H = 2*SigmaMx;
```

```
%create a vector of length numAssets with zeros
f = zeros(numAssets,1);
```

```
%create right hand and left hand side of inequality constraints
A = -transpose(muVec);
b = -targetReturn;
```

For example, the inequality constraint

$$\mathbf{w}' \boldsymbol{\mu} \geq r_{\text{target}}$$

in the mean-variance formulation is mapped to the inequality constraint assumed by the `quadprog` function

$$\mathbf{A} \mathbf{x} \leq \mathbf{b}$$

by rewriting the mean-variance constraint as

$$-\mathbf{w}' \boldsymbol{\mu} \leq -r_{\text{target}}$$

and setting $\mathbf{A} = -\boldsymbol{\mu}'$ and $\mathbf{b} = -r_{\text{target}}$.

Suppose we are given a portfolio with a number of stocks equal to `numAssets`, expected returns for the stocks stored in a vertical vector `muVec`, covariance matrix `SigmaMx`, and required expected return of `targetReturn`. Consider a simple portfolio of two stocks with expected returns of 9.1% and 12.1%, standard deviations of returns of 16.5% and 15.8%, and a correlation of -0.22 (covariance of -57.35). A MATLAB script that uses input data for the two stocks, calls the optimization solver for several instances of the problem with different values of `targetReturn`, and plots the efficient frontier looks as follows:

```

%create lower bounds array for asset weights (negative infinity)
lb = -inf*ones(numAssets,1);

%create upper bounds array for asset weights (infinity)
ub = inf*ones(numAssets,1);

%create right hand and left hand side of equality constraints
beq = [1];
Aeq = transpose(ones(numAssets,1));
[weights,variance] = quadprog(H,f,A,b,Aeq,beq,lb,ub);

%print results to screen
stdDev = sqrt(variance)
weights

%EFFICIENT FRONTIER
%loop through different values of the target portfolio returns, compute the
%optimal portfolio standard deviation, and plot the efficient frontier

iCounter = 1;

for iTRet = 9.5:0.5:12
    b = -iTRet;
    [weights,variance] = quadprog(H,f,A,b,Aeq,beq,lb,ub);
    y(iCounter) = iTRet;
    x(iCounter) = sqrt(variance);
    iCounter = iCounter + 1;
end

%plot efficient frontier
plot(x,y);
xlabel('Portfolio standard deviation');
ylabel('Portfolio expected return');
title('Efficient Frontier');

```

The command

```
[weights,variance] = quadprog(H,f,A,b,
Aeq,beq,lb,ub);
```

ensures that the optimal solution to the optimization problem is stored in a vector called `weights`, and the optimal objective function value (the minimum portfolio variance) is stored in the scalar `variance`. This is an example of using a MATLAB built-in function.

The portfolio standard deviation is computed as the square root of variance.

The MATLAB output from running the code above is as follows:

```
stdDev =
    10.4928
weights =
    0.3667
    0.6333
```

The script also contains an example of a `for` loop that runs the optimization problem for values of the target return between 9.5 and 12, increasing the target return by 0.5 at each iteration. The expected portfolio return and the optimal standard deviation obtained from the optimization output are stored in vectors `x` and `y`. The last few lines in the code plot the efficient frontier using the values stored in `x` and `y`, and label the graph.

Pricing a European Call Option by Simulation

Simulation is a technique for replicating uncertain processes and evaluating decisions under uncertain conditions. In the financial context, it typically involves generation of random numbers from particular probability distributions, using those for approximating the behavior of exogenous variables such as stock returns, and assessing outcomes of interest, such as the performance of a portfolio or the price of a financial instrument.

Through the Statistics Toolbox, MATLAB provides commands for generating the most commonly used random numbers directly. For example, a normal random variable can be simulated with

```
>> normrnd(mean, stdev, numRows,
           numColumns)
```

In the expression above, `mean` and `stdev` are the mean and the standard deviation of the normal random variable. `numRows` and `numColumns` specify the dimension of the array of random numbers we would like to generate.

We show how to use MATLAB's Statistics Toolbox to compute the price of a European call option with simulation under the assumptions that there are no transaction costs or market frictions, and the price of the underlying follows geometric Brownian motion. (The closed-form formula for pricing the option under these assumptions is the Black-Scholes for-

mula.) Option pricing by simulation was first suggested by Boyle (1977). For further details on the implementation and more examples, see Pachamano and Fabozzi (2010).

The evolution of the asset price at time t , S_t , can be described by the equation

$$dS_t = \mu S_t dt + \sigma S_t dW_t$$

where W_t is standard Brownian motion and μ and σ are the drift and the volatility of the process, respectively. For technical reasons (absence of arbitrage), when pricing an option, the drift μ is replaced by the risk-free rate r .

Under the assumption for the random process followed by the asset price, the value of the asset price S_T at time T given the asset price S_t at time t can be computed as

$$S_T = S_t e^{(r - \frac{1}{2}\sigma^2) \cdot (T-t) + \sigma \cdot \sqrt{(T-t)} \cdot \tilde{\varepsilon}}$$

where $\tilde{\varepsilon}$ is a standard normal random variable. (If the stock pays a continuously compounded dividend yield of q , then we use $(r - q - 0.5 \cdot \sigma^2)$ instead of $(r - 0.5 \cdot \sigma^2)$ as the drift term.)

The price of the option can be approximated by creating scenarios for the stock price S_T at time T , computing the discounted payoffs of the option, and finding the expected payoff of the option. Suppose we generate N scenarios for $\tilde{\varepsilon}$: $\varepsilon^{(1)}, \dots, \varepsilon^{(N)}$. Then, the price of a European call option with strike price K will be

$$C_t = e^{-r(T-t)} \cdot \sum_{n=1}^N \frac{1}{N} \cdot \max \left\{ S_t e^{(r - \frac{1}{2}\sigma^2) \cdot (T-t) + \sigma \cdot \sqrt{(T-t)} \cdot \varepsilon^{(n)}} - K, 0 \right\}$$

The expression above is the expected value of the option payoffs; that is, the weighted average of the option payoffs. The "weight," or the probability of each scenario, is $1/N$.

In MATLAB, we create a function `EuropeanCall` (stored in a file `EuropeanCall.m`), which follows.

```

function CEPrice = EuropeanCall(initPrice,K,r,T,sigma,q,numPaths)
%function for evaluating the price of a European call option using crude
%Monte Carlo
%initPrice is the initial price, K is the strike price, r is the annual interest
%rate, T is the time to maturity, sigma is the annual volatility, q is the
%continuous dividend yield, numPaths is the number of scenarios to generate for
%the evaluation

CEpayoffs = zeros(numPaths,1);

%compute a vector array of asset prices, one for each scenario
assetPrices = initPrice*exp((r-q-0.5*sigma^2)*T+sigma*sqrt(T)*
normrnd(zeros(1,numPaths),ones(1,numPaths))));

CEpayoffs = exp(-r*T)*max(assetPrices - K,0);

CEPrice = mean(CEpayoffs);

```

In the function, we generate the (random) end points of `numPaths` paths for the underlying stock price under the assumption that the price follows geometric Brownian motion. We use the Statistics Toolbox function `normrnd(mu,sigma)`, which in this case returns a vector array with the realizations of normal random variables. The array has the dimension of the `mu` and `sigma` vectors, which are vectors of zeros and ones, respectively, with length `numPaths`. Then, we generate a vector array of asset prices by calculating the asset price in each scenario. We use a nice feature in MATLAB, which is that we can pass an array (namely, `normrnd(zeros(1,numPaths),ones(1,numPaths))`) into a formula (namely, `initPrice*exp((r-q-0.5*sigma^2)*T + sigma*sqrt(T)*normrnd(zeros(1,numPaths),ones(1,numPaths)))`), and MATLAB automatically creates an array with results (`assetPrices`). In other programming languages, we would need to implement this by creating a `for` loop.

Finally, we calculate the option price `CEPrice` as the average of the payoffs of the option in each scenario by using the function `mean`.

Pricing a European Call Option Using a Sobol Sequence

In the function `EuropeanCall`, we used the MATLAB built-in function `normrnd` from the Statistics Toolbox with arguments that were arrays of zeros and ones to generate a set of realizations drawn from a standard normal probability distribution and compute a set of paths for the price of the underlying. Alternatively, we could have generated a set of quasirandom numbers that sometimes lead to a faster and more accurate estimation for the option price. (See the discussion in Chapter 14 of Pachamanova and Fabozzi, 2010; Chapter 6 in McLeish, 2005; or section 5.2.3 of Chapter 5 in Glasserman, 2004.) MATLAB's Statistics Toolbox contains built-in syntax for computing the elements of some low-discrepancy sequences, such as the Sobol sequence (Sobol, 1967). Namely, the function `sobolset(d)` computes a Sobol sequence of dimension `d`, and the sequence can then be retrieved with the command `net`. For example,

```
seq = sobolset(3); net(seq,5)
```

returns the first five elements of a Sobol sequence of dimension 3.

The calculation of the European call option price using the Sobol sequence is shown in the function `EuropeanCallSobol` below.

```
function SCEPrice = EuropeanCallSobol(initPrice,K,r,T,sigma,q,numPaths)
%function for evaluating the price of a European option using
%a Sobol sequence
%initPrice is the initial price, K is the strike price
%r is the annual interest rate, T is the time to maturity, sigma is the
%annual volatility
%q is the continuous dividend yield
%numPaths is the maximum number of scenarios to generate for the evaluation

SCEpayoffs = zeros(numPaths,1);
%use the sobolset function in the Statistics Toolbox to generate the
%sequence
seq = sobolset(1);
SobolPoints = net(seq,numPaths+1);
%drop the first element, which is 0
SobolPoints = SobolPoints(2:numPaths+1);

%compute a vector array of asset prices, one for each Sobol point
assetPrices = initPrice*exp((r-q-0.5*sigma^2)*T+sigma*sqrt(T)*
norminv(SobolPoints));

%compute a vector array of discounted payoffs, one for each scenario
%generated from a Sobol point

SCEpayoffs = exp(-r*T)*max(assetPrices - K,0);

%compute price of option
SCEPrice = mean(SCEpayoffs);
```

Again, in this function, we passed an array (`SobolPoints`) into a formula (`initPrice * exp((r-q-0.5*sigma^2)*T + sigma*sqrt(T)*norminv(SobolPoints))`), and MATLAB automatically created an array with results (`assetPrices`).

The Sobol sequence generated in the function is of dimension 1 and length `numPaths+1`. We created it with the commands

```
seq = sobolset(1);
SobolPoints = net(seq,numPaths+1);
```

and remove the first element, which is 0, with the command

```
SobolPoints = SobolPoints(2:numPaths+1);
```

(As explained in Chapter 14 of Pachamanova and Fabozzi [2010], it is common to drop some number of elements of low-discrepancy sequences. It takes a certain “warming up” for the low-discrepancy sequence to begin producing stable and accurate estimates.)

Computing the Black-Scholes Price of a European Option Using the Financial Toolbox

The price for the European option obtained in the ways described in the previous two sections is, of course, an approximation. It will vary slightly depending on the specific set of scenarios simulated with the `normrnd` function, or on the number of points generated with the Sobol sequence. The true option price under the stated assumptions is given by the Black-Scholes formula. (See Black and Scholes, 1973; Hull, 2008; or Pachamanova and Fabozzi, 2010.) As we mentioned earlier in this entry, the function `blsprice` in MATLAB's Financial Toolbox can compute this price. For example, for an initial price of 100, a strike price of 110, an interest rate of 6%, time to maturity of 1 year, and volatility 40%, the Black-Scholes price for the European call option will be computed by typing

```
>> blsprice(100, 110, 0.06, 1, 0.40)
```

at the MATLAB prompt. MATLAB returns

```
ans =
    14.4018
```

You should get a similar price by typing the names of the user-defined functions we wrote previously,

```
>> EuropeanCall(100,110,0.06,1,0.40,
    0,20,1000)
```

to compute it with simulation, or

```
>> EuropeanCallSobol(100,110,0.06,1,
    0.40,0,1000)
```

to compute it by using a Sobol sequence. Here we are requesting that the price be evaluated with 1,000 paths for the price of the underlying. The greater the number of paths, the closer

the estimates will be to the Black-Scholes price. For this example, we obtained 14.3772 for the option price by crude Monte Carlo simulation, and 14.0882 by using the Sobol low-discrepancy sequence. The variability for the option price estimated using the crude Monte Carlo simulation approach is large, so readers can expect answers that differ quite a bit.

KEY POINTS

- MATLAB uses a number-array-oriented programming language; that is, a programming language in which vectors and matrices are the basic data structures.
- Array operations are very efficient in MATLAB.
- Specialized MATLAB toolboxes provide additional capabilities, save time, and simplify model building. Some toolboxes build on the capabilities of other toolboxes and need to be purchased in groups.
- An M-file is a file with instructions that MATLAB executes sequentially. Such files are saved with the suffix ".m" and can be called from the prompt in MATLAB's Command window by typing their name without the suffix ".m".
- M-files can be scripts, that is, a simple listing of instructions for MATLAB, or functions, which take in a certain number of arguments and return a certain number of outputs.
- While general script M-files can contain any sequence of instructions that will be completed when the name of the file is typed at the MATLAB prompt, function M-files need to start with a specific first line. That line contains the word "function" and a declaration of the function name, inputs, and outputs. The function name and the name of the M-file should be the same.
- Control flow statements in MATLAB include `for` loops, `if` statements, `while` loops, `switch-case` constructions, and `try-catch` blocks.

- MATLAB has beautiful 2-D and 3-D graphing capabilities. The most common function for plotting 2-D graphs is `plot`.
- MATLAB has the ability to interact efficiently with Microsoft Excel. The core product contains commands that allow importing data from and exporting data to Excel.
- Spreadsheet Link EX is a useful toolbox that allows a more complex interface between MATLAB and Excel. With Spreadsheet Link EX, one can call MATLAB's functions directly from within Excel, thus ensuring access to MATLAB's superior computational and graphical capabilities.
- Optimization in MATLAB can be performed through the Optimization and the Global Optimization Toolboxes. These capabilities are especially useful for quantitative portfolio management.
- MATLAB expects optimization formulations to be passed to its solvers in an array form and has functions that can call specific solvers for specific types of optimization problems.
- The MATLAB Statistics Toolbox contains functions for

random number generation and can be used when performing financial simulations.

Introduction to Visual Basic for Applications

DESSISLAVA A. PACHAMANOVA, PhD

Associate Professor of Operations Research, Babson College

Abstract: Visual Basic for Applications (VBA) is a programming language environment that allows Microsoft Excel users to automate tasks, create their own functions, perform complex calculations, and interact with spreadsheets. Despite some important limitations, VBA adds useful capabilities to spreadsheet modeling and is a good tool to know for finance professionals for whom Microsoft Excel is the platform of choice.

This entry is a brief introduction to Visual Basic for Applications (VBA), the *programming language* environment that allows *Microsoft Excel* users to *automate* tasks, create their own functions, perform complex calculations, and interact with *spreadsheets*. We focus on features of VBA useful for financial applications. For a comprehensive introduction to VBA, good references are Walkenbach (2004) and Roman (2002). The Excel VBA help is also useful as a quick reference. All Excel commands listed in this entry are based on Microsoft Office 2007.

A SIMPLE EXAMPLE OF A VBA PROGRAM

Before we review some important characteristics of the VBA language, let us create a simple example of a VBA program. Excel has a tool for recording tasks performed in a spreadsheet, which can then be replayed as a macro. Macros

in Excel record a sequence of commands, so that you do not have to repeat the same set of instructions if you need to perform the task several times. Macros are in effect computer programs whose commands are hidden from the user, but can be seen if you open the VBA editor (VBE). You can access the VBE by using a shortcut, **Alt-F11**, in all versions of Excel. In Excel 2007, VBE can be accessed from the **Developer** tab. If the **Developer** tab is not visible, do the following to set it up: Click on the main MS Excel button , then **Excel Options**. Under the **Popular Options** tab, check **Show Developer Tab in Ribbon**. Once the **Developer** tab is available in Excel's top menu, you can click on the Visual Basic button in the ribbon associated with it to open the editor. (See Figure 1.)

Use the **Macro Security** button to enable macros. (It is always a good idea to return to the default—disabled macros—after you are finished working with macros.)

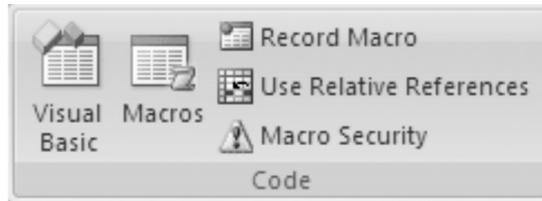

Figure 1 Visual Basic Button in the Developer Ribbon in Excel 2007

Open a new file and name it **ReturnCalc.xlsm**. (Excel 2007 will automatically make the file extension .xlsm if there are macros already in the file. Here, we do not have macros yet, so the default in Excel 2007 will be to save the file as .xlsx. To save the file with extension .xlsm, you need to select **Excel Macro-Enabled Workbook** from the drop-down menu next to **Save as Type** in the **Save** dialog box.)

We are trying to create the layout shown in Figure 2. First, enter the text in columns A and B; that is, enter stock prices for three points in time. Suppose we want to compute the realized cumulative return over the two time periods for any set of three stock prices in column B. We can do that by, for example, computing the realized returns over each of the two periods in column C, and then computing the cumulative return between times 1 and 3 in cell D5.

Let us record the entries and the calculations as a macro. To record a macro, click on **Record Macro** in the **Developer** tab. Delete the default name **Macro 1**, and replace it with something more meaningful, for example, **ReturnCalc**. Click **OK**. Once the macro recorder is on, do the following:

1. Enter $= (B3 - B2) / B2$ in cell C3 (this will compute the return for time period 1–2).
2. With the cursor in cell C3, enter **Ctrl-C** to copy the contents of cell C3, move the cursor to cell C4, and enter **Ctrl-V** to paste. This will fill cells C4 with the formula for computing the return between times 2 and 3.
3. Highlight cells C3–C4, right-click, select **Format Cells | Number | Percentage | Decimal Points 2** to format the returns as percentages.
4. Click on cell D3, enter $= (1 + C3)$. Then right-click, select **Format Cells | Number | Number | Decimal Points 2** to format the contents of the cell as a number.
5. Click on cell D4, enter $= D3 * (1 + C4)$.
6. Type **Total Return** in cell C5.
7. Enter $= D4 - 1$ in cell D5 to compute the total return over the five periods.
8. Highlight cells C5:D5. Right-click, then select **Format Cells | Border**. Select the double-line,

	A	B	C	D	E
1			Returns	Cumulative	
2	Stock price 1	100			
3	Stock price 2	110	10.00%	1.10	
4	Stock price 3	105	-4.55%	1.05	
5			Total return	5.00%	
6					

Figure 2 Macro Recording Example

then click the upper line of the cell in the **Border** window to make the double-line appear. Click **OK**.

9. Click on the stop button in the macro recorder to stop recording.

Now let us see what the macro does. You can use the file you created. Delete all contents from the array C3:D5. Press **Alt-F8** or, equivalently, click on the **Macro** button in the **Developer** tab. Select `ReturnCalc`, press **OK**. The spreadsheet

should fill up with the entries that you entered before. If you had changed the value of the stock price in any of the three cells in column B, the macro should calculate the correct corresponding value for total return in cell D5.

Behind the scenes, Excel recorded VBA code with instructions that tell Excel what functions to perform when you run the macro. You can see these instructions by opening the VBA editor and clicking on **Modules | Module 1**. The instructions look like this:

```

1 Sub ReturnCalc()
2 '
3 ' ReturnCalc Macro
4 ' Macro recorded month/day/year by you
5 '
6
7 '
8 Range("C3").Select
9 ActiveCell.FormulaR1C1 = "= (RC[-1]-R[-1]C[-1])/R[-1]C[-1]"
10 Range("C3").Select
11 Selection.Copy
12 Range("C4").Select
13 ActiveSheet.Paste
14 Range("C3:C4").Select
15 Selection.NumberFormat = "0.00%"
16 Range("D3").Select
17 ActiveCell.FormulaR1C1 = " = 1+RC[-1]"
18 Range("D3").Select
19 Selection.NumberFormat = "0.00"
20 Range("D4").Select
21 ActiveCell.FormulaR1C1 = " = R[-1]C*(1+RC[-1])"
22 Range("C5").Select
23 ActiveCell.FormulaR1C1 = "Total return"
24 Range("D5").Select
25 ActiveCell.FormulaR1C1 = " = R[-1]C-1"
26 Range("D5").Select
27 Selection.Style = "Percent"
28 Selection.NumberFormat = "0.00%"
29 Range("C5:D5").Select
30 Selection.Borders(xlDiagonalDown).LineStyle = xlNone
31 Selection.Borders(xlDiagonalUp).LineStyle = xlNone
32 Selection.Borders(xlEdgeLeft).LineStyle = xlNone
33 With Selection.Borders(xlEdgeTop)
34     .LineStyle = xlDouble

```

```

35     .Weight = xlThick
36     .ColorIndex = xlAutomatic
37 End With
38 Selection.Borders(xlEdgeBottom).LineStyle = xlNone
39 Selection.Borders(xlEdgeRight).LineStyle = xlNone
40 Selection.Borders(xlInsideVertical).LineStyle = xlNone
41 Range("D5").Select
42 End Sub

```

Knowing the actions we took to create the macro, it is relatively straightforward to trace what the program is doing at every step. To understand better how the macro works, however, and to know how to create such scripts without recording them in the spreadsheet, we need to understand some basic facts about VBA.

OBJECTS, PROPERTIES, AND METHODS

The most important fact about VBA is that it tries to act as an object-oriented language. (VBA does not quite qualify as an object-oriented language for technical reasons; however, for all practical purposes it is helpful to remember that VBA shares many of the same concepts as “real” object-oriented programming languages.) This means that it treats every component of Excel, such as a worksheet, a cell, a range of cells, and a chart, as an object. Objects are arranged in a hierarchy and have properties (attributes) that can be modified by entering the name of the object followed by dot and a specific command. In addition, objects are associated with actions (methods) that the objects can perform or have applied to them. You can view all objects by selecting **View | Object Browser** from the top menu in the VBE window. In Excel 2007, you can also view a detailed list of objects, their properties, and their methods by clicking on **Help** (pressing **F1**) and selecting **Excel Object Model Reference**.

The largest object, the object on top of the hierarchy, is Excel itself. It is the `Application` object. Worksheets, ranges, selections, charts, and

so on are all objects that are lower in the hierarchy. Objects in the same class are organized in collections. For instance, the `Workbooks` collection contains all workbooks (Excel files) that are currently open. Similarly, the `Worksheets` collection contains all Excel spreadsheets in the files that are currently open, the `Sheets` collection contains all Excel spreadsheets and charts in the files that are currently open, and so on. Thus, for example, to reference cell C3 in Worksheet **Return** in file (Workbook) **ReturnCalc.xlsm**, you would type

```

Application.Workbooks("ReturnCalc
    .xlsm").Sheets("Return").Range("C3")

```

This reference is rather long and, as we can see from the actual VBA code, it is not necessary, as long as the macro is saved within the active Excel workbook and the identification of the cell range that is referenced is unique. In our example, `Range("C3")` is sufficient to reference cell C3, because the objects higher in the hierarchy, such as the name of the worksheet and the name of the file, are implied in the reference.

An example of an action (method) that can be performed on an object is the command `Select`. The `Select` method applies to several objects, including `Worksheet`, `Chart`, and `Range`. Notice that it was used often in the macro we created, because clicking on a cell or highlighting on an array performed the action. For example, in line 14 we selected the range C3:C4. Similarly, in line 10 we selected the cell C3 with the command

```

Range("C3").Select

```

Then, the `Selection` property of an object in the background (the `Window` object) was used to return a `Range` object (representing the selected range on the spreadsheet) on which we can apply other methods, such as `Copy` (line 11 of the code):

```
Selection.Copy
```

VBA usually suggests actions and properties that can be used with an object, so you can select from a list.

Another example of modifying the properties of the object is in lines 14–15 of the VBA code. They request that the format of the cell range C3:C4 be changed to percentage with two digits after the decimal point. Namely, we selected the range C3:C4, and the `NumberFormat` property of the `Range` object that was returned by the `Selection` property was set to percentage with two digits after the decimal point.

While the code we created by recording a macro is helpful in understanding the basics of the VBA language, it can be confusing because it is unnecessarily verbose. For example, the same result as lines 14–15,

```
Range("C3:C4").Select
Selection.NumberFormat = "0.00%"
```

can be achieved with the command

```
Range("C3:C4").NumberFormat =
    "0.00%"
```

which modifies directly the property `NumberFormat` of the object `Range("C3:C4")`.

You can test that this is the case by deleting lines 14–15 in the VBA code in your file and replacing them with `Range("C3:C4").NumberFormat = "0.00%"`. Save the code by pressing **Ctrl-S** or selecting **Save** from the list under the main Excel button . Next, delete cells C3:D5 in the spreadsheet, and run the `ReturnCalc` macro again. The result and the formatting should be the same.

The effect of the `With/End` structure in lines 33–36 is another piece of code that can be repli-

cated easily through other commands; the advantage of the structure is that it allows you to reduce the number of listed objects in the code, and that it makes the code more readable. A `With/End` statement requires the specification of an object. Inside the `With/End` statement, one can omit mentioning the object with every modification of a property or application of a method to the object. In this particular example, lines 33–36 could be replaced with

```
Range("C5:D5").Borders(xlEdgeTop)
    .LineStyle = xlDouble
Range("C5:D5").Borders(xlEdgeTop)
    .Weight = xlThick
Range("C5:D5").Borders(xlEdgeTop)
    .ColorIndex = xlAutomatic
```

with the same effect as the `With/End` statement that references `Range("C5:D5").Borders(xlEdgeTop)`. However, the `With/End` statement is more concise.

In general, when writing VBA code you do not need to select cells explicitly in order to enter data into them. However, if you are new to VBA, it is helpful to record the macro first to see the code VBA suggests, and clean up afterward. In addition, it is a good idea to “comment out” the redundant statements at first, rather than deleting them. (Commenting out is done by entering an apostrophe (') at the front of the line of code that you wish VBA to ignore.) After commenting out overly verbose statements, save the macro by pressing **Ctrl-S**, make sure it still does what you would like it to do, and only then go back and delete the redundant statements.

A less verbose version of the VBA code is

```
Sub ReturnCalc()
    '
    ' ReturnCalc Macro
    ' Less verbose
    '
    Range("C3").Formula = "=" & (RC[-1]
        -R[-1]C[-1])/R[-1]C[-1] "
    Range("C3").Copy
    Range("C4").Select
```

```

ActiveSheet.Paste
Range("C3:C4").NumberFormat =
"0.00%"
Range("D3").Formula = "= 1+RC[-1]"
Range("D3").NumberFormat = "0.00"
Range("D4").Formula = "= R[-1]C*
(1+RC[-1])"
Range("C5").Formula = "Total
return"
Range("D5").FormulaR1C1 = "=
R[-1]C-1"
Range("D5").Style = "Percent"
Range("D5").NumberFormat = "0.00%"
With Range("C5:D5")
    .Borders(xlDiagonalDown)
    .LineStyle = xlNone
    .Borders(xlDiagonalUp)
    .LineStyle = xlNone
    .Borders(xlEdgeLeft).LineStyle
    = xlNone
    With .Borders(xlEdgeTop)
        .LineStyle = xlDouble
        .Weight = xlThick
        .ColorIndex = xlAutomatic
    End With
    .Borders(xlEdgeBottom).LineStyle
    = xlNone
    .Borders(xlEdgeRight).LineStyle
    = xlNone
    .Borders(xlInsideVertical)
    .LineStyle = xlNone
End With
Range("D5").Select
End Sub

```

Notice how the `With/End` structure was used to reduce the number of words we need to use, and how `With/End` structures can be nested inside one another. You can test that this code achieves the same effect by replacing the current code in the module in your file **ReturnCalc.xlsm**, saving the new code, and rerunning the macro `ReturnCalc`.

Before we end this section, we would like to mention a useful property of the `Range` object, `Offset(v, h)`. It points to a cell that is v cells

above or below (vertical direction) and h cells to the right or left (horizontal direction) from a specific cell. For example,

```

Range("C5").Select
ActiveCell.Offset(1,2) = 10

```

sets the value of the cell that is 1 cell down and 2 cells to the right from cell C5 (i.e., cell E6) to 10. Similarly,

```

Range("C5").Select
ActiveCell.Offset(-1,-2) = 20

```

sets the value of the cell that is 1 cell up and 2 cells to the left from cell C5 (i.e., cell A4) to 20.

We saw the idea of referencing cells above and below and to the left and right of the current cells in the example code at the beginning of this section. For example, the formula in line 9 of the original macro,

```

ActiveCell.FormulaR1C1 = "= (RC[-1]
-R[-1]C[-1])/R[-1]C[-1]"

```

uses the cell in the same row and one column to the left (`RC[-1]`) and the cell one row up and one column to the left (`R[-1]C[-1]`) to compute the value in the active cell. These kinds of commands help when one prefers to create relative references—in other words, to perform tasks relative to a prespecified location in the spreadsheet without changing the code when the starting location is changed.

The default in VBA is to record macros in absolute reference mode. To change the mode to relative references, make sure that the relative references button in the **Developer** tab ( Use Relative References) is “pressed in” before starting the macro recorder.

PROGRAMMING TIPS

While some desired formatting of an Excel spreadsheet can be recorded with the macro recorder, knowing basic programming in VBA opens up a whole lot of additional functionality. For example, suppose that you have a set of data on stock returns over several months and,

as often happens with real-world data, it is not recorded well—there are some duplicate rows. You could record a macro as you go through the spreadsheet and clean them by hand, but next time you have a set of data, duplicate entries will not be exactly in the same rows as the first set of data. How can you tell Excel to sort through the data and remove duplicate rows in *any* set of data? You need to construct a program from scratch and make the code general enough to enable the script to be transferable.

In the remainder of this section, we cover some basic VBA programming concepts. We discuss the difference between subroutines and user-defined functions, explain variable declaration in VBA, and introduce some important control flow statements. These concepts are not unique to VBA—versions of them exist in most programming languages.

Subroutines versus User-Defined Functions

Subroutines and user-defined *functions* in VBA are both blocks of code saved in modules. (If you do not see a module when you open VBE, select **Insert | Module** from the top menu in VBE to create one.) The difference is that subroutines are general scripts; that is, lists of instructions, whereas functions complete a list of instructions and return a value to the user. Subroutines have the general form

```
Sub ()
[commands]
End Sub
```

whereas functions have the form

```
Function FunctionName(list of inputs)
  As type [commands]
FunctionName = Return value
  'Computed from [commands]
End Function
```

The macro recorded at the beginning of this entry was an example of subroutine code. Next, we provide another small example in order to

illustrate the difference between a subroutine and a function. Do not worry about the details of the commands right now; we will explain each part of the code in subsequent sections.

Suppose we would like to calculate $n!$ (pronounced “ n factorial”), where n is an integer number the user provides as input. $n!$ is the product of all integer numbers less than or equal to n ; that is, $n! = 1 \cdot 2 \cdot \dots \cdot n$. Next, we provide several examples of subroutines and user-defined functions that accomplish this goal. The subroutine

```
Sub FactorialSub1()
'Compute factorial using control flow
statements

'Declare the variable that will
'store the value for factorial
  Dim Factorial As Integer
'Declare the variable that will
'store the number n
  Dim inNumber As Integer
'Declare the variable that will be
'used as counter in the loop
  Dim i As Integer

'Read in the number from cell B1,
'store it in inNumber
  inNumber = Range("B1").Value

'Calculate factorial
  Factorial = 1
  For i = 1 To inNumber
    Factorial = i * Factorial
  Next i

  Range("B2").Value = Factorial
End Sub
```

takes the number specified in cell B1, computes the factorial of that number, and sets the value of the cell B2 to the value of that factorial. To see how this subroutine works, copy the code in a new module in the VBE window of a new Excel file. Enter the number 5 in cell B1. Press **Alt-F8**, and select `FactorialSub1`. The

subroutine fills cell B2 with 120 ($5! = 1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 = 120$).

The function `FactorialFun1` whose code is provided next computes the same result, but works in a different way. It takes a number as an input (`inNumber`), and returns a number as an output (`FactorialFun1`). The output to be returned should have the same name as the function.

```
Function FactorialFun1(inNumber)
    As Integer
        Dim i As Integer
        'Calculate factorial
        FactorialFun1 = 1
        For i = 1 To inNumber
            FactorialFun1 = i * FactorialFun1
        Next i
End Function
```

Add this function to the module in the VBE in your file. To call this function, type in a cell in your spreadsheet (say, cell B3) = `FactorialFun1(B1)`. If the value in cell B1 was still 5 (the value you entered in the previous example), then the value of cell B3 will be 120. Notice that the syntax for calling your (user-defined) function is not different from the syntax for calling built-in Excel functions. In fact, Excel has a function for computing a factorial, = `Fact(number)`, and if you entered the expression = `Fact(B1)` in, say, cell B4 of your spreadsheet, you would get the same result (120).

Excel built-in functions can be used also inside VBA code with the prefix `Application`. It is worthwhile to note, though, that VBA itself has some built-in numeric functions. In particular, functions such as `Abs` (absolute value), `Exp` (exponential), `Int` (integer part), `Cos` (cosine), `Sin` (sine), `Log` (natural log), `Rnd` (random number generator), `Sign` (sign function), `Tan` (tangent), and `Sqr` (square root) can be used directly within VBA code without the prefix `Application`. Although it seems that this should make things easier, it may also be a source of confusion. Notice that Excel has equivalent nu-

merical functions for formulas that are entered into cells in spreadsheets, but the syntax for some of the functions is different. For example, the natural logarithm function in Excel is `Ln`, and the square root function is `Sqrt`. So, typing `Sqr` in your program in VBA is equivalent to typing `Application.Sqrt`. In practice, you would want to use the shorter syntax `Sqr`. It is important to be aware of inconsistencies between names of equivalent functions in Excel and VBA.

The subroutine `FactorialSub1()` and the function `FactorialFun2()` whose code is provided below illustrate how the factorial can be computed by calling the built-in Excel function `Fact`.

```
Sub FactorialSub2()
    'Compute factorial using Excel's FACT
    'function within a subroutine
    Range("B5") = Application.Fact_
        (Range("B1"))
End Sub
```

```
Function FactorialFun2(inNumber) As
Integer
    'Calculate factorial
    FactorialFun2 = Application_
        .Fact(inNumber)
End Function
```

Copy the code above in the module in your file. The subroutine `FactorialSub2()` uses the number entered in cell B1 in the spreadsheet as an input and calls the Excel function `Fact()` to compute the factorial of the value in cell B1. The function `FactorialFun2()` is called with an input argument that is a number and returns the factorial of that number. If you type = `FactorialFun2(B1)` in cell B6 and the value in cell B1 is still 5, you should obtain 120 in cell B6.

What is the advantage of using user-defined functions rather than subroutines? In some cases, you can only use one or the other. However, in cases in which both are possible, it may be preferable to structure the script as

a function as opposed to a subroutine. User-defined functions are more “transferable”—in other words, it is easier to use them in different places in the spreadsheet. There are some other conveniences—for example, check what happens when the number for n in cell B1 is changed from 5 to 6. Cell B3 (which contains the call to the function `FactorialFun1`) immediately updates to 720, which is the correct result. However, cells B2 and B5—those that are output ranges for the subroutines `FactorialSub1` and `FactorialSub2`—do not update until you rerun the macros associated with them.

Variable Declaration

Variables are a basic common concept in computer languages. They are used to store numerical and text data and handle intermediate output in subroutines and functions. For example, `inNumber` in the code for `FactorialSub1` was a variable that stored the value of n for which the factorial should be computed. There is no convention for naming variables, but a good practice is to give them meaningful names (rather than x , y , and z), so that your code is easier to follow. We prefer to start names of variables with small letters. If there is a second word in the name, that word starts with a capital letter. We also like to differentiate variables that store inputs (such as `inNumber`) and variables that record output (e.g., `outFactorialValue`).

Depending on their type, variables are handled differently and are allocated a different amount of memory. For example, we specified that `inNumber` should be an integer number by declaring it with the syntax `Dim variableName As variableType`:

```
Dim inNumber As Integer
```

Other types of variables include `String`, `Single`, `Double`, `Long`, `Boolean`, `Date`, `Object`, `Variant`, and so on. For example, when you need a variable that will hold a fractional (also called “floating point”)

value, then you should use the `Single` or `Double` data type. When you need a variable to store text data, use the `String` type. The `Variant` type can be used to replace any type; however, it also uses up the largest amount of space, so it is better to specify a particular type for a variable if you know it.

When specifying a variable type, make sure that you have enough space for the data you are planning to store in that variable. If the value gets too large for the variable type, your program may crash. For example, the `Integer` type can store values between $-32,768$ and $32,767$. If you need to store an integer number outside this range, use the `Long` variable type. Similarly, the `Single` (floating point) type can store numbers between $-3.402823E38$ and $-1.401298E-45$ for negative values, and numbers between $1.401298E-45$ and $3.402823E38$ for positive values.¹ If you need to work with fractional numbers outside this range, use the `Double` (floating point) variable type.

Variables can be grouped into arrays. For example,

```
Dim myArray(5) As Integer
```

declares an array of integers of size 6.

One of the most confusing things about VBA is the way it handles arrays. The default is to index the first element in arrays as 0, which is the convention in most programming languages, which is why the total number of elements in `myArray` is 6. However, in some special circumstances arrays are treated as starting with the index 1. To ensure consistency and minimize confusion, it is helpful to use the command

```
Option Base 1
```

at the beginning of the module, which makes sure that the indexing of arrays always starts at 1. If this option is stated, then declaring

```
Dim myArray(5) As Integer
```

will result in an array of 5 elements. Those elements can be referenced as `myArray(1)`, ..., `myArray(5)` later in the program.

You can specify arrays of multiple dimensions as well, for example,

```
Dim myMultiArray(5,2) As Integer
```

will result in an array of 5 rows and 2 columns.

You can also declare dynamic arrays, that is, arrays that do not have specific dimensions from the beginning. This may happen if, for example, you have a set of data and you need to read it in before you know how many elements it has. In that case, you would declare an array

```
Dim myDynamicArray() As Integer
```

which will be filled as necessary. Once the number of elements is counted, the array can be resized by using the command `ReDim`, for example,

```
ReDim myDynamicArray(10)
```

`ReDim` reinitializes (sets to empty) all values within an array. If you want to preserve the values that are already there, use `ReDim Preserve`, which preserves as many elements as can fit in the new array dimensions.

Working with arrays within VBA is cumbersome and prone to errors. Often, one needs to resort to loops (see the introduction to loops in the next section) to handle array operations. In many cases, it may be preferable to use built-in Excel array manipulation functions, such as `SUMPRODUCT`, which performs vector multiplication. As we mentioned earlier, such built-in Excel functions can be called with `Application.FunctionName`. For example, `Array3 = Application.SUMPRODUCT(Array1, Array2)` will fill a variable array `Array3` with the result of the elementwise multiplication and summation of the matrix arrays `Array1` and `Array2`.

VBA will assume that you are creating a new variable whenever you use an expression that is not one of the standard commands. Stating the type of variables you use in the program can save you a lot of headache. (Typically, variable declaration is done at the beginning of the program.)

We also strongly recommend that you write the statement `Option Explicit` in the first line of your modules. This statement makes sure that Excel will report an error if it encounters an undeclared variable in your code. (This also can be accomplished by checking **Require Variable Declaration** under **Tools | Options** in the top VBE menu.) While this may seem like an inconvenience, think about a situation in which you mistype the name of a variable somewhere in your program. If Excel is not in the `Option Explicit` mode, it will treat the mistyped name as a new variable, ignoring any value that your variable may have had at that point in the program, and you will get nonsensical output. If Excel reports an error instead, you will know to fix the typo.

Control Flow Statements: For and If

Control flow statements in VBA allow for building more sophisticated programs than simple input and output of data to Excel. We briefly review a couple of important control statements that are used in VBA code: an example of an iterative statement (the `For` loop) and an example of checking a condition (the `If` statement).

The general syntax of a `For` loop in VBA is as follows:

```
For i = 1 to n
  commands
Next i
```

The commands inside the `For` loop are executed once for every value of `n`. (One can also specify a step by writing `For i = 1 to n Step k`. For example, if `n = 10` and step `k = 2`, then the commands in the loop will be executed for `n = 1, 3, 5, 7, 9`.)

We saw an example of a `For` loop in the code for calculating the factorial of a number `n`. Let us walk through the `For` loop code inside `FactorialSub1`.

```
'Calculate factorial
Factorial = 1
```

```

For i = 1 To inNumber
    Factorial = i * Factorial
Next i

```

The initial value of `Factorial` is set to 1. Suppose the value for `inNumber` is 5. The loop starts at `i = 1`. During the first iteration, the new value of `Factorial` equals the current value of `i` (which is 1) times the current value of `Factorial` (which is 1 as well). At the end of the first run through the loop, the value of `Factorial` is 1. Next, the value of `i` is set to 2. The new value of `Factorial` equals the current value of `i` (which is 2) times the current value of `Factorial` (which is 1); that is, it equals 2. At the third iteration, the value of `i` is 3 and the current value of `Factorial` is 2; that is, the new value of `Factorial` is $3 \cdot 2 = 6$. And so on and so forth for the next values of `i`, which are 4 and 5. The value of `Factorial` keeps getting updated until it reaches 720 ($= 5!$) in the last iteration of the loop.

There are other commands that enable iterating through commands multiple times, such as the **Do While** and **Do Until**. See VBE's **Help** for description of the syntax and use of these alternatives.

The general form of the `If` statement is

```

If condition Then
    commands
End If

```

When the condition is true, the block of commands executes. More generally, you can use a statement of the kind

```

If condition1 Then
    commands1
ElseIf condition2 Then
    commands2
Else
    commands3
End If

```

`Commands1` will be executed if `condition1` is true. If `condition1` is not true, then (and only then) `condition2` will be checked. If

`condition2` is true, then `commands2` will be executed. If `condition2` is not true, then `commands2` will be executed.

When using `If` statements, one typically needs to compare values of variables and check whether conditions are true. Therefore, it is useful to know about the logical operators that allow for such comparisons and checks. The comparison operators are the following:

=	tests for equality
<>	tests for inequality
<	tests whether the variable to the left of it is less than the variable on the right
>	tests whether the variable to the right of it is less than the variable on the left
<= and >=	test for less than or equal to/ greater than or equal to

Additional useful operators are **AND**, **OR**, and **NOT**. **AND** allows checking whether more than one statement is true at the same time. **OR** returns a `True` result if at least one of the statements is true. **NOT** returns a `True` result if the statement is false.

To illustrate how we can use these operators, consider a couple of simple examples that involve three numerical variables, `var1`, `var2`, and `var3`. Let `var1 = 5`, `var2 = 10`.

The code

```

If (var1 <> var2) Then
    var3 = 100
Else
    var3 = -100
End If

```

checks whether the value for `var1` is different from the value of `var2`. If it is (i.e., the value of the logical statement (`var1 <> var2`) is `True`), then the value of `var3` is set to `-100`; otherwise the value of `var3` is set to `100`. In this example, the value of `var3` at the end of the loop is `100`, since the value for `var1` (5) is indeed different from the value of `var2` (10).

Consider also the example

```
If (var1 < 5) Or (var2 > = 7) Then
    var3 = 100
Else
    var3 = -100
End If
```

The code checks if at least one of the statements $(var1 < 5)$ and $(var2 \geq 7)$ is true. If at least one of them is true, then the value of `var3` is set to 100; otherwise the value of `var3` is set to -100. In our case, the first statement is false, because the value of `var1` is not less than 5 (it is equal to 5). However, the second statement is true: The value of `var2` (10) is indeed greater than or equal to 7. Therefore, the combined statement $(var1 < 5) \text{ Or } (var2 \geq 7)$ is true, and the value of `var3` will be set to 100.

User Interaction in VBA

While we covered the most fundamental concepts about the VBA language, it is fun to learn about some additional capabilities that enable your programs to interact better with

their users. For example, once you have created a macro, you can associate it with a button that the user can press every time he or she wants the macro to run. To do that, go to the **Developer** tab, select **Insert | Form Controls**, and click on the button. When Excel pops up in the Macro dialog box, click on the macro you would like to have associated with this button.

Sometimes, it is convenient to ask the user to input information through an *input dialog box*. This can be done with the command `InputBox("question for user", "title of the input box")`. For example,

```
inNumber = InputBox("Enter an
integer", "Factorial Calculation")
```

will prompt the user to enter an integer number and will save that number into the variable `inNumber`. The title of the input box will be `Factorial Calculation`.

Other useful user interaction tools include `Message Box (MsgBox)`, which allows you to report output not in a cell on the spreadsheet, but in a message box. To test how it works, let us go through the following modification of the factorial calculation program (save it in your file as subroutine `FactorialSubMsgBox()`):

```
1 Sub FactorialSubMsgBox()
2     Dim inNumber As Variant
3     Dim numberType As Boolean
4     Dim outFactorial As Integer
5
6     inNumber = InputBox("Enter an integer number", "Factorial Calculation")
7
8     numberType = IsNumeric(inNumber)
9
10    If numberType = True Then
11        outFactorial = Application.Fact(inNumber)
12        MsgBox ("The factorial of " & inNumber & " equals " & outFactorial)
13    ElseIf numberType = False Then
14        MsgBox ("Not a number. Please enter an integer number.")
15    End If
16 End Sub
```

On line 6, we ask the user to specify the number for which we want to compute the factorial. On line 8, we check whether this is indeed a number. Note that the variable `numberType` is specified as `Boolean`, which means that it can only take `True` or `False` values. If it is true, that is, if `inNumber` is indeed a number, then we call the Excel built-in function `Fact` to calculate the factorial of this number, and print the statement “**The factorial of the number the user entered is the result obtained**” in a message box on the screen. If it is not true, then we prompt the user to enter a number.

Note that in line 2, we specified the type of variable for `inNumber` as `Variant`, which allows it to be anything. If we had declared `inNumber` `As Integer` and had entered a letter instead of a number, Excel itself would have returned an error, complaining that there is a variable type mismatch between what was declared and what the actual value of the variable is. Thus, declaring the exact type of variable whenever we know the type is very important for minimizing errors in output.

DEBUGGING

VBA has useful *debugging* tools that allow you to look at the code in more detail if your programs do not work as expected. These tools can be accessed through commands under the **Debug** item in the top menu of the VBE.

The “Step Into” button  (shortcut F8) lets you execute your program step by step. When you are executing a program step-by-step, your program is in “break mode.” Every time you press F8, the “break” is moved to the next command. While the break is set on a particular command, placing the cursor over any variable above the break point will give you an updated stored value for that variable. This makes it easy to catch calculation errors and inconsistencies. You can “step over” (i.e., skip) some subroutines that you are not interested in double-checking (use the button  or the

shortcut **Shift-F8**) and “step out” of the break mode (use the button  or the shortcut **Ctrl-Shift-F8**). Equivalently, you can click on the **Reset** button in the top VBE menu () to get out of debug mode.

Rather than going through the program step-by-step, it is sometimes helpful in long programs to set breakpoints in advance, so that the program runs until it gets to a particular breakpoint. A breakpoint can be specified by placing the cursor at the place where it should be inserted, and clicking on the button  in the **Debug** menu (or using the shortcut F9). When the program gets to the breaking point, it automatically goes into break mode and allows you to follow the subsequent commands step-by-step and check the values of the variables at that point in the program. To remove a breakpoint, simply place the cursor in the corresponding line, and click on the breakpoint button again.

EXAMPLES

The best way to learn to program in VBA is to see and implement many examples. Let us discuss three examples of using VBA in financial applications. The first example is a function that computes the Black-Scholes price of a European call option. It shows how a function is created, how variables are declared, and how Excel functions are accessed from within VBA. The second example is a function that generates possible paths for an asset price assumed to follow geometric Brownian motion. It involves using the random number generator in VBA, manipulating arrays, and iterating with loops. The third example is a function that computes the price of a European call option by simulation. It illustrates how user-defined and Excel functions can be called from within VBA functions, and provides another example of array manipulation and loops in VBA. Further examples of VBA scripts for financial applications, such as calculating the price of an Asian option, or computing and graphing the mean-variance efficient

portfolio frontier (see Markowitz, 1952), can be found in Pachamanova and Fabozzi (2010). See also Jackson and Staunton (2001).

Pricing a European Call Option with the Black-Scholes formula

The Black-Scholes formula for a European call option (C) is as follows (Black and Scholes, 1973):

$$C = S_0 \cdot e^{-qT} \cdot \Phi(d_1) - K \cdot e^{-rT} \cdot \Phi(d_2)$$

where

$$d_1 = \frac{\ln(S_0/K) + (r - q + \sigma^2/2) \cdot T}{\sigma \cdot \sqrt{T}}$$

$$d_2 = d_1 - \sigma \cdot \sqrt{T}$$

K is the strike price

T is the time to maturity

q is the percentage of stock value paid annually in dividends

Φ denotes the cumulative probability density function for the normal distribution

The value for $\Phi(d)$ can be found in Excel by using the built-in formula =NORMDIST(d , 0, 1, 1) or, equivalently, the formula =NORMSDIST(d).

To illustrate the Black-Scholes option pricing formula, assume the following values:

Current stock price (S_0) = \$50

Strike price (K) = \$52

Time remaining to expiration (T) = 183 days = 0.5 years (183 days/365, rounded)

Stock return volatility (σ) = 0.25 (25%)

Short-term risk-free interest rate = 0.10 (10%)

Plugging into the formula, we obtain

$$d_1 = \frac{\ln(50/52) + (0.10 - 0 + 0.25^2/2) \cdot 0.5}{0.25 \cdot \sqrt{0.5}} = 0.1502$$

$$d_2 = 0.1502 - 0.25 \cdot \sqrt{0.5} = -0.0268$$

$$\Phi(0.1502) = 0.5597$$

$$\Phi(-0.0268) = 0.4893$$

$$C = 50 \cdot 1 \cdot 0.5597 - 52 \cdot e^{-0.10 \cdot 0.5} \cdot 0.4893 = \$3.79$$

Next, we provide the code of a VBA function that computes the price of a European call option with the Black-Scholes formula.

```
Function BSCallPrice(initPrice As _
    Double, _
    K As Double, _
    T As Double, _
    r As Double, _
    sigma As Double, _
    q As Double)
    'Computes the Black-Scholes price of a
    'European call option
    'initPrice is the initial price of the
    'stock
    'r is the interest rate
    'T is the time to maturity of the
    'option
    'sigma is the volatility of the stock
    'q is the continuous dividend yield

    Dim dOne As Double

    dOne = (Log(initPrice / K) + (r - q _
    + 0.5 * sigma ^ 2) * T) / _
    (sigma * Sqr(T))

    BSCallPrice = initPrice * Exp(-q * T) _
    * Application.NormSDist(dOne) - _
    K * Exp(-r * T) * Application. _
    NormSDist(dOne - sigma * Sqr(T))

End Function
```

In the code above, all input variables ($initPrice$, r , T , $sigma$ and q) are specified to be of type `Double`. A variable `dOne` is declared as type `Double` within the function. `dOne` stands for d_1 in the definition of the Black-Scholes formula above. It takes the value of the expression $(\text{Log}(\text{initPrice} / K) + (r - q + 0.5 * \text{sigma} ^ 2) * T) / (\text{sigma} * \text{Sqr}(T))$. (Note that this expression contained an underscore (“_”) in the code above. The underscore is used when transferring a part of an expression to a new line.) The price of the option is stored

	A	B	C	D	E
1	Black-Scholes option pricing formula (VBA)				
2					
3	Initial price	\$ 50.00			
4	Strike price	\$ 52.00			
5	Time to expiration	0.50			
6	Interest rate	10%			
7	Volatility	25%			
8	Dividend yield	0			
9					
10	Call price	\$ 3.79	=BSCallPrice(B3,B4,B5,B6,B7,B8)		

Figure 3 Example of Using the User-Defined Function BSCallPrice in a Spreadsheet

in BSCallPrice. The functions Log and Exp used in the calculation are VBA functions. We also call the Excel function NormSDist with the expression Application.NormSDist.

The function BSCallPrice can then be used in a spreadsheet. An example is given in Figure 3. The inputs are stored in cells B3:B8, and the function is called with arguments that are cell references to cells where the information is stored.

VBA is forgiving if you are sloppy in writing the function. For example, the code below (without any variable declarations) would have worked as well.

```
Function BSCallPrice(initPrice,K,T,r,
sigma,q)

dOne = (Log(initPrice / K) + (r - q
+ 0.5 * sigma ^ 2) * T) / _ (sigma
* Sqr(T))

BSCallPrice = initPrice * Exp(-q * T)
* Application.NormSDist(dOne) -
K * Exp(-r * T) * Application.
NormSDist(dOne - sigma * Sqr(T))

End Function
```

However, as we mentioned earlier, it is a good practice to keep your code well organized. It helps minimize errors and saves you time in the long run.

Generating Paths for the Price of an Asset That Follows Geometric Brownian Motion

In finance, the dynamics of asset price processes in discrete time increments are typically described by two kinds of models: trees (such as binomial trees) and random walks. When the time increment used to model the asset price dynamics becomes infinitely small, such processes are referred to as stochastic processes in continuous time. The ability to generate paths for asset prices following these processes is important for computing prices of securities that depend on the asset price under consideration, as well as for calculating various risk measures associated with holding the asset in a portfolio.

The most widely used stochastic process in finance is geometric Brownian motion. The evolution of the underlying asset price is described by the equation

$$dS_t = \mu S_t dt + \sigma S_t dW_t$$

where W_t is standard Brownian motion, and μ and σ are the drift and the volatility of the process, respectively. (See a more detailed introduction in Hull [2008] or Pachamanova and Fabozzi [2010].) It turns out that the value of the asset price S_T at time T given the asset price S_t at time t can be computed as

$$S_T = S_t e^{(\mu - \frac{1}{2}\sigma^2)(T-t) + \sigma \cdot \sqrt{(T-t)} \cdot \varepsilon}$$

where $\tilde{\varepsilon}$ is a standard normal random variable. If the stock pays a continuously compounded dividend yield of q , then we use $(\mu - q - 0.5\sigma^2)$ instead of $(\mu - 0.5\sigma^2)$ in the above formula.

Let us create a function, `GBMPaths`, that generates a prespecified number of paths (`numPaths`) for the asset. Each path consists

```
Function GBMPaths(initPrice As Double, _
    mu As Double, _
    sigma As Double, _
    T As Double, _
    q As Double, _
    numSteps As Integer, _
    numPaths As Integer)

    Randomize
    Dim iPath, iStep As Integer
    Dim paths() As Variant
    ReDim paths(1 To numSteps + 1, 1 To numPaths)

    For iPath = 1 To numPaths
        paths(1, iPath) = initPrice
        For iStep = 2 To numSteps + 1
            paths(iStep, iPath) = paths(iStep - 1, iPath) * _
                Exp((mu - q - 0.5 * sigma ^ 2) * (T / numSteps) + _
                    sigma * (T / numSteps) ^ (1 / 2) * _
                    (Application.NormSInv(Rnd)))
        Next
    Next
    GBMPaths = paths
End Function
```

Let us now see what this function does. First, we use the command `Randomize` to make sure that VBA creates a different sequence each time we generate normal random variables to compute the paths for the asset. (If you do not type `Randomize` before you use the VBA random generator function `Rnd`, `Rnd` will always return the same sequence of numbers.)

Next, we declare variables we will use in the function. The variables `iPath` and `iStep` will be counters for the number of paths and the number of steps we have generated so far. They are, of course, integers. The two-dimensional array `paths` will store the values of the asset

of a prespecified number of steps (`numSteps`). The value of the asset at each step is computed according to the formula for S_T above. In the formula, we replace time t with time 0 (i.e., the present), and time T with the time corresponding to the step.

The code of the function is

along each path and for each step. We use `ReDim` to specify the dimensions of the array.

We next use a `for` loop to populate the array `paths`. In fact, we have two nested `for` loops—one that iterates through the number for paths, and one that iterates through the points in each path. For each point `iStep` on each path `iPath`, we calculate the price of the asset and store it in `paths(iStep, iPath)`. The formula that computes the price of the asset contains the expression `Application.NormSInv(Rnd)`, which generates a value for the normal random variable $\tilde{\varepsilon}$ in the formula for S_T earlier in this section. `Rnd` is the VBA random

number generator—it returns a random number between 0 and 1. The reason we used the command `Randomize` at the beginning of the function is so that we could force `Rnd` to generate different sequences of random numbers every time you call the function `GBMPaths`. `NormSInv` is an Excel function that finds the number on the horizontal axis of the normal distribution that corresponds to the value for cumulative probability generated by `Rnd`. (See, for example, Chapter 4 in Pachamanova and Fabozzi [2010] for an explanation of how random numbers from different probability distributions are generated.) As in the previous example, in order to indicate to VBA that `NormSInv` is an Excel function, we use `Application`. in front of `NormSInv`.

The function returns a two-dimensional array, `GBMPaths` (which is equal to `paths`, as set in the second-to-last line of the function). Every column of the array contains a randomly generated path for the asset price; that is, it has `numSteps` values that represent the values of the asset price along that path.

Pricing a European Call Option by Simulation

Let us now use the function we created in the previous section to write a function that prices a European call option by simulation. While this is not the most efficient way to price a European call option by simulation, it will illustrate how user-defined functions are called within other functions, and how arrays are handled as outputs of a function.

As in the previous section, we will make the assumption that the asset price follows geometric Brownian motion, which means that the value of the asset price S_T at time T given the asset price S_t at time t can be computed as

$$S_T = S_t e^{(r - \frac{1}{2}\sigma^2) \cdot (T-t) + \sigma \cdot \sqrt{(T-t)} \cdot \tilde{\varepsilon}}$$

where $\tilde{\varepsilon}$ is a standard normal random variable. (When we generate asset price paths for the purpose of valuing an option, we use r (the risk-free rate) in place of the drift term μ . This is done for technical reasons (absence of arbitrage).) As in the previous section, if the stock pays a continuously compounded dividend yield of q , then we use $(r - q - 0.5 \cdot \sigma^2)$ instead of $(r - 0.5 \cdot \sigma^2)$ in the formula above.

The price of the option can be approximated by creating scenarios for the stock price S_T at time to maturity T , computing the discounted payoffs of the option, and finding the expected payoff of the option. (Option pricing by simulation was first suggested by Boyle, 1977. See also Boyle et al., 1997; Pachamanova and Fabozzi, 2010; Glasserman, 2004; or McLeish, 2005.)

Suppose we generate N scenarios for $\tilde{\varepsilon}$ at time T : $\varepsilon^{(1)}, \dots, \varepsilon^{(N)}$. Then, the price of a European call option with strike price K will be

$$C_t = e^{-r(T-t)} \cdot \sum_{n=1}^N \frac{1}{N} \times \max \left\{ S_t e^{(r - \frac{1}{2}\sigma^2) \cdot (T-t) + \sigma \cdot \sqrt{(T-t)} \cdot \varepsilon^{(n)}} - K, 0 \right\}$$

The expression above is the expected value of the option payoffs, that is, the weighted average of the option payoffs.

The VBA code of the function is given below.

```
Function EuropeanCall(initPrice As Double, _
    K As Double, _
    r As Double, _
    T As Double, _
    sigma As Double, _
    q As Double, _
    numSteps As Integer, _
    numPaths As Integer)
```

```

Dim iPath As Integer
Dim payoffs() As Variant
ReDim payoffs(1 To numPaths)
Dim paths() As Variant
ReDim paths(1 To numSteps + 1, 1 To numPaths)

paths = GBMPaths(initPrice, r - q, sigma, T, q, numSteps, numPaths)
For iPath = 1 To numPaths
    payoffs(iPath) = Exp(-r * T) * _
        Application.Max(paths(numSteps + 1, iPath) - K, 0)
Next

EuropeanCall = Application.Average(payoffs)
End Function

```

The variable declarations are similar to the declarations in the previous sections; however, now we have an additional array, `payoffs`, that will store the payoff of the option at the end of each generated path (that is, for each generated scenario). The dimension of the array is therefore $1 \times \text{numPaths}$.

After declaring the variables in the function, we call the function we created in the previous section, `GBMPaths`, and store the output in the array `paths`. This is achieved with the command

```
paths = GBMPaths(initPrice, r - q,
    sigma, T, q, numSteps, numPaths)
```

The arguments of the function `GBMPaths` were `initPrice`, `mu`, `sigma`, `T`, `q`, `numSteps` and `numPaths`. Note that when we call the function `GBMPaths` from within the function `EuropeanCall`, we input `r - q` in place of the argument `mu`.

After generating `numPaths` paths for the price of the underlying asset, we compute the payoffs of the option. We only need the payoffs at the time of maturity of the option, time T , so we only use `paths(numSteps + 1, iPath)` in the calculation.

The payoff along path `iPath` is calculated as the maximum of zero and the difference between the strike price K and the value of the underlying at the end of path `iPath` at time T .

We use the Excel function `Max` to compute the maximum and call it as `Application.Max`. Each payoff is discounted, and is added to the array `payoffs`.

After the array `payoffs` is filled, we compute the average of the payoffs to get the price of the option. We use the Excel function `Average`, which we call with the command `Application.Average`.

KEY POINTS

- Macros contain prerecorded tasks that can be performed in a spreadsheet. Macros are in effect computer programs whose commands are hidden from the user, but they can be seen if the VBA editor is open.
- The most important fact about VBA is that it tries to act as an object-oriented language. This means that it treats every component of Excel, such as a worksheet, a cell, a range of cells, and a chart, as an object.
- Objects are arranged in a hierarchy and have properties (attributes) that can be modified by entering the name of the object followed by a dot and a specific command. In addition, objects are associated with actions (methods) that the objects can perform or have applied to them.
- Subroutines and user-defined functions in VBA are both blocks of code saved in

modules. The difference is that subroutines are general scripts; that is, lists of instructions, whereas functions complete a list of instructions and return a value to the user.

- Variable types in VBA include Integer, String, Single, Double, Long, Boolean, Date, Object, and Variant. A different amount of memory is allocated to storing values of variables of different types.
- The default in VBA is to index the first element in arrays as 0, which is the convention in most programming languages. The command `Option Base 1` at the beginning of a module makes sure that the indexing of arrays starts at 1.
- Control flow statements such as `For` and `If` allow for building more sophisticated programs than simple input and output of data to Excel.
- Excel functions can be accessed from VBA by prefixing them with `Application`.
- VBA has some built-in numeric functions, but it is important to know that their syntax is not always the same as the syntax of the same function in Excel. For example, the function `Sqrt` (square root) in Excel is `Sqr` in VBA.
- Useful tools in Excel and VBA that allow for interaction with users include buttons, input dialog boxes, and message boxes.
- VBA has debugging tools that allow you to look at the code in more detail if your programs do not work as expected. These tools can be accessed through commands under the **Debug** item in the top menu of the VBE.

NOTE

1. The notation E in Excel denotes multiplication by 10 to a specific power. For example, 5E40 means $5 \cdot 10^{40}$, and 5E-45 means $5 \cdot 10^{-45}$.

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Calculus is an important tool because it provides two key ideas for financial modeling: (1) the concept of instantaneous rate of change, and (2) a framework and rules for linking together quantities and their instantaneous rates of change. Calculus made the concept of infinitely small quantities precise with the notion of limit. If the rate of change can get arbitrarily close to a definite number by making the time interval sufficiently small, that number is the instantaneous rate of change. The instantaneous rate of change is the limit of the rate of change when the length of the interval gets infinitely small. This limit is referred to as the derivative of a function, or simply derivative. Starting from this definition and with the help of a number of rules for computing a derivative, it was shown that the instantaneous rate of change of a number of functions can be explicitly computed as a closed formula. The process of computing a derivative, referred to as differentiation, solves the problem of finding the steepness of the tangent to a curve; the process of integration solves the problem of finding the area below a given curve. A key result of calculus is the discovery that integration and derivation are inverse operations: Integrating the derivative of a function yields the function itself. Standard calculus deals with deterministic functions. As such, there are limits as to the application of integration of determinist functions to financial modeling such as pricing contingent claims. The major application of integration to financial modeling involves stochastic integrals. An understanding of stochastic integrals is needed to understand an important tool in contingent claims valuation: stochastic differential equations.

In elementary calculus, integration is an operation performed on single, deterministic functions; the end product is another single, deterministic function. Integration defines a process of *cumulation*: The integral of a function represents the area below the function. However, the usefulness of deterministic functions in financial modeling is limited. Given the amount of uncertainty, few laws in finan-

cial theory can be expressed through them. It is necessary to adopt an ensemble view, where the path of economic variables must be considered a realization of a stochastic process, not a deterministic path. We must therefore move from deterministic integration to *stochastic integration*. In doing so we have to define how to *cumulate random shocks in a continuous-time environment*. These concepts require rigorous

definition. In this entry, we define the concept and the properties of stochastic integration. Based on the concept of stochastic integration, an important tool used in financial modeling, stochastic differential equations can be understood.

Two observations are in order. First, although ordinary integrals and derivatives operate on functions and yield either individual numbers or other functions, stochastic integration operates on stochastic processes and yields either random variables or other stochastic processes. Therefore, while a definite integral is a number and an indefinite integral is a function, a stochastic integral is a random variable or a stochastic process. A differential equation—when equipped with suitable initial or boundary conditions—admits as a solution a single function while a stochastic differential equation admits as a solution a stochastic process.

Second, moving from a deterministic to a stochastic environment does not necessarily require leaving the realm of standard calculus. In fact, all the stochastic laws of financial theory could be expressed as laws that govern the distribution of transition probabilities. An example of this mathematical strategy is the application of the forward Komogorov differential equation or the Fokker-Planck differential equation to term structure modeling, which are deterministic partial differential equations that govern the probability distributions of prices. Nevertheless it is often convenient to represent uncertainty directly through stochastic integration and stochastic differential equations. This approach is not limited to financial theory: It is also used in the domain of the physical sciences. In financial theory, stochastic differential equations have the advantage of being intuitive: Thinking in terms of a deterministic path plus an uncertain term is easier than thinking in terms of abstract probability distributions. There are other reasons why stochastic calculus is the methodology of choice in economics and finance but easy intuition plays a key role.

For example, a risk-free bank account, which earns a deterministic instantaneous interest rate $f(t)$, evolves according to the deterministic law:

$$y = A \exp\left(\int f(t)dt\right)$$

which is the general solution of the differential equation:

$$\frac{dy}{y} = f(t)dt$$

The solution of this differential equation tells us how the bank account cumulates over time.

However, if the rate is not deterministic but is subject to volatility—that is, at any instant the rate is $f(t)$ plus a random disturbance—then the bank account evolves as a stochastic process. That is to say, the bank account might follow any of an infinite number of different paths: Each path cumulates the rate $f(t)$ plus the random disturbance. In a sense that will be made precise in this entry and with an understanding of stochastic differential equations, we must solve the following equation:

$$\frac{dy}{y} = f(t)dt \text{ plus random disturbance}$$

Here is where stochastic integration comes into play: It defines how the stochastic rate process is transformed into the stochastic account process. This is the direct stochastic integration approach.

It is possible to take a different approach. At any instant t , the instantaneous interest rate and the cumulated bank account have two probability distributions. We could use a partial differential equation to describe how the probability distribution of the cumulated bank account is linked to the interest rate probability distribution.

Similar reasoning applies to stock and derivative price processes. In continuous-time finance, these processes are defined as stochastic processes that are the solution of a stochastic differential equation. Hence, the importance of stochastic integrals in continuous-time finance theory should be clear.

Following some remarks on the informal intuition behind stochastic integrals, we proceed to define Brownian motions and outlines the formal mathematical process through which stochastic integrals are defined. A number of properties of stochastic integrals are then established. After introducing stochastic integrals informally, we go on to define more rigorously the mathematical process for defining stochastic integrals.

THE INTUITION BEHIND STOCHASTIC INTEGRALS

Let's first contrast ordinary integration with *stochastic integration*. A definite integral

$$A = \int_a^b f(x)dx$$

is a number A associated to each function $f(x)$ while an indefinite integral

$$y(x) = \int_a^x f(s)ds$$

is a function y associated to another function f . The integral represents the cumulation of the infinite terms $f(s)ds$ over the integration interval.

A *stochastic integral*, which we will denote by

$$W = \int_a^b X_t dB_t$$

or

$$W = \int_a^b X_t \circ dB_t$$

is a random variable W associated to a stochastic process if the time interval is fixed or, if the time interval is variable, is another stochastic process W_t . The stochastic integral represents the cumulation of the stochastic products $X_t dB_t$. The rationale for this approach is that we need

to represent how random shocks feed back into the evolution of a process. We can cumulate separately the deterministic increments and the random shocks only for linear processes. In nonlinear cases, as in the simple example of the bank account, random shocks feed back into the process. For this reason we define stochastic integrals as the cumulation of the product of a process X by the random increments of a *Brownian motion*.

Consider a stochastic process X_t over an interval $[S, T]$. Recall that a stochastic process is a real variable $X(\omega)_t$ that depends on both time and the state of the economy ω . For any given ω , $X(\cdot)_t$ is a path of the process from the origin S to time T . A stochastic process can be identified with the set of its paths equipped with an appropriate probability measure. A stochastic integral is an integral associated to each path; it is a random variable that associates a real number, obtained as a limit of a sum, to each path. If we fix the origin and let the interval vary, then the stochastic integral is another stochastic process.

It would seem reasonable, *prima facie*, to define the stochastic integral of a process $X(\omega)_t$ as the definite integral in the sense of Riemann-Stieltjes associated to each path $X(\cdot)_t$ of the process. If the process $X(\omega)_t$ has continuous paths $X(\cdot, \omega)$, the integrals

$$W(\omega) = \int_S^T X(s, \omega)ds$$

exist for each path. However, as discussed in the previous section, this is not the quantity we want to represent. In fact, we want to represent the cumulation of the stochastic products $X_t dB_t$. Defining the integral

$$W = \int_a^b X_t dB_t$$

pathwise in the sense of Riemann-Stieltjes would be meaningless because the paths of a Brownian motion are not of *finite variation*. If we define

stochastic integrals simply as the limit of $X_t dB_t$ sums, the stochastic integral would be infinite (and therefore useless) for most processes.

However, Brownian motions have bounded *quadratic variation*. Using this property, we can define stochastic integrals pathwise through an approximation procedure. The approximation procedure to arrive at such a definition is far more complicated than the definition of the Riemann-Stieltjes integrals. Two similar but not equivalent definitions of stochastic integral have been proposed, the first by the Japanese mathematician Kiyoshi Ito (1951), the second by the Russian physicist Ruslan Stratonovich in the 1960s.¹ The definition of stochastic integral in the sense of Ito integral or of Stratonovich stochastic replaces the increments Δx_i with the increments ΔB_i of a fundamental stochastic process called Brownian motion.² The increments ΔB_i represent the “noise” of the process.

The definition proceeds in the following three steps:

- *Step 1.* The first step consists in defining a fundamental stochastic process—the *Brownian motion*. In intuitive terms, a Brownian motion $B_t(\omega)$ is a continuous limit (in a sense that will be made precise in the following sections) of a simple *random walk*. A simple random walk is a discrete-time stochastic process defined as follows. A point can move one step to the right or to the left. Movement takes place only at discrete instants of time, say at time 1, 2, 3, . . . At each discrete instant, the point moves to the right or to the left with probability $\frac{1}{2}$.

The random walk represents the cumulation of completely uncertain random shocks. At each point in time, the movement of the point is completely independent from its past movements. Hence, the Brownian motion represents the cumulation of random shocks in the limit of continuous time and of continuous states. It can be demonstrated that a.s. each path of the Brownian motion is not of

bounded total variation but it has bounded quadratic variation.

Recall that the total variation of a function $f(x)$ is the limit of the sums

$$\sum |f(x_i) - f(x_{i-1})|$$

while the quadratic variation is defined as the limit of the sums

$$\sum |f(x_i) - f(x_{i-1})|^2$$

Quadratic variation can be interpreted as the *absolute volatility* of a process. Thanks to this property, the ΔB_i of the Brownian motion provides the basic increments of the stochastic integral, replacing the Δx_i of the Riemann-Stieltjes integral.

- *Step 2.* The second step consists in defining the stochastic integral for a class of simple functions called *elementary functions*. Consider the time interval $[S, T]$ and any partition of the interval $[S, T]$ in N subintervals: $S \equiv t_0 < t_1 < \dots < t_i < \dots < t_N \equiv T$. An elementary function ϕ is a function defined on the time t and the outcome ω such that it assumes a constant value on the i -th subinterval. Call $I[t_{i+1}, t_i]$ the indicator function of the interval $[t_{i+1}, t_i]$. The indicator function of a given set is a function that assumes value 1 on the points of the set and 0 elsewhere. We can then write an elementary function ϕ as follows:

$$\phi(t, \omega) = \sum_i \varepsilon_i(\omega) I[t_{i+1}, t_i]$$

In other words, the constants $\varepsilon_i(\omega)$ are random variables and the function $\phi(t, \omega)$ is a stochastic process made up of paths that are constant on each i -th interval.

We can now define the stochastic integral, in the sense of Ito, of elementary functions $\phi(t, \omega)$ as follows:

$$\begin{aligned} W &= \int_S^T \phi(t, \omega) dB_t(\omega) \\ &= \sum_i \varepsilon_i(\omega) [B_{i+1}(\omega) - B_i(\omega)] \end{aligned}$$

where B is a Brownian motion.

It is clear from this definition that W is a random variable $\omega \rightarrow W(\omega)$. Note that the *Ito integral* thus defined for elementary functions cumulates the products of the elementary functions $\phi(t, \omega)$ and of the increments of the Brownian motion $B_i(\omega)$.

It can be demonstrated that the following property, called *Ito isometry*, holds for Ito stochastic integrals defined for bounded elementary functions as above:

$$E \left[\left(\int_S^T \phi(t, \omega) dB_i(\omega) \right)^2 \right] = E \left[\int_S^T \phi(t, \omega)^2 dt \right]$$

The Ito isometry will play a fundamental role in Step 3.

- *Step 3.* The third step consists in using the Ito isometry to show that each function g which is square-integrable (plus other conditions that will be made precise in the next section) can be approximated by a sequence of elementary functions $\phi_n(t, \omega)$ in the sense that

$$E \left[\int_S^T [g - \phi_n(t, \omega)]^2 dt \right] \rightarrow 0$$

If g is bounded and has a continuous time-path, the functions $\phi_n(t, \omega)$ can be defined as follows:

$$\phi_n(t, \omega) = \sum_i g(t_i, \omega) I[t_{i+1}, t_i)$$

where I is the indicator function. We can now use the Ito isometry to define the stochastic integral of a generic function $f(t, \omega)$ as follows:

$$\int_S^T f(t, \omega) dB_i(\omega) = \lim_{n \rightarrow \infty} \int_S^T \phi_n(t, \omega) dB_i(\omega)$$

The Ito isometry ensures that the Cauchy condition is satisfied and that the above sequence thus converges.

In outlining the above definition, we omitted an important point that will be dealt with in the next section: The definition of the stochastic integral in the sense of Ito requires that the el-

ementary functions be without anticipation—that is, they depend only on the past history of the Brownian motion. In fact, in the case of continuous paths, we wrote the approximating functions as follows:

$$\phi_n(t, \omega) = \sum_i g(t_i, \omega) [B_{i+1}(\omega) - B_i(\omega)]$$

taking the function g in the left extreme of each subinterval.

However, the definition of stochastic integrals in the sense of Stratonovich *admits anticipation*. In fact, the stochastic integral in the sense of Stratonovich, written as follows

$$\int_S^T f(t, \omega) \circ dB_i(\omega)$$

uses the following approximation under the assumption of continuous paths:

$$\phi_n(t, \omega) = \sum_i g(t_i^*, \omega) [B_{i+1}(\omega) - B_i(\omega)]$$

where

$$t_i^* = \frac{t_{i+1} - t_i}{2}$$

is the midpoint of the i -th subinterval.

Whose definition—Ito's or Stratonovich's—is preferable? Note that neither can be said to be correct or incorrect. The choice of the one over the other is a question of which one best represents the phenomena under study. The lack of anticipation is one reason why the Ito integral is generally preferred in finance theory.

We have just outlined the definition of stochastic integrals leaving aside mathematical details and rigor. The following two sections will make the above process mathematically rigorous and will discuss the question of anticipation of information. While these sections are a bit technical and might be skipped by those not interested in the mathematical details of stochastic calculus, they explain a number of concepts that are key to the modern development of finance theory.

BROWNIAN MOTION DEFINED

The previous section introduced Brownian motion informally as the limit of a simple random walk when the step size goes to zero. This section defines Brownian motion formally. The term “Brownian motion” is due to the Scottish botanist Robert Brown who in 1828 observed that pollen grains suspended in a liquid move irregularly. This irregular motion was later explained by the random collision of the molecules of the liquid with the pollen grains. It is therefore natural to represent Brownian motion as a continuous-time stochastic process that is the limit of a discrete random walk.

Let’s now formally define Brownian motion and demonstrate its existence. Let’s first go back to the probabilistic representation of the economy. The economy can be represented as a probability space $(\Omega, \mathfrak{S}, P)$, where Ω is the set of all possible economic states, \mathfrak{S} is the event σ -algebra, and P is a probability measure. The economic states $\omega \in \Omega$ are not instantaneous states but represent full histories of the economy for the time horizon considered, which can be a finite or infinite interval of time. In other words, the economic states are the possible realization outcomes of the economy.

In this probabilistic representation of the economy, time-variable economic quantities—such as interest rates, security prices or cash flows as well as aggregate quantities such as economic output—are represented as stochastic processes $X_t(\omega)$. In particular, the price and dividend of each stock are represented as two stochastic processes $S_t(\omega)$ and $d_t(\omega)$.

Stochastic processes are time-dependent random variables defined over the set Ω . It is critical to define stochastic processes so that there is no anticipation of information, that is, at time t no process depends on variables that will be realized later. Anticipation of information is possible only within a deterministic framework. However the space Ω in itself does not contain any coherent specification of time. If we asso-

ciate random variables $X_t(\omega)$ to a time index without any additional restriction, we might incur the problem of anticipation of information. Consider, for instance, an arbitrary family of time-indexed random variables $X_t(\omega)$ and suppose that, for some instant t , the relationship $X_t(\omega) = X_{t+1}(\omega)$ holds. In this case there is clearly anticipation of information as the value of the variable $X_{t+1}(\omega)$ at time $t + 1$ is known at an earlier time t . All relationships that lead to anticipation of information must be treated as deterministic.

The formal way to specify in full generality the evolution of time and the propagation of information without anticipation is through the concept of *filtration*. The concept of filtration is based on identifying all events that are known at any given instant. It is the propagation of information assuming that it is possible to associate to each moment t a σ -algebra of events $\mathfrak{S}_t \subset \mathfrak{S}$ formed by all events that are known prior to or at time t . It is assumed that events are never “forgotten,” that is, that $\mathfrak{S}_t \subset \mathfrak{S}_s$, if $t < s$. An increasing sequence of σ -algebras, each associated to the time at which all its events are known, represents the propagation of information. This sequence (called a filtration) is typically indicated as \mathfrak{S}_t .

The economy is therefore represented as a probability space $(\Omega, \mathfrak{S}, P)$ equipped with a filtration $\{\mathfrak{S}_t\}$. The key point is that every process $X_t(\omega)$ that represents economic or financial quantities must be *adapted* to the filtration $\{\mathfrak{S}_t\}$, that is, the random variable $X_t(\omega)$ must be measurable with respect to the σ -algebras \mathfrak{S}_t . In simple terms, this means that each event of the type $X_t(\omega) \leq x$ belongs to \mathfrak{S}_t while each event of the type $X_s(\omega) \leq y$ for $t \leq s$ belongs to \mathfrak{S}_s . For instance, consider a process $P_t(\omega)$, which might represent the price of a stock. Any coherent representation of the economy must ensure that events such as $\{\omega: P_s(\omega) \leq c\}$ are not known at any time $t < s$. The filtration $\{\mathfrak{S}_t\}$ prescribes all events admissible at time t .

Why do we have to use the complex concept of filtration? Why can’t we simply identify

information at time t with the values of all the variables known at time t as opposed to identifying a set of events? The principal reason is that in a continuous-time continuous-state environment any individual value has probability zero; we cannot condition on single values as the standard definition of conditional probability would become meaningless. In fact, in the standard definition of conditional probability, the probability of the conditioning event appears in the denominator and cannot be zero.

It is possible, however, to reverse this reasoning and construct a filtration starting from a process. Suppose that a process $X_t(\omega)$ does not admit any anticipation of information, for instance because the $X_t(\omega)$ are all mutually independent. We can therefore construct a filtration \mathfrak{F}_t as the strictly increasing sequence of σ -algebras generated by the process $X_t(\omega)$. Any other process must be adapted to \mathfrak{F}_t .

Let's now go back to the definition of the Brownian motion. Suppose that a probability space $(\Omega, \mathfrak{F}, P)$ equipped with a filtration \mathfrak{F}_t is given. A *one-dimensional standard Brownian motion* is a stochastic process $B_t(\omega)$ with the following properties:

- $B_t(\omega)$ is defined over the probability space $(\Omega, \mathfrak{F}, P)$.
- $B_t(\omega)$ is continuous for $0 \leq t < \infty$.
- $B_0(\omega) = 0$.
- $B_t(\omega)$ is adapted to the filtration \mathfrak{F}_t .
- The increments $B_t(\omega) - B_s(\omega)$ are independent and normally distributed with variance $(t-s)$ and zero mean.

The above conditions³ state that the standard Brownian motion is a stochastic process that starts at zero, has continuous paths and normally distributed increments whose variance grows linearly with time. Note that in the last condition the increments are independent of the σ -algebra \mathfrak{F}_s and not of the previous values of the process. As noted above, this is because any single realization of the process has probability zero and it is therefore impossible to use the standard concept of conditional proba-

bility: Conditioning must be with respect to a σ -algebra \mathfrak{F}_s . Once this concept has been firmly established, one might speak loosely of independence of the present values of a process from its previous values. It should be clear, however, that what is meant is independence with respect to a σ -algebra \mathfrak{F}_s .

Note also that the filtration \mathfrak{F}_t is an integral part of the above definition of the Brownian motion. This does not mean that, given any probability space and any filtration, a standard Brownian motion with these characteristics exists. For instance, the filtration generated by a discrete-time continuous-state random walk is insufficient to support a Brownian motion. The definition states only that we call a one-dimensional standard Brownian motion a mathematical object (if it exists) made up of a probability space, a filtration, and a time dependent random variable with the properties specified in the definition.

However, it can be demonstrated that Brownian motions exist by constructing them. Several construction methodologies have been proposed, including methodologies based on the Kolmogorov extension theorem or on constructing the Brownian motion as the limit of a sequence of discrete random walks. To prove the existence of the standard Brownian motion, we will use the *Kolmogorov extension theorem*.

The Kolmogorov theorem can be summarized as follows. Consider the following family of probability measures

$$\begin{aligned} &\mu_{t_1, \dots, t_m}(H_1 \times \dots \times H_m) \\ &= P[(X_{t_1} \in H_1, \dots, X_{t_m} \in H_m), H_i \in \mathcal{B}^n] \end{aligned}$$

for all $t_1, \dots, t_k \in [0, \infty)$, $k \in N$ and where the H s are n -dimensional Borel sets. Suppose that the following two consistency conditions are satisfied

$$\begin{aligned} &\mu_{t_{\sigma(1)}, \dots, t_{\sigma(m)}}(H_1 \times \dots \times H_m) \\ &= \mu_{t_1, \dots, t_m}(H_{\sigma^{-1}(1)} \times \dots \times H_{\sigma^{-1}(m)}) \end{aligned}$$

for all permutations σ on $\{1, 2, \dots, k\}$, and

$$\begin{aligned} & \mu_{t_1, \dots, t_k}(H_1 \times \dots \times H_k) \\ &= \mu_{t_1, \dots, t_k, t_{k+1}, \dots, t_m}(H_1 \times \dots \times H_k \times R^n \times \dots \times R^n) \end{aligned}$$

for all m . The Kolmogorov extension theorem states that, if the above conditions are satisfied, then there is (1) a probability space $(\Omega, \mathfrak{F}, P)$ and (2) a stochastic process that admits the probability measures

$$\begin{aligned} & \mu_{t_1, \dots, t_m}(H_1 \times \dots \times H_m) \\ &= P[(X_{t_1} \in H_1, \dots, X_{t_m} \in H_m), H_i \in \mathcal{B}^n] \end{aligned}$$

as finite dimensional distributions.

The construction is lengthy and technical and we omit it here, but it should be clear how, with an appropriate selection of finite-dimensional distributions, the Kolmogorov extension theorem can be used to prove the existence of Brownian motions. The finite-dimensional distributions of a one-dimensional Brownian motion are distributions of the type

$$\begin{aligned} & \mu_{t_1, \dots, t_k}(H_1 \times \dots \times H_k) \\ &= \int p(t, x, x_1) p(t_2 - t_1, x_1, x_2) \dots \\ & \quad p(t_k - t_{k-1}, x_{k-1}, x_k) dx_1 \dots dx_k H_1 \times \dots \times H_k \end{aligned}$$

where

$$p(t, x, y) = (2\pi t)^{-\frac{1}{2}} \exp\left(-\frac{|x - y|^2}{2t}\right)$$

and with the convention that the integrals are taken with respect to the Lebesgue measure. The distribution $p(t, x, x_1)$ in the integral is the initial distribution. If the process starts at zero, $p(t, x, x_1)$ is a Dirac delta, that is, it is a distribution of mass 1 concentrated in one point.

It can be verified that these distributions satisfy the above consistency conditions; the Kolmogorov extension theorem therefore ensures that a stochastic process with the above finite dimensional distributions exists. It can be demonstrated that this process has normally distributed independent increments with variance that grows linearly with time. It is

therefore a one-dimensional Brownian motion. These definitions can be easily extended to an n -dimensional Brownian motion.

In the initial definition of a Brownian motion, we assumed that a filtration \mathfrak{F}_t was given and that the Brownian motion was adapted to the filtration. In the present construction, however, we reverse this process. Given that the process we construct has normally distributed, stationary, independent increments, we can define the filtration \mathfrak{F}_t as the filtration \mathfrak{F}_t^B generated by $B_t(\omega)$. The independence of the increments of the Brownian motion guarantee the absence of anticipation of information. Note that if we were given a filtration \mathfrak{F}_t larger than the filtration \mathfrak{F}_t^B , $B_t(\omega)$ would still be a Brownian motion with respect to \mathfrak{F}_t .

In stochastic differential equations, there are two types of solutions of stochastic differential equations—strong and weak—depending on whether the filtration is given or generated by the Brownian motion. The implications of these differences for economics and finance will be discussed in the same section.

The above construction does not specify uniquely the Brownian motion. In fact, there are infinite stochastic processes that start from the same point and have the same finite dimensional distributions but have totally different paths. However, it can be demonstrated that only one Brownian motion has continuous paths a.s. (*a.s.* means almost surely; that is, for all paths except a set of measure zero). This process is called the *canonical Brownian motion*. Its paths can be identified with the space of continuous functions.

The Brownian motion can also be constructed as the continuous limit of a discrete random walk. Consider a simple random walk W_i where i are discrete time points. The random walk is the motion of a point that moves Δx to the right or to the left with equal probability $1/2$ at each time increment Δx . The total displacement X_i at time i is the sum of i independent increments each distributed as a Bernoulli variable. Therefore the random variable X has a binomial

distribution with mean zero and variance:

$$\frac{\Delta^2 x}{\Delta t}$$

Suppose that both the time increment and the space increment approach zero: $\Delta t \rightarrow 0$ and $\Delta x \rightarrow 0$. Note that this is a very informal statement. In fact what we mean is that we can construct a sequence of random walk processes W_i^n , each characterized by a time step and by a time displacement. It can be demonstrated that if

$$\frac{\Delta^2 x}{\Delta t} \rightarrow \sigma$$

(i.e., the square of the spaced interval and the time interval are of the same order) then the sequence of random walks approaches a Brownian motion. Though this is intuitive as the binomial distributions approach normal distributions, it should be clear that it is far from being mathematically obvious.

Figure 1 illustrates 100 realizations of a Brownian motion approximated as a random walk. The exhibit clearly illustrates that the standard

deviation grows with the square root of the time as the variance grows linearly with time. In fact, as illustrated, most paths remain confined within a parabolic region.

PROPERTIES OF BROWNIAN MOTION

The paths of a Brownian motion are rich structures with a number of surprising properties. It can be demonstrated that the paths of a canonical Brownian motion, though continuous, are nowhere differentiable. It can also be demonstrated that they are fractals of fractal dimension $3/2$. The fractal dimension is a concept that measures quantitatively how a geometric object occupies space. A straight line has fractal dimension one, a plane has fractal dimension two, and so on. Fractal objects might also have intermediate dimensions. This is the case, for example, of the path of a Brownian motion, which is so jagged that, in a sense, it occupies more space than a straight line.

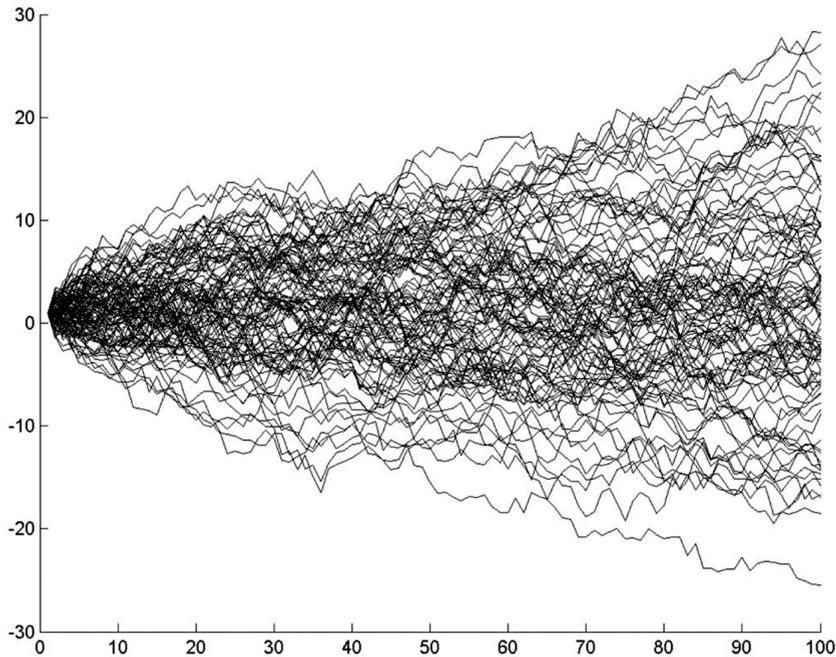

Figure 1 Illustration of 100 Paths of a Brownian Motion Generated as an Arithmetic Random Walk

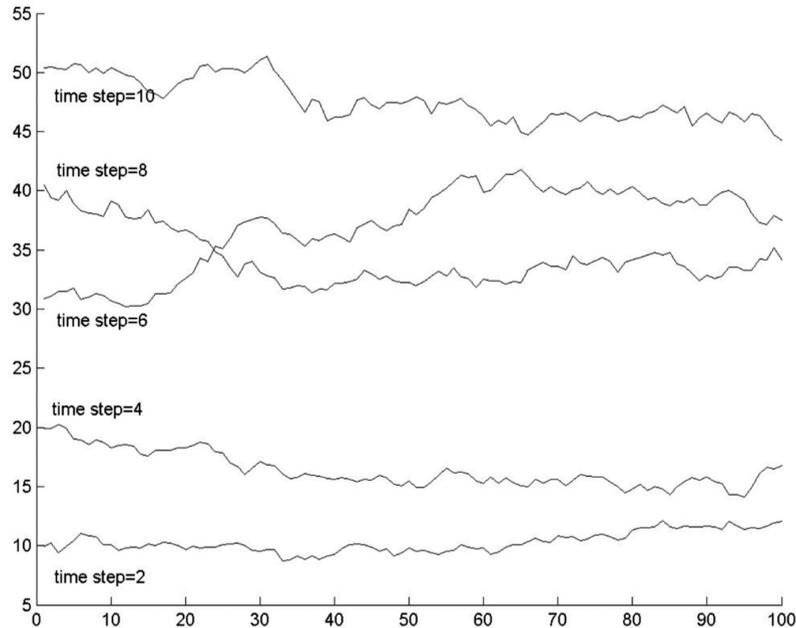

Figure 2 Illustration of the Fractal Properties of the Paths of a Brownian Motion

Note: Five paths of a Brownian motion are generated as random walks with different time steps and then magnified.

The fractal nature of Brownian motion paths implies that each path is a self-similar object. This property can be illustrated graphically. If we generate random walks with different time steps, we obtain jagged paths. If we allow paths to be graphically magnified, all paths look alike regardless of the time step with which they have been generated. In Figure 2, sample paths are generated with different time steps and then portions of the paths are magnified. Note that they all look perfectly similar.

This property was first observed by Mandelbrot (1963) in sequences of cotton prices in the 1960s. In general, if one looks at asset or commodity price time series, it is difficult to recognize their time scale. For instance, weekly or monthly time series look alike. (Recent empirical and theoretical research work has made this claim more precise.)

Let's consider a one-dimensional standard Brownian motion. If we wait a sufficiently long period of time, every path except a set of paths of measure zero will return to the ori-

gin. The path between two consecutive passages through zero is called an *excursion* of the Brownian motion. The distribution of the maximum height attained by an excursion and of the time between two passages through zero or through any level have interesting properties. The distribution of the time between two passages through zero has infinite mean. This is at the origin of the so-called St. Petersburg paradox described by the Swiss mathematician Bernoulli. The paradox consists of the following. Suppose a player bets increasing sums on a game that can be considered a realization of a random walk. As the return to zero of a random walk is a sure event, the player is certain to win—but while the probability of winning is one, the average time before winning is infinite. To stay the game, the capital required is also infinite. Difficult to imagine a banker ready to put up the money to back the player.

The distribution of the time to the first passage through zero of a Brownian motion is not Gaussian. In fact, the probability of a very long

waiting time before the first return to zero is much higher than in a normal distribution. It is a fat-tailed distribution in the sense that it has more weight in the tail regions than a normal distribution. The distribution of the time to the first passage through zero of a Brownian motion is an example of how fat-tailed distributions can be generated from Gaussian variables.

STOCHASTIC INTEGRALS DEFINED

Let's now go back to the definition of stochastic integrals, starting with one-dimensional stochastic integrals. Suppose that a probability space $(\Omega, \mathfrak{F}, P)$ equipped with a filtration \mathfrak{F}_t is given. Suppose also that a Brownian motion $B_t(\omega)$ adapted to the filtration \mathfrak{F}_t is given. We will define Ito integrals following the three-step procedure outlined earlier in this entry. We have just completed the first step defining Brownian motion. The second step consists in defining the Ito integral for elementary functions.

Let's first define the set $\Phi(S, T)$ of functions $\phi(S, T) \equiv \{f(t, \omega): [(0, \infty) \times \Omega \rightarrow R]\}$ with the following properties:

- Each f is jointly $\mathcal{B} \times \mathfrak{F}$ measurable.
- Each $f(t, \omega)$ is adapted to \mathfrak{F}_t .
- $E \left[\int_S^T f^2(t, \omega) dt \right] < \infty$ (this condition can be weakened).

This is the set of paths for which we define the Ito integral.

Consider the time interval $[S, T]$ and, for each integer n , partition the interval $[S, T]$ in subintervals: $t_0 < t_1 < \dots < t_n < \dots < t_N \equiv T$ in this way:

$$t_k = t_k^n = \begin{cases} k2^{-n} & \text{if } S \leq k2^{-n} \leq T \\ S & \text{if } k2^{-n} < S \\ T & \text{if } k2^{-n} > T \end{cases}$$

This rule provides a family of partitions of the interval $[S, T]$ which can be arbitrarily refined.

Consider the elementary functions $\phi(t, \omega) \in \Phi$ which we write as

$$\phi(t, \omega) = \sum_i \varepsilon_i(\omega) I[t_{i+1} - t_i]$$

As $\phi(t, \omega) \in \Phi$, $\varepsilon_i(\omega)$ are \mathfrak{F}_{t_i} measurable random variables.

We can now define the stochastic integral, in the sense of Ito, of elementary functions $\phi(t, \omega)$ as

$$W = \int_S^T \phi(t, \omega) dB_t(\omega) = \sum_{i \geq 0} \varepsilon_i(\omega) [B_{t_{i+1}}(\omega) - B_{t_i}(\omega)]$$

where B is a Brownian motion. Note that the $\varepsilon_i(\omega)$ and the increments $B_j(\omega) - B_i(\omega)$ are independent for $j > i$. The key aspect of this definition that was not included in the informal outline is the condition that the $\varepsilon_i(\omega)$ are \mathfrak{F}_{t_i} measurable.

For bounded elementary functions $\phi(t, \omega) \in \Phi$ the Ito isometry holds

$$E \left[\left(\int_S^T \phi(t, \omega) dB_t(\omega) \right)^2 \right] = E \left[\int_S^T \phi(t, \omega)^2 dt \right]$$

The demonstration of the Ito isometry rests on the fact that

$$E[\varepsilon_i \varepsilon_j (B_{t_{i+1}} - B_{t_i})(B_{t_{j+1}} - B_{t_j})] = \begin{cases} 0 & \text{if } i \neq j \\ E(\varepsilon_i^2) & \text{if } i = j \end{cases}$$

This completes the definition of the stochastic integral for elementary functions.

We have now completed the introduction of Brownian motions and defined the Ito integral for elementary functions. Let's next introduce the approximation procedure that allows us to define the stochastic integral for any $\phi(t, \omega)$. We will develop the approximation procedure in the following three additional steps that we will state without demonstration:

- *Step 1.* Any function $g(t, \omega) \in \Phi$ that is bounded and such that all its time paths $\phi(\cdot, \omega)$ are

continuous functions of time can be approximated by

$$\phi_n(t, \omega) = \sum_i g(t_i, \omega) I[t_{i+1} - t_i]$$

in the sense that:

$$E \int_S^T [(g - \phi_n)^2 dt] \rightarrow 0, \quad n \rightarrow \infty, \forall \omega$$

where the intervals are those of the partition defined above. Note that $\phi_n(t, \omega) \in \Phi$ given that $g(t, \omega) \in \Phi$.

- *Step 2.* We release the condition of time-path continuity of the $\phi_n(t, \omega)$. It can be demonstrated that any function $h(t, \omega) \in \Phi$ which is bounded but not necessarily continuous can be approximated by functions $g_n(t, \omega) \in \Phi$, which are bounded and continuous in the sense that

$$E \left[\int_S^T (h - g_n)^2 dt \right] \rightarrow 0$$

- *Step 3.* It can be demonstrated that any function $f(t, \omega) \in \Phi$, not necessarily bounded or continuous, can be approximated by a sequence of bounded functions $h_n(t, \omega) \in \Phi$ in the sense that

$$E \left[\int_S^T (f - h_n)^2 dt \right] \rightarrow 0$$

We now have all the building blocks to complete the definition of Ito stochastic integrals. In fact, by virtue of the above three-step approximation procedure, given any function $f(t, \omega) \in \Phi$, we can choose a sequence of elementary functions $\phi_n(t, \omega) \in \Phi$ such that the following property holds:

$$E \left[\int_S^T (f - \phi_n)^2 dt \right] \rightarrow 0$$

Hence we can define the Ito stochastic integral as follows:

$$I[f](\omega) = \int_S^T f(t, \omega) dB_t(\omega) = \lim_{n \rightarrow \infty} \left[\int_S^T \phi_n(t, \omega) dt \right]$$

The limit exists as

$$\int_S^T \phi_n(t, \omega) dB_t(\omega)$$

forms a Cauchy sequence by the Ito isometry, which holds for every bounded elementary function.

Let's now summarize the definition of the Ito stochastic integral: Given any function $f(t, \omega) \in \Phi$, we define the Ito stochastic integral by

$$I[f](\omega) = \int_S^T f(t, \omega) dB_t(\omega) = \lim_{n \rightarrow \infty} \left[\int_S^T \phi_n(t, \omega) dt \right]$$

where the functions $\phi_n(t, \omega) \in \Phi$ are a sequence of elementary functions such that

$$E \left[\int_S^T (f - \phi_n)^2 dt \right] \rightarrow 0$$

The multistep procedure outlined above ensures that the sequence $\phi_n(t, \omega) \in \Phi$ exists. In addition, it can be demonstrated that the Ito isometry holds in general for every $f(t, \omega) \in \Phi$

$$E \left[\left(\int_S^T f(t, \omega) dB_t(\omega) \right)^2 \right] = E \left[\int_S^T f(t, \omega)^2 dt \right]$$

SOME PROPERTIES OF ITO STOCHASTIC INTEGRALS

Suppose that $f, g \in \Phi(S, T)$ and let $0 < S < U < T$. It can be demonstrated that the following

properties of Ito stochastic integrals hold:

$$\int_s^T f dB_t = \int_s^u f dB_t + \int_u^T f dB_t \text{ for a.a. } \omega$$

$$E \left[\int_s^T f dB_t \right] = 0$$

$$\int_s^T (cf + dg) dB_t = c \int_s^T f dB_t + d \int_s^T g dB_t,$$

for a.a. ω, c, d constants

If we let the time interval vary, say $(0, t)$, then the stochastic integral becomes a stochastic process:

$$I_t(\omega) = \int_0^t f dB_t$$

It can be demonstrated that a continuous version of this process exists. The following three properties can be demonstrated from the definition of integral:

$$\int_0^t dB_s = B_t$$

$$\int_0^t s dB_s = tB_t - \int_0^t B_s ds$$

$$\int_0^t B_s dB_s = \frac{1}{2} B_t^2 - \frac{1}{2} t$$

The last two properties show that, after performing stochastic integration, deterministic terms might appear.

KEY POINTS

- Stochastic integration provides a coherent way to represent that instantaneous uncer-

tainty (or volatility) cumulates over time. It is thus fundamental to the representation of financial processes such as interest rates, security prices, or cash flows as well as aggregate quantities such as economic output.

- Stochastic integration operates on stochastic processes and produces random variables or other stochastic processes.
- Stochastic integration is a process defined on each path as the limit of a sum. However, these sums are different from the sums of the Riemann-Lebesgue integrals because the paths of stochastic processes are generally not of bounded variation.
- Stochastic integrals in the sense of Ito are defined through a process of approximation.
- Step 1 consists in defining Brownian motion, which is the continuous limit of a random walk.
- Step 2 consists in defining stochastic integrals for elementary functions as the sums of the products of the elementary functions multiplied by the increments of the Brownian motion.
- Step 3 extends this definition to any function through approximating sequences.

NOTES

1. The publications of Stratonovich can be found in Romanovski (2007).
2. A history of stochastic integrations and financial mathematics is provided by Jarrow and Protter (2004). For a more detailed discussion of stochastic integration, see Protter (1990).
3. The set of conditions defining a Brownian motion can be more parsimonious. If a process has stationary, independent increments and continuous paths a.s. it must have normally distributed increments. A process with stationary independent increments and with paths that are continuous to the right and limited to the left (the *cadlag* functions) is called a Levy process.

Stochastic Differential Equations

SERGIO M. FOCARDI, PhD
Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

Abstract: In nontechnical terms, differential equations are equations that express a relationship between a function and one or more derivatives (or differentials) of that function. It would be difficult to overemphasize the importance of differential equations in financial modeling where they are used to express laws that govern the evolution of price probability distributions, the solution of economic variational problems (such as intertemporal optimization), and conditions for continuous hedging (such as in the Black-Scholes equation). The two broad types of differential equations are ordinary differential equations and partial differential equations. The former are equations or systems of equations involving only one independent variable; the latter are differential equations or systems of equations involving partial derivatives. When one or more of the variables is a stochastic process, we have the case of stochastic differential equations and the solution is also a stochastic process. An assumption must be made about driving noise in a stochastic differential equation. In most applications, it is assumed that the noise term follows a Gaussian random variable, although types of random variables can be assumed.

Stochastic differential equations solve the problem of giving meaning to a differential equation where one or more of its terms are subject to random fluctuations. For instance, consider the following deterministic equation:

$$\frac{dy}{dt} = f(t)y$$

We know from differential equations that, by separating variables, the general solution of this equation can be written as follows:

$$y = A \exp \left[\int f(t) dt \right]$$

A stochastic version of this equation might be obtained, for instance, by perturbing the term f , thus resulting in the *stochastic differential equation*

$$\frac{dy}{y} = [f(t) + \varepsilon] dt$$

where ε is a random noise process.

As with stochastic integrals, in defining stochastic differential equations it is necessary to adopt an ensemble view: The solution of a stochastic differential equation is a stochastic process, not a single function. In this entry, we first provide the basic intuition behind

stochastic differential equations and then proceed to formally define the concept and the properties.

THE INTUITION BEHIND STOCHASTIC DIFFERENTIAL EQUATIONS

Let's go back to the equation

$$\frac{dy}{dt} = [f(t) + \varepsilon]y$$

where ε is a continuous-time noise process. It would seem reasonable to define a continuous-time noise process informally as the continuous-time limit of a zero-mean, IID sequence, that is, a sequence of independent and identically distributed variables with zero mean. In a discrete time setting, a zero-mean, IID sequence is called a *white noise*. We could envisage defining a continuous-time white noise as the continuous-time limit of a discrete-time white noise. Each path of ε is a function of time $\varepsilon(\cdot, \omega)$. It would therefore seem reasonable to define the solution of the equation pathwise, as the family of functions that are solutions of the equations

$$\frac{dy}{dt} = [f(t) + \varepsilon(t, \omega)]y$$

where each equation corresponds to a specific white noise path.

However, this definition would be meaningless in the domain of ordinary functions. In other words, it would generally not be possible to find a family of functions $y(\cdot, \omega)$ that satisfy the above equations for each white-noise path and that form a reasonable stochastic process.

The key problem is that it is not possible to define a white noise process as a zero-mean stationary stochastic process with independent increments and continuous paths. Such a process does not exist in the domain of ordinary functions.¹ In discrete time the white noise process is obtained as the first-difference process of a random walk. *Random walk* is an integrated

nonstationary process, while its first-difference process is a stationary IID sequence.

The continuous-time limit of the random walk is the *Brownian motion*. However, the paths of a Brownian motion are not differentiable. As a consequence, it is not possible to take the continuous-time limit of first differences and to define the white noise process as the derivative of a Brownian motion. In the domain of ordinary functions in continuous time, the white noise process can be defined only through its integral, which is the Brownian motion. The definition of stochastic differential equations must therefore be recast in integral form.

A sensible definition of a stochastic differential equation must respect a number of constraints. In particular, the solution of a stochastic differential equation should be a "perturbation" of the associated deterministic equation. In the above example, for instance, we want the solution of the stochastic equation

$$\frac{dy}{dy} = [f(t) + \varepsilon(t, \omega)]dt$$

to be a perturbation of the solution

$$y = A \exp\left(\int f(t)dt\right)$$

of the associated deterministic equation

$$\frac{dy}{y} = f(t)dt$$

In other words, the solution of a stochastic differential equation should tend to the solution of the associated deterministic equation in the limit of zero noise. In addition, the solutions of a stochastic differential equation should be the continuous-time limit of some discrete-time process obtained by discretization of the stochastic equation.

A formal solution of this problem was proposed by Kiyoshi Itô (1951) and, in a different setting, by Ruslan Stratonovich in the 1960s. Itô and Stratonovich proposed to give meaning to a stochastic differential equation through its integral equivalent. The Itô definition proceeds in two steps: In the first step, Itô processes are

defined; in the second step, stochastic differential equations are defined.

- *Step 1: Definition of Itô processes.* Given two functions $\varphi(t, \omega)$ and $\psi(t, \omega)$ that satisfy usual conditions to be defined later, an *Itô process*—also called a **stochastic integral**—is a stochastic process of the form:

$$Z(t, \omega) = \int_0^t \varphi(s, \omega) ds + \int_0^t \psi(s, \omega) dB_s(s, \omega)$$

An Itô process is a process that is the result of the sum of two summands: The first is an ordinary integral, the second an Itô integral. Itô processes are stable under smooth maps, that is, any smooth function of an Itô process is an Itô process that can be determined through the Itô formula (see Itô processes below).

- *Step 2: Definition of stochastic differential equations.* As we have seen, it is not possible to write a differential equation plus a white-noise term that admits solutions in the domain of ordinary functions. However, we can meaningfully write an integral stochastic equation of the form

$$X(t, \omega) = \int_0^t \varphi(s, X) ds + \int_0^t \psi(s, X) dB_s$$

It can be demonstrated that this equation admits solutions in the sense that, given two functions φ and ψ , there is a stochastic process X that satisfies the above equation. We stipulate that the above integral equation can be written in differential form as follows:

$$dX(t, \omega) = \varphi(t, X)dt + \psi(t, X)dB_t$$

Note that this is a definition; a stochastic differential equation acquires meaning only through its integral form. In particular, we *cannot* divide both terms by dt and rewrite the equation as follows:

$$\frac{dX(t, \omega)}{dt} = \varphi(t, X) + \psi(t, X) \frac{dB_t}{dt}$$

The above equation would be meaningless because the Brownian motion is not differentiable.

This is the difficulty that precludes writing stochastic differential equations adding white noise pathwise. The differential notation of a stochastic differential equation is just a shorthand for the integral notation.

However, we can consider a discrete approximation:

$$\Delta X(t, \omega) = \varphi^*(t, X)\Delta t + \psi^*(t, X)\Delta B_t$$

Note that in this approximation the functions $\varphi^*(t, X)$, $\psi^*(t, X)$ will not coincide with the functions $\varphi(t, X)$, $\psi(t, X)$. Using the latter would (in general) result in a poor approximation.

The following sections will define Itô processes and stochastic differential equations and study their properties.

ITÔ PROCESSES

Let's now formally define Itô processes and establish key properties, in particular the Itô formula. In the previous section we stated that an Itô process is a stochastic process of the form

$$Z(t, \omega) = \int_0^t a(s, \omega) ds + \int_0^t b(s, \omega) dB(s, \omega)$$

To make this definition rigorous, we have to state the conditions under which (1) the integrals exist, and (2) there is no anticipation of information. Note that the two functions a and b might represent two stochastic processes and that the Riemann-Stieltjes integral might not exist for the paths of a stochastic process. We have therefore to demonstrate that both the Itô integral and the ordinary integral exist. To this end, we define Itô processes as follows.

Suppose that a one-dimensional Brownian motion B_t is defined on a probability space $(\Omega, \mathfrak{F}, P)$ equipped with a filtration \mathfrak{F}_t . The filtration might be given or might be generated by the Brownian motion B_t . Suppose that both a and b are adapted to \mathfrak{F}_t and jointly measurable in $\mathfrak{F} \times \mathfrak{R}$. Suppose, in addition, that the

following two integrability conditions hold:

$$P \left[\int_0^t b^2(s, \omega) ds < \infty \text{ for all } t \geq 0 \right] = 1$$

and

$$P \left[\int_0^t |a(s, \omega)| ds < \infty \text{ for all } t \geq 0 \right] = 1$$

These conditions ensure that both integrals in the definition of Itô processes exist and that there is no anticipation of information. We can therefore define the Itô process as the following stochastic process:

$$Z(t, \omega) = \int_0^t a(s, \omega) ds + \int_0^t b(s, \omega) dB_s(s, \omega)$$

Itô processes can be written in the shorter differential form as

$$dZ_t = a dt + b dB_t$$

It should be clear that the latter formula is just a shorthand for the integral definition.

THE ONE-DIMENSIONAL ITÔ FORMULA

One of the most important results concerning Itô processes is a formula established by Itô that allows one to explicitly write down an Itô process that is a function of another Itô process. Itô's formula is the stochastic equivalent of the change-of-variables formula of ordinary integration. We will proceed in two steps. First we will introduce Itô's formula for functions of Brownian motion and then for functions of general Itô processes. Suppose that the function $g(t, x)$ is twice continuously differentiable in $[0, \infty) \times R$ and that B_t is a one-dimensional Brownian motion. The function $Y_t = g(t, B_t)$ is a stochastic process. It can be demonstrated that the process $Y_t = g(t, B_t)$ is an Itô process of the following form

$$dY_t = \left(\frac{\partial g}{\partial t}(t, B_t) + \frac{1}{2} \frac{\partial^2 g}{\partial x^2}(t, B_t) \right) dt + \frac{\partial g}{\partial x}(t, B_t) dB_t$$

The preceding is Itô's formula in the case the underlying process is a Brownian motion. For example, let's suppose that $g(t, x) = x^2$. In this case we can write

$$\frac{\partial g}{\partial t} = 0, \quad \frac{\partial g}{\partial x} = 2x, \quad \frac{\partial^2 g}{\partial x^2} = 2$$

Inserting the above in Itô's formula we see that the process B_t^2 can be represented as the following Itô process

$$dY_t = dt + 2B_t dB_t$$

or, explicitly in integral form

$$Y_t = t + 2 \int_0^t B_s dB_s$$

The nonlinear map $g(t, x) = x^2$ introduces a second term in dt .

Let's now generalize Itô's formula. Suppose that X_t is an Itô process given by $dX_t = a dt + b dB_t$. As X_t is a stochastic process, that is, a function $X(t, \omega)$ of both time and the state, it makes sense to consider another stochastic process Y_t , which is a function of the former, $Y_t = g(t, X_t)$. Suppose that g is twice continuously differentiable on $[0, \infty) \times R$.

It can then be demonstrated (we omit the detailed proof) that Y_t is another Itô process that admits the representation

$$dY_t = \frac{\partial g}{\partial t}(t, X_t) dt + \frac{\partial g}{\partial x}(t, X_t) dX_t + \frac{1}{2} \frac{\partial^2 g}{\partial x^2}(t, X_t) (dX_t)^2$$

where differentials are computed formally according to the rules known as Box algebra

$$dt \cdot dt = dt \cdot dB_t = dB_t \cdot dt = 0, \quad dB_t \cdot dB_t = dt$$

Itô's formula can be written (perhaps more) explicitly as

$$dY_t = \left(\frac{\partial g}{\partial t} + \frac{\partial g}{\partial x} a + \frac{1}{2} \frac{\partial^2 g}{\partial x^2} b^2 \right) dt + \frac{\partial g}{\partial x} b dB_t$$

This formula reduces to the ordinary formula for the differential of a compound function in the case where $b = 0$ (that is, when there is no noise).

As a second example of application of Itô's formula, consider the geometric Brownian motion:

$$dX_t = \mu X_t dt + \sigma X_t dB_t$$

where μ, σ are real constants, and consider the map $g(t, x) = \log x$. In this case, we can write

$$\frac{\partial g}{\partial t} = 0, \frac{\partial g}{\partial x} = \frac{1}{x}, \frac{\partial^2 g}{\partial x^2} = -\frac{1}{x^2}$$

and Itô's formula yields

$$dY_t = d \log X_t = \left(\mu - \frac{1}{2} \sigma^2 \right) dt + \sigma dB_t$$

STOCHASTIC DIFFERENTIAL EQUATIONS

An Itô process defines a process $Z(t, \omega)$ as the sum of the time integral of the process $a(t, \omega)$ plus the Itô integral of the process $b(t, \omega)$. Suppose that two functions $\varphi(t, x), \psi(t, x)$ that satisfy conditions established below are given. Given an Itô process $X(t, \omega)$, the two processes $\varphi(t, X), \psi(t, X)$ admit respectively a time integral and an Itô integral. It therefore makes sense to consider the following Itô process:

$$Z(t, \omega) = \int_0^t \varphi[s, X(s, \omega)] ds + \int_0^t \psi[s, X(s, \omega)] dB_s$$

The term on the right side transforms the process X into a new process Z . We can now ask if there are stochastic processes X that are mapped into themselves such that the following stochastic equation is satisfied:

$$X(t, \omega) = \int_0^t \varphi[s, X(s, \omega)] ds + \int_0^t \psi[s, X(s, \omega)] dB_s$$

The answer is positive under appropriate conditions. It is possible to prove the following theorem of existence and uniqueness. Suppose that a one-dimensional Brownian motion B_t is defined on a probability space $(\Omega, \mathfrak{F}, P)$ equipped with a filtration \mathfrak{F}_t and that B_t is adapted to the filtration \mathfrak{F}_t . Suppose also that the two measurable functions $\varphi(t, x), \psi(t, x)$ map $[0,$

$T] \times R \rightarrow R$ and that they satisfy the following conditions:

$$\begin{aligned} |\varphi(t, x)|^2 + |\psi(t, x)|^2 &\leq C(1 + |x|)^2, \\ t &\in [0, T], x \in R \end{aligned}$$

and

$$\begin{aligned} |\varphi(t, x) - \varphi(t, y) + |\psi(t, x) - \psi(t, y)| \\ \leq D|x - y|, t \in [0, T], x \in R \end{aligned}$$

for appropriate constants C, D . The first condition is known as the linear growth condition, the last condition is the Lipschitz condition. Suppose that Z is a random variable independent of the σ -algebra \mathfrak{F}_∞ generated by B_t for $t \geq 0$ such that $E(|Z|^2) < \infty$. Then there is a unique stochastic process X , defined for $0 \leq t \leq T$, with time-continuous paths such that $X_0 = Z$ and such that the following equation is satisfied:

$$\begin{aligned} X(t, \omega) = X_0 + \int_0^t \varphi[s, X(s, \omega)] ds \\ + \int_0^t \psi[s, X(s, \omega)] dB_s \end{aligned}$$

The process X is called a strong solution of the above equation.

The above equation can be written in differential form as follows:

$$dX(t, \omega) = \varphi[t, X(t, \omega)] dt + \psi[t, X(t, \omega)] dB_t$$

The differential form does not have an independent meaning; a differential stochastic equation is just a short albeit widely used way to write the integral equation.

The key requirement of a strong solution is that the filtration \mathfrak{F}_t is given and that the functions φ, ψ are adapted to the filtration \mathfrak{F}_t . From the economic (or physics) point of view, this requirement translates the notion of causality. In simple terms, a strong solution is a functional of the driving Brownian motion and of the "inputs" φ, ψ . A strong solution at time t is determined only by the "history" up to time t of the inputs and of the random shocks embodied in the Brownian motion.

These conditions can be weakened. Suppose that we are given only the two functions $\varphi(t, x)$, $\psi(t, x)$ and that we must construct a process X_t , a Brownian motion B_t , and the relative filtration so that the above equation is satisfied. The equation still admits a unique solution with respect to the filtration generated by the Brownian motion B . It is, however, only a weak solution in the sense that, though there is no anticipation of information, it is not a functional of a given Brownian motion. (See, for example, Karatzas and Shreve [1991].) Weak and strong solutions do not necessarily coincide. However, any strong solution is also a weak solution with respect to the same filtration.

Note that the solution of a differential equation is a stochastic process. Initial conditions must therefore be specified as a random variable and not as a single value as for ordinary differential equations. In other words, there is an initial value for each state. It is possible to specify a single initial value as the initial condition of a stochastic differential equation. In this case the initial condition is a random variable where the probability mass is concentrated in a single point.

We omit the detailed proof of the theorem of uniqueness and existence. Uniqueness is proved using the Itô isometry and the Lipschitz condition. One assumes that there are two different solutions and then demonstrates that their difference must vanish. The proof of existence of a solution is similar to the proof of existence of solutions in the domain of ordinary equations. The solution is constructed inductively by a recursive relationship of the type

$$X^{(k+1)}(t, \omega) = \int_0^t \varphi[s, X^k(s, \omega)] ds + \int_0^t \psi[s, X^k(s, \omega)] dB_s$$

It can be shown that this recursive relationship produces a sequence of processes that converge to the unique solution.

GENERALIZATION TO SEVERAL DIMENSIONS

The concepts and formulas established so far for Itô (and Stratonovich) integrals and processes can be extended in a straightforward but often cumbersome way to multiple variables. The first step is to define a d -dimensional Brownian motion.

Given a probability space $(\Omega, \mathfrak{F}, P)$ equipped with a filtration $\{\mathfrak{F}_t\}$, a d -dimensional standard Brownian motion $B_t(\omega)$, is a stochastic process with the following properties:

- $B_t(\omega)$ is a d -dimensional process defined over the probability space $(\Omega, \mathfrak{F}, P)$ that takes values in R^d .
- $B_t(\omega)$ has continuous paths for $0 \leq t \leq \infty$.
- $B_0(\omega) = 0$.
- $B_t(\omega)$ is adapted to the filtration \mathfrak{F}_t .
- The increments $B_t(\omega) - B_s(\omega)$ are independent of the σ -algebra \mathfrak{F}_s and have a normal distribution with mean zero and covariance matrix $(t - s)I_d$, where I_d is the identity matrix.

The above conditions state that the standard Brownian motion is a stochastic process that starts at zero, has continuous paths, and has normally distributed increments whose variances grow linearly with time.

The next step is to extend the definition of the Itô integral in a multidimensional environment. This is again a straightforward but cumbersome extension of the one-dimensional case. Suppose that the following $r \times d$ -dimensional matrix is given:

$$\mathbf{v} = \begin{bmatrix} v_{11} & \cdot & v_{1d} \\ \cdot & \cdot & \cdot \\ v_{r1} & \cdot & v_{rd} \end{bmatrix}$$

where each entry $v_{ij} = v_{ij}(t, \omega)$ satisfies the following conditions:

1. v_{ij} are $\mathfrak{B}^d \times \mathfrak{S}$ measurable.
2. v_{ij} are \mathfrak{F}_t -adapted.
3. $P[\int_0^t (v_{ij})^2 ds < \infty \text{ for all } t \geq 0] = 1$.

Then, we define the multidimensional Itô integral

$$\int_0^t \mathbf{v} dB = \int_0^t \begin{bmatrix} v_{11} & \cdot & v_{1d} \\ \cdot & \cdot & \cdot \\ v_{r1} & \cdot & v_{rd} \end{bmatrix} \begin{bmatrix} dB_1 \\ \cdot \\ dB_d \end{bmatrix}$$

as the r -dimensional column vector whose components are the following sums of one-dimensional Itô integrals:

$$\sum_{i=1}^d \int_0^t v_{ij}(s, \omega) dB_j(s, \omega)$$

Note that the entries of the matrix are functions of time and state: They form a vector of stochastic processes. Given the previous definition of Itô integrals, we can now extend the definition of Itô processes to the multidimensional case. Suppose that the functions u and v satisfy the conditions established for the one-dimensional case. We can then form a multidimensional Itô process as the following vector of Itô processes:

$$\begin{aligned} dX_1 &= u_1 dt + v_{11} dB_1 + \dots + v_{1d} dB_d \\ \dots & \\ dX_{1r} &= u_r dt + v_{r1} dB_1 + \dots + v_{rd} dB_d \end{aligned}$$

or, in matrix notation

$$d\mathbf{X} = \mathbf{u}dt + \mathbf{v}dB$$

After defining the multidimensional Itô process, multidimensional stochastic equations are defined in differential form in matrix notation as follows:

$$\begin{aligned} d\mathbf{X}(t, \omega) &= \mathbf{u}[t, X_1(t, \omega), \dots, X_d(t, \omega)]dt \\ &+ \mathbf{v}[t, X_1(t, \omega), \dots, X_d(t, \omega)]dB \end{aligned}$$

Consider now the multidimensional map: $g(t, x) \equiv [g_1(t, x), \dots, g_d(t, x)]$, which maps the process X into another process $Y = g(t, X)$. It can be demonstrated that Y is a multidimensional Itô process whose components are defined

according to the following rules:

$$\begin{aligned} dY_k &= \frac{\partial g_k(t, X)}{\partial t} dt + \sum_i \frac{\partial g_k(t, X)}{\partial X_i} dX_i \\ &+ \frac{1}{2} \sum_{i,j} \frac{\partial^2 g_k(t, X)}{\partial X_i \partial X_j} dX_i dX_j \end{aligned}$$

$$dB_i dB_j = 1 \text{ if } i = j, \text{ 0 if } i \neq j, dB_i dt = dt dB_i = 0$$

SOLUTION OF STOCHASTIC DIFFERENTIAL EQUATIONS

It is possible to determine an explicit solution of stochastic differential equations in the linear case and in a number of other cases that can be reduced to linear equations through functional transformations. Let's first consider linear stochastic equations of the form:

$$\begin{aligned} dX_t &= [A(t)X_t + a(t)]dt + \sigma(t)dB_t, \quad 0 \leq t < \infty \\ X_0 &= \xi \end{aligned}$$

where B is an r -dimensional Brownian motion independent of the d -dimensional initial random vector ξ and the $(d \times d)$, $(d \times d)$, $(d \times r)$ matrices $A(t)$, $a(t)$, $\sigma(t)$ are nonrandom and time dependent.

The simplest example of a linear stochastic equation is the equation of an arithmetic Brownian motion with drift, written as follows:

$$\begin{aligned} dX_t &= \mu dt + \sigma dB_t, \quad 0 \leq t < \infty \\ X_0 &= \xi, \mu, \sigma \text{ constants} \end{aligned}$$

In linear equations of this type, the stochastic part enters only in an additive way through the terms $\sigma_{ij}(t)dB_t$. The functions $\sigma(t)$ are sometimes called the instantaneous variances and covariances of the process. In the example of the arithmetic Brownian motion, μ is called the drift of the process and σ the volatility of the process.

It is intuitive that the solution of this equation is given by the solution of the associated deterministic equation, that is, the ordinary differential equation obtained by removing the stochastic part, plus the cumulated random

disturbances. Let's first consider the associated deterministic differential equation

$$\frac{dx}{dt} = A(t)x + a(t), 0 \leq t < \infty$$

where $x(t)$ is a d -dimensional vector with initial conditions $x(0) = \xi$.

It can be demonstrated that this equation has an absolutely continuous solution in the domain $0 \leq t < \infty$. To find its solution, let's first consider the matrix differential equation

$$\frac{d\Phi}{dt} = A(t)\Phi, 0 \leq t < \infty$$

This matrix differential equation has an absolutely continuous solution in the domain $0 \leq t < \infty$. The matrix $\Phi(t)$ that solves this equation is called the fundamental solution of the equation. It can be demonstrated that $\Phi(t)$ is a nonsingular matrix for each t . Lastly, it can be demonstrated that the solution of the equation:

$$\frac{dx}{dt} = A(t)x + a(t), 0 \leq t < \infty$$

with initial condition $x(0) = \xi$, can be written in terms of the fundamental solution as follows:

$$x(t) = \Phi(t) \left[x(0) + \int_0^t \Phi^{-1}(s)a(s)ds \right], 0 \leq t < \infty$$

Let's now go back to the stochastic equation

$$dX_t = [A(t)X_t + a(t)]dt + \sigma(t)dB_t, 0 \leq t < \infty$$

$$X_0 = \xi$$

Using Itô's formula, it can be demonstrated that the above linear stochastic equation admits the following unique solution:

$$X(t) = \Phi(t) \left[\xi + \int_0^t \Phi^{-1}(s)a(s)ds + \int_0^t \Phi^{-1}(s)\sigma(s)dB_s \right], 0 \leq t < \infty$$

This effectively demonstrates that the solution of the linear stochastic equation is the solution of the associated deterministic equation plus

the cumulated stochastic term

$$\int_0^t \Phi^{-1}(s)\sigma(s)dB_s$$

To illustrate this, below we now specialize the above solutions in the case of arithmetic Brownian motion, Ornstein-Uhlenbeck processes, and geometric Brownian motion.

The Arithmetic Brownian Motion

The *arithmetic Brownian motion* in one dimension is defined by the following equation:

$$dX_t = \mu dt + \sigma dB_t$$

In this case, $A(t) = 0$, $a(t) = \mu$, $\sigma(t) = \sigma$ and the solution becomes

$$X = \mu t + \sigma B$$

The Ornstein-Uhlenbeck Process

The *Ornstein-Uhlenbeck process* in one dimension is a mean-reverting process defined by the following equation:

$$dX_t = -\alpha X_t dt + \sigma dB_t$$

It is a mean-reverting process because the drift is pulled back to zero by a term proportional to the process itself. In this case, $A(t) = -\alpha$, $a(t) = 0$, $\sigma(t) = \sigma$ and the solution becomes

$$X_t = X_0 + e^{-\alpha t} + \sigma \int_0^t e^{-\alpha(t-s)} dB_s$$

The Geometric Brownian Motion

The *geometric Brownian motion* in one dimension is defined by the following equation:

$$dX = \mu X dt + \sigma X dB$$

This equation can be easily reduced to the previous linear case by the transformation:

$$Y = \log X$$

Let's apply Itô's formula

$$dY_t = \left(\frac{\partial g}{\partial t} + \frac{\partial g}{\partial x} a + \frac{1}{2} \frac{\partial^2 g}{\partial x^2} b^2 \right) dt + \frac{\partial g}{\partial x} b dB_t$$

where

$$g(t, x) = \log x, \quad \frac{\partial g}{\partial t} = 0, \quad \frac{\partial g}{\partial x} = \frac{1}{x}, \quad \frac{\partial^2 g}{\partial x^2} = -\frac{1}{x^2}$$

We can then verify that the logarithm of the geometric Brownian motion becomes an arithmetic Brownian motion with drift

$$\mu' = \mu - \frac{1}{2}\sigma^2$$

The geometric Brownian motion evolves as a lognormal process:

$$X_t = x_0 \exp \left\{ \left(\mu - \frac{1}{2}\sigma^2 \right) t + \sigma B_t \right\}$$

KEY POINTS

- Stochastic differential equations give meaning to ordinary differential equations where some terms are subject to random perturbation.
- Following Itô and Stratonovich, stochastic differential equations are defined through their integral equivalent: The differential notation is just a shorthand.
- Itô processes are the sum of a time integral plus an Itô integral.
- Itô processes are closed with respect to smooth maps: A smooth function of an Itô process is another Itô process defined through the Itô formula.
- Stochastic differential equations are equations established in terms of Itô processes.
- Linear equations can be solved explicitly as the sum of the solution of the associated deterministic equation plus a stochastic cumulative term.

NOTE

1. It is possible to define a "generalized white noise process" in the domain of "tempered distributions." See Oksendal (1992).

Abstract: The dynamic of a financial asset's returns and prices can be expressed using a deterministic process if there is no uncertainty about its future behavior, or with a stochastic process in the more likely case when the value is uncertain. Stochastic processes in continuous time are the most used tool to explain the dynamics of a financial asset's returns and prices. They are the building blocks with which to construct financial models for portfolio optimization, derivatives pricing, and risk management. Continuous-time processes allow for more elegant theoretical modeling compared to discrete-time models and many results proven in probability theory can be applied to obtain a simple evaluation method.

In 1900, the father of modern option pricing theory, Louis Bachelier, proposed using *Brownian motion* for modeling stock market prices. There are several reasons why Brownian motion is a popular process. First, Brownian motion is the milestone of the theory of stochastic processes.

However, more realistic general processes that are better suited for financial modeling such as Lévy, additive, or self-similar processes have been developed only since the mid 1990s (see Samorodnitsky and Taqqu (1994), Sato (1999), and Embrechts and Maejima (2002)). Most of

Dr. Bianchi acknowledges that the views expressed in this entry are his own and do not necessarily reflect those of the Bank of Italy.

the practical problems in mathematical finance can be solved by taking into consideration these new processes. For example, the concept of stochastic integral with respect to Brownian motion was introduced in 1933 and only in the 1990s has the general theory of stochastic integration with respect to semi-martingale appeared. From a practical point of view, the second reason for the popularity of Brownian motion is that the normal distribution allows one to solve real-world pricing problems such as option prices as estimations and simulations in a few seconds, and most of the problems have a closed-form solution which can be easily used. See Øksendal (2003) or Karatzas and Shreve (1991) for a complete theoretical treatment of financial applications of continuous-time stochastic processes driven by Brownian motion.

The two basic classes of continuous-time stochastic processes are Brownian motion and the *Poisson process*. The name of the former is due to the botanist Robert Brown who in 1827 described the movement of pollen suspended in water. The theory of Brownian motion was founded by the work of Norbert Wiener who was the first to prove its existence and, as a result, Brownian motion is sometimes also referred to as a Wiener process. The Poisson process generated by the Poisson distribution is the building block of pure *jump processes*. Both processes are fundamentally different with respect to their path properties and they belong to the larger class of *Lévy processes* (for more details about Lévy processes see Sato [1999]). Schoutens (2003), Cont and Tankov (2004), and Rachev et al. (2011) provide details of Lévy processes with applications to option pricing.

Infinitely divisible distributions, including α -stable and tempered stable distributions, can be considered to define continuous-time stochastic processes. In order to model the behavior of a financial asset's returns and prices, one can consider (1) a Brownian motion, (2) a process defined as the sum of a Brownian motion and a Poisson process, or (3) a pure jump Lévy process.

In this entry, we will discuss continuous-time stochastic processes. We will first consider processes consisting of jumps and then we will discuss continuous processes without jumps. We then turn our focus to processes having random time instead of physical time. Finally, we will discuss a general process that contains all of these processes.

SOME PRELIMINARIES

Before we continue with the discussion and the construction of processes, we will briefly define terms that will be used in this entry.

- A *stochastic process* $X = (X_t)_{t \geq 0}$ is a family of \mathbb{R} -valued random variables X_t with parameter $t \geq 0$, defined on the sample space Ω . For every outcome $\omega \in \Omega$, the function $t \mapsto X_t(\omega)$ is called a sample path of the process X .
- Let X be a stochastic process. Given $0 < t_1 < t_2 < \dots < t_n$, if the random variables $X_{t_1} - X_0, X_{t_2} - X_{t_1}, \dots, X_{t_n} - X_{t_{n-1}}$ are independent, we say that X has independent increments. Moreover, for $t \geq 0$, if the distribution of $X_{t+h} - X_t$ does not depend on $t \geq 0$, we say that X has stationary increments. Loosely speaking, one could say that the distribution of the future changes does not depend on past realizations.
- A process X is said to be non-decreasing, if $Y_t \geq 0$ almost surely (a.s.) for $t \geq 0$, and $Y_t \geq Y_s$ a.s. for $0 \leq s \leq t$. Usually, a non-decreasing process is called a *subordinator*. A process X is said to be non-increasing if $Y_t \leq 0$ a.s. for $t \geq 0$, and $Y_t \leq Y_s$ a.s. for $0 \leq s \leq t$.
- We say that a process X has finite (infinite) variation if its sample paths are of finite (infinite) variation, that is, the variation

$$V(X(\omega))_t = \lim_{n \rightarrow \infty} \sum_{k=1}^n |X_{tk/n}(\omega) - X_{t(k-1)/n}(\omega)|, \quad \forall t > 0$$

is finite (infinite) for almost every $\omega \in \Omega$.

- The characteristic function of the stochastic process $X = (X_t)_{t \geq 0}$ on \mathbb{R} is defined as the

function $\phi : \mathbb{R} \rightarrow \mathbb{C}$

$$\phi_{X_t}(u) = E[e^{iuX_t}]$$

POISSON PROCESS

Consider a process $N = (N_t)_{t \geq 0}$ derived by a Poisson distribution with parameter λ as follows:

1. $N_0 = 0$
2. N has independent increments and stationary increments.
3. For any real numbers $t \geq 0$ and $h \geq 0$, the variable $(N_{t+h} - N_t)$ is a Poisson distributed random variable with parameter λh , that is,

$$\mathbb{P}(N_{t+h} - N_t = n) = e^{-\lambda h} \frac{(\lambda h)^n}{n!}, \quad n = 0, 1, 2, \dots$$

The process N is referred to as the *Poisson process* with intensity λ .

If $(\tau_j)_{j \in \mathbb{N}}$ are independent exponential random variables with parameter λ and the random variable N_t is given by

$$N_t = \inf \left\{ n \geq 1 : \sum_{j=1}^n \tau_j > t \right\}$$

then it can be proven that the process $(N_t)_{t \geq 0}$ is the Poisson process with intensity λ .

The Poisson process is a fundamental example of a stochastic process with discontinuous trajectories, and a building block for constructing more complex jump processes.

Compounded Poisson Process

The process $X = (X_t)_{t \geq 0}$ is referred to as a compounded Poisson process if X is defined by

$$X_t = \sum_{k=1}^{N_t} Y_k$$

where

- Y_1, Y_2, \dots are independent and identically distributed (IID) random variables, and f is the probability density function of Y_1 .
- $(N_t)_{t \geq 0}$ is a Poisson process with intensity λ .
- N_t and Y_k are independent for all $t \geq 0$ and $k = 1, 2, \dots$.

The characteristic function of X_t is equal to

$$\phi_{X_t}(u) = \exp \left(\lambda t \int_{-\infty}^{\infty} (e^{iux} - 1) f(x) dx \right)$$

Moreover, if f is given by the probability density function of the normal distribution, then X is referred to as a jump diffusion process.

PURE JUMP PROCESS

Consider a process $X^x = (X_t^x)_{t \geq 0}$ for a given real number x such that

$$X_t^x = x N_t^{\lambda(x)}$$

where $(N_t^{\lambda(x)})_{t \geq 0}$ is the Poisson process with intensity $\lambda(x)$. The number x represents the jump size and the intensity $\lambda(x)$ is the expected number of jumps with size x in the unit time.

Let $S = \{x_j \in \mathbb{R} : x_j \neq 0, j = 1, 2, \dots\}$ be a discrete subset of jump sizes, $\lambda(x_j) > 0$ for all $x_j \in S$, and $Y = (Y_t)_{t \geq 0}$ be a process defined by

$$Y_t = \gamma t + \sum_{j=1}^{\infty} X_t^{x_j}$$

If S consists of positive real numbers and $\gamma > 0$, then the process Y is non-decreasing. Conversely, if S consists of negative real numbers and $\gamma < 0$, Y is non-increasing.

Since the characteristic function of X_t^x is equal to

$$\phi_{X_t^x}(u) = \exp(\lambda(x)t(e^{-iux} - 1))$$

the characteristic function of Y_t is obtained by

$$\phi_{Y_t} = \exp \left(i\gamma ut + t \sum_{j=1}^{\infty} \lambda(x_j)(e^{iux_j} - 1) \right)$$

For the process Y , the function ν defined by $\nu(A) = \sum_{x_j \in A} \lambda(x_j)$ represents the expected number of jumps with size $x \in A$ in the unit time interval, where A is a subset of S . For example, the expected number of jumps whose sizes are in $\{x_1, x_2, \dots, x_n\}$ is equal to $\nu(\{x_1, x_2, \dots, x_n\}) = \sum_{j=1}^n \lambda(x_j)$.

Now, we extend the set of jump size S to the real number set \mathbb{R} . Then the expected number of jumps is defined by a map ν from a subset of \mathbb{R} to a positive number. The map ν is a jump

measure, that is, the expected number of jumps whose sizes are in a real interval $[a, b]$ is represented by $\nu([a, b])$. Using ν , we can obtain an extended process Y such that the characteristic function of Y_t is given by

$$\phi_{Y_t} = \exp\left(i\gamma ut + t \int_{-\infty}^{\infty} (e^{iux} - 1)\nu(dx)\right) \quad (1)$$

where $\gamma \in \mathbb{R}$. Jump sizes of process Y can be defined continuously. In this case, the measure ν is referred to as a Lévy measure, that is, a Borel measure on \mathbb{R} satisfying $\nu(0) = 0$ and

$$\int_{-\infty}^{\infty} \min\{1, x^2\}\nu(dx) < \infty$$

The class of jump processes satisfying (1) cannot contain infinite variation processes. To include infinite variation processes in the class of jump processes we will be using, we need a more general definition. Consider a process $Z = (Z_t)_{t \geq 0}$ such that the characteristic function of Z_t is given by

$$\phi_{Z_t} = \exp\left(i\gamma ut + t \int_{-\infty}^{\infty} (e^{iux} - 1 - iux1_{|x| \leq 1})\nu(dx)\right) \quad (2)$$

The process Z is referred to as the pure jump process. If

$$\int_{-1}^1 |x|\nu(dx) = \infty$$

then the characteristic function (1) is not defined, but the function (2) is well defined. The details can be found in Sato (1999) and Cont and Tankov (2004). The path behavior of the pure jump process is determined by the Lévy measure ν and real number γ .

- $\gamma > 0$ and $\nu(A) = 0$ for all $A \subset (-\infty, 0)$, then Z is non-decreasing.
- $\gamma < 0$ and $\nu(A) = 0$ for all $A \subset (0, \infty)$, then Z is non-increasing.
- If $\nu(\mathbb{R}) < \infty$ (i.e., the expected number of jumps on the unit time is finite), then we say that Z has a finite activity.
- If $\nu(\mathbb{R}) = \infty$ (i.e., the expected number of jumps on the unit time is infinite), then we say that Z has an infinite activity.

- If $\int_{-1}^1 |x|\nu(dx) < \infty$, the process Z has finite variation.
- If $\int_{-1}^1 |x|\nu(dx) = \infty$, the process Z has infinite variation.

The building block of the pure jump process Z is the Poisson process. Hence, Z has the following properties:

- $Z_0 = 0$.
- Z has independent and stationary increments; that is, the random variable $(Z_t - Z_s)$ is independent of the random variable $(Z_v - Z_u)$ for all real number s, t, u , and v with $0 \leq s < t < u < v$.
- $Z_{s+t} - Z_s \stackrel{d}{=} Z_t$ for $s \geq 0$ and $t > 0$. Moreover, we have

$$\log \phi_{z_t}(u) = t \log \phi_{z_1}(u) \quad (3)$$

where $\phi_{z_t}(u)$ is the characteristic function of Z_t for $t > 0$.

If $t = 1$, then we obtain the purely non-Gaussian infinitely divisible random variable. In fact, there is a one-to-one correspondence between a purely non-Gaussian infinitely divisible random variable and a pure jump process.

Gamma Process

Consider the gamma distribution with parameter (c, λ) . Since the gamma distribution is a purely non-Gaussian infinitely divisible distribution, we can define a pure jump process $G = (G_t)_{t \geq 0}$ such that $G_1 \sim \text{Gamma}(c, \lambda)$. By equation (3), the characteristic function ϕ_{G_t} of G_t is given by

$$\phi_{G_t} = \left(\frac{\lambda}{\lambda - iu}\right)^{ct} \quad (4)$$

In this case, the process G is referred to as the *gamma process* with parameter (λ, c) . The sample path of the gamma process is non-decreasing, since the gamma distribution is supported only on the positive real line. When we take $c = 1$ of the gamma process, the process is referred to as an *exponential process*.

Inverse Gaussian Process

Consider the inverse Gaussian distribution with parameter (c, λ) . Since the inverse Gaussian distribution is also a purely non-Gaussian infinitely divisible distribution, we can define a pure jump process $X = (X_t)_{t \geq 0}$ such that $X_1 \sim IG(c, \lambda)$. By equation (3), the characteristic function ϕ_{X_t} of X_t is given by

$$\phi_{X_t} = \exp\left(-ct(\sqrt{\lambda^2 - 2iu} - \lambda)\right) \tag{5}$$

In this case, the process X is referred to as the *inverse Gaussian (IG) process* with parameter (c, λ) . The sample path of the gamma process is nondecreasing, since the inverse Gaussian distribution is supported only on the positive real line.

Variance Gamma Process

The variance gamma process is an infinitely divisible distribution. Thus we can define pure jump processes $X = (X_t)_{t \geq 0}$ such that $X_1 \sim VG(C, \lambda_+, \lambda_-)$. By equation (3), the characteristic function ϕ_{X_t} of X_t is given by

$$\phi_{X_t} = \left(\frac{\lambda_+ \lambda_-}{(\lambda_+ - iu)(\lambda_- + iu)}\right)^{Ct} \tag{6}$$

In this case, the process X is referred to as the *variance gamma (VG) process* with parameter $(C, \lambda_+, \lambda_-)$.

α -Stable Process

The pure jump process $X = (X_t)_{t \geq 0}$ is referred to as the *α -stable process* with parameters $(\alpha, \sigma, \beta, \mu)$ if X_1 is an α -stable random variable, that is, $X_1 \sim S_\alpha(\sigma, \beta, \mu)$. By equation (3), the characteristic function ϕ_{X_t} of X_t is given by

$$\phi_{X_t}(u) = \begin{cases} \left(\exp(i\mu ut - t|\sigma u|^\alpha \times \left(1 - i\beta(\text{sign } u) \tan \frac{\pi\alpha}{2}\right))\right), & \alpha \neq 1 \\ \left(\exp(i\mu ut - t\sigma|u| \times \left(1 + i\beta \frac{2}{\pi}(\text{sign } u) \ln|u|\right))\right), & \alpha = 1 \end{cases}$$

Recall the Lévy measure of the α -stable process can be written as

$$\nu(dx) = \left(\frac{C_+}{x^{1+\alpha}} 1_{x>0} + \frac{C_-}{|x|^{1+\alpha}} 1_{x<0}\right) dx$$

where C_+ and C_- are positive constants. Then we can prove that

$$\nu(\mathbb{R}) = \int_{-\infty}^{\infty} \nu(dx) = \infty$$

and hence the α -stable process is an infinite activity process. On the other hand, since we have

$$\int_{-1}^1 |x| \nu(dx) = \begin{cases} \frac{C_+ + C_-}{1-\alpha}, & \alpha < 1 \\ \infty, & \alpha \geq 1 \end{cases}$$

we conclude that the α -stable process has finite variation if $\alpha < 1$ and the infinite variation if $\alpha \geq 1$.

Tempered Stable Process

The pure jump process $X = (X_t)_{t \geq 0}$ is referred to as the *tempered stable process* if X_1 is the tempered stable random variable.

- The process X is referred to as the classical tempered stable (CTS) process with parameters $(\alpha, C, \lambda_+, \lambda_-, m)$ if $X_1 \sim \text{CTS}(\alpha, C, \lambda_+, \lambda_-, m)$. The process X is referred to as the *standard CTS process* with parameters $(\alpha, \lambda_+, \lambda_-)$ if $X_1 \sim \text{stdCTS}(\alpha, \lambda_+, \lambda_-)$.
- The process X is referred to as the *generalized tempered stable (GTS) process* with parameters $(\alpha_+, \alpha_-, C_+, C_-, \lambda_+, \lambda_-, m)$ if $X_1 \sim \text{GTS}(\alpha_+, \alpha_-, C_+, C_-, \lambda_+, \lambda_-, m)$. The process X is referred to as the *standard GTS process* with parameters $(\alpha_+, \alpha_-, \lambda_+, \lambda_-, p)$ if $X_1 \sim \text{stdGTS}(\alpha_+, \alpha_-, \lambda_+, \lambda_-, p)$.
- The process X is referred to as the *modified tempered stable (MTS) process* with parameters $(\alpha, C, \lambda_+, \lambda_-, m)$ if $X_1 \sim \text{MTS}(\alpha, C, \lambda_+, \lambda_-, m)$. The process X is referred to as the *standard MTS process* with parameters $(\alpha, \lambda_+, \lambda_-)$ if $X_1 \sim \text{stdMTS}(\alpha, \lambda_+, \lambda_-)$.
- The process X is referred to as the *normal tempered stable (NTS) process* with parameters $(\alpha, C, \lambda, \beta, m)$ if $X_1 \sim \text{NTS}(\alpha, C, \lambda, \beta, m)$. The process X is referred to as the *standard*

NTS process with parameters (α, λ, β) if $X_1 \sim \text{stdNTS}(\alpha, \lambda, \beta)$.

- Moreover, the process X is referred to as the *normal inverse Gaussian (NIG) process* with parameters (c, λ, β, m) if $X_1 \sim \text{NIG}(c, \lambda, \beta, m)$. The process X is referred to as the *standard NIG process* with parameters (λ, β) if $X_1 \sim \text{stdNIG}(\lambda, \beta)$.
- The process X is referred to as the *Kim-Rachev tempered stable (KRTS) process* with parameters $(\alpha, k_+, k_-, r_+, r_-, p_+, p_-, m)$ if $X_1 \sim \text{KRTS}(\alpha, k_+, k_-, r_+, r_-, p_+, p_-, m)$. The process X is referred to as the *standard KRTS process* with parameters $(\alpha, r_+, r_-, p_+, p_-)$ if $X_1 \sim \text{stdKRTS}(\alpha, r_+, r_-, p_+, p_-)$.
- The process X is referred to as the *rapidly decreasing tempered stable (RDTS) process* with parameters $(\alpha, C, \lambda_+, \lambda_-, m)$ if $X_1 \sim \text{RDTS}(\alpha, C,$

$\lambda_+, \lambda_-, m)$. The process X is referred to as the *standard RDTS process* with parameters $(\alpha, \lambda_+, \lambda_-)$ if $X_1 \sim \text{stdRDTS}(\alpha, \lambda_+, \lambda_-)$.

The characteristic function ϕ_{X_t} of X_t is obtained by equation (3). For example, if X is the CTS process with parameters $(\alpha, C, \lambda_+, \lambda_-, m)$, then

$$\begin{aligned} \phi_{X_t}(u) &= \exp(t \log(\phi_{\text{CTS}}(u; \alpha, C, \lambda_+, \lambda_-, m))) \\ &= \exp(iumt - iutC\Gamma(1 - \alpha)(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1}) \\ &\quad + tC\Gamma(-\alpha)((\lambda_+ - iu)^\alpha - \lambda_+^\alpha \\ &\quad + (\lambda_- + iu)^\alpha - \lambda_-^\alpha)) \end{aligned}$$

Characteristic exponents of tempered stable processes are presented in Table 1.

Let $\nu(dx)$ be the Lévy measure of the tempered stable process. Then we can prove that $\nu(\mathbb{R}) = \infty$, $\int_{-1}^1 |x|\nu(dx) < \infty$ if $\alpha < 1$, and $\int_{-1}^1 |x|\nu(dx) = \infty$ if $\alpha \geq 1$. Consequently, the

Table 1 Characteristic Exponents of Tempered Stable Processes

Process	$\psi_{X_t}(u) = \log \phi_{X_t}(u)$
CTS	$iumt - iutC\Gamma(1 - \alpha)(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1}) + tC\Gamma(-\alpha)((\lambda_+ - iu)^\alpha - \lambda_+^\alpha + (\lambda_- + iu)^\alpha - \lambda_-^\alpha)$
GTS	$iumt - iut\Gamma(1 - \alpha)(C_+\lambda_+^{\alpha-1} - C_-\lambda_-^{\alpha-1}) + tC_+\Gamma(-\alpha_+)((\lambda_+ - iu)^{\alpha_+} - \lambda_+^{\alpha_+}) + tC_-\Gamma(-\alpha_-)((\lambda_- + iu)^{\alpha_-} - \lambda_-^{\alpha_-})$
MTS	$iumt + tC(G_R(u; \alpha, \lambda_+) + G_R(u; \alpha, \lambda_-)) + iutC(G_I(u; \alpha, \lambda_+) - G_I(u; \alpha, \lambda_-))$ where $G_R(x; \alpha, \lambda) = 2^{-\frac{\alpha+3}{2}} \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) ((\lambda^2 + x^2)^{\frac{\alpha}{2}} - \lambda^\alpha)$ and $G_I(x; \alpha, \lambda) = 2^{-\frac{\alpha+1}{2}} \Gamma\left(\frac{1-\alpha}{2}\right) \lambda^{\alpha-1} \left[{}_2F_1\left(1, \frac{1-\alpha}{2}; \frac{3}{2}; -\frac{x^2}{\lambda^2}\right) - 1 \right]$
NTS	$iumt - iut2^{-\frac{\alpha-1}{2}} C \sqrt{\pi} \Gamma\left(1 - \frac{\alpha}{2}\right) \beta (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-1} + t2^{-\frac{\alpha+1}{2}} C \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) ((\lambda^2 - (\beta + iu)^2)^{\frac{\alpha}{2}} - (\lambda^2 - \beta^2)^{\frac{\alpha}{2}})$
NIG	$iumt - \frac{iutc\beta}{\sqrt{\lambda^2 - \beta^2}} - tc \left(\sqrt{\lambda^2 - (\beta + iu)^2} - \sqrt{\lambda^2 - \beta^2} \right)$
KRTS	$iumt - iut\Gamma(1 - \alpha) \left(\frac{k_+r_+}{p_+ + 1} - \frac{k_-r_-}{p_- + 1} \right) + tk_+H(iu; \alpha, r_+, p_+) + tk_-H(-iu; \alpha, r_-, p_-)$ where $H(x; \alpha, r, p) = \frac{\Gamma(-\alpha)}{p} ({}_2F_1(p, -\alpha; 1 + p; rx) - 1)$
RDTS	$iumt + tC(G(iu; \alpha, \lambda_+) + G(-iu; \alpha, \lambda_-))$ where $G(x; \alpha, \lambda) = 2^{-\frac{\alpha}{2}-1} \lambda^\alpha \Gamma\left(-\frac{\alpha}{2}\right) \left(M\left(-\frac{\alpha}{2}, \frac{1}{2}; \frac{x^2}{2\lambda^2}\right) - 1 \right) + 2^{-\frac{\alpha}{2}-\frac{1}{2}} \lambda^{\alpha-1} x \Gamma\left(\frac{1-\alpha}{2}\right) \left(M\left(\frac{1-\alpha}{2}, \frac{3}{2}; \frac{x^2}{2\lambda^2}\right) - 1 \right)$

tempered stable process has infinite activity, and has finite variation if $\alpha < 1$ and infinite variation if $\alpha \geq 1$, as explained in Carr et al. (2002), Kim (2005), and Kim et al. (2008 and 2010).

BROWNIAN MOTION

In this section, we will discuss *Brownian motion* by means of an example. We begin with a short summary of the most important and defining properties of a standard Brownian motion $W = (W_t)_{t \geq 0}$

1. $W_0 = 0$
2. W has independent increments and stationary increments.
3. For any real numbers $t \geq 0$ and $h \geq 0$, the variable $(W_{t+h} - W_t)$ is a normally distributed random variable with mean zero and variance h .
4. The paths of $W = (W_t)_{t \geq 0}$ are continuous.

Every process fulfilling the above four properties is referred to as the standard Brownian motion. From the second and third conditions it can be deduced that Brownian motion W_t at time t (which equals the increment from time 0 to time t) is normally distributed with mean zero and variance t .

The paths of Brownian motion are highly irregular and nowhere differentiable. In order to draw a true path, one would have to calculate the value of the process for every real number, which is clearly not feasible. Due to its characteristic path property, it is impossible to draw a real path of Brownian motion. The process can only be evaluated for a discrete set of points. Figure 1 illustrates possible paths of Brownian motion. Strictly speaking, the plotted paths are only discrete approximations to the true paths.

From the above definition of the process, it may not be clear how one can envision a Brownian motion or how one could construct it. Therefore, we will present a constructive method demonstrating how one can generate a Brownian motion as the limit of very simple processes. We restrict the presentation to

the unit interval (i.e., we assume $0 \leq t \leq 1$) but the generalization to the abstract case should be obvious. The procedure is iterative, which means that on the k th step of the iteration we define a process $(X_t^{(k)})_{0 \leq t \leq 1}$, which will serve as an approximation for a standard Brownian motion.

Let random variables I_1, I_2, I_3, \dots be IID with

$$I_j = \begin{cases} 1 & \text{with probability } p = 0.5 \\ -1 & \text{with probability } 1 - p = 0.5 \end{cases}, \\ j = 1, 2, \dots$$

Define $X_t^{(k)} = \frac{1}{\sqrt{k}} \sum_{j=1}^n I_j$ where $t = n/k$ and $n = 0, 1, \dots, k$. If the value t is on the interval $(\frac{n}{k}, \frac{n+1}{k})$, then we take a value obtained by a linear interpolation as

$$X_t^{(k)} = (kt - n)X_{n/k}^{(k)} + (kt - n - 1)X_{(n+1)/k}^{(k)}$$

By doing so, we get a stochastic process with continuous paths.

Let's start with $k = 1$. Then we have

$$X_0^{(1)} = 0, \\ X_1^{(1)} = \begin{cases} 1 & \text{with probability } p = 0.5 \\ -1 & \text{with probability } 1 - p = 0.5 \end{cases}$$

At any time t the random variable $X_1^{(1)}$ can take only two possible values, namely $-t$ and t . At any time, the process has zero mean and the variance at time $t = 1$ equals

$$V(X_1^{(1)}) = 1^2 \cdot 0.5 + (-1)^2 \cdot 0.5 = 1$$

That is not so bad for the first step, but obviously the distribution of $X_1^{(1)}$ is far from being normal.

What we do in the next step, $k = 2$, is allow for two different values until time $t = \frac{1}{2}$ and three different values for $\frac{1}{2} \leq t \leq 1$. We do so by defining:

$$X_0^{(2)} = 0, \\ X_{0.5}^{(2)} = \begin{cases} \frac{1}{\sqrt{2}} & \text{with probability } p = 0.5 \\ -\frac{1}{\sqrt{2}} & \text{with probability } 1 - p = 0.5 \end{cases} \\ X_1^{(2)} = \begin{cases} \sqrt{2} & \text{with probability } p^2 = 0.25 \\ 0 & \text{with probability } p(1 - p) = 0.5 \\ -\sqrt{2} & \text{with probability } (1 - p)^2 = 0.25 \end{cases}$$

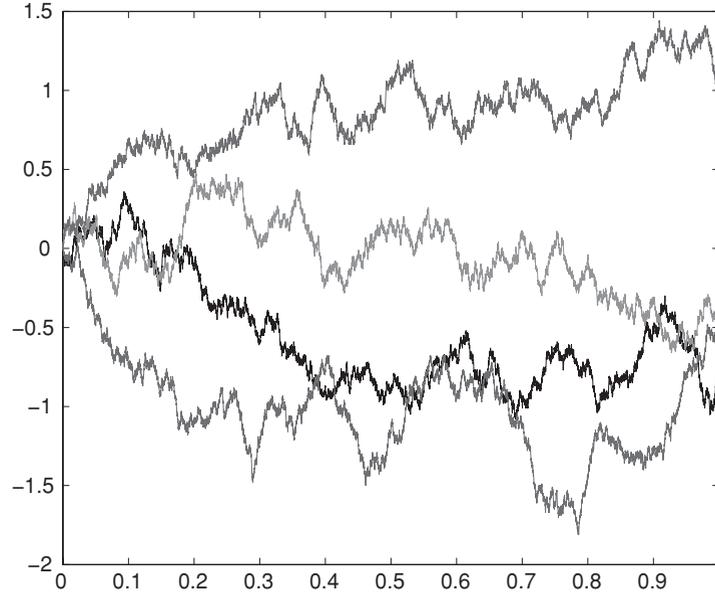

Figure 1 Possible Paths of a Standard Brownian Motion (Every Path Consists of 10,000 Equally Spaced Observations)

The process $X_t^{(2)}$ now has four possible paths. The mean of $X_t^{(2)}$ is zero and the variance of $X_t^{(2)}$ equals

$$V\left(X_{0.5}^{(2)}\right) = \left(\frac{1}{\sqrt{2}}\right)^2 \cdot 0.5 + \left(-\frac{1}{\sqrt{2}}\right)^2 \cdot 0.5 = 0.5$$

$$V\left(X_1^{(2)}\right) = \sqrt{2}^2 \cdot 0.25 + (-\sqrt{2})^2 \cdot 0.25 = 1$$

but still the distribution of $X_t^{(2)}$ is far from being normal.

By iterating the stated procedure, the probability of $X_t^{(k)}$ is given by

$$\mathbf{P}\left(X_t^{(k)} = \frac{n-2m}{\sqrt{k}}\right) = \binom{n}{m} \left(\frac{1}{2}\right)^n$$

if $m \in \{0, 1, 2, \dots, n\}$, $t = n/k$, $n \in \{0, 1, 2, \dots, k\}$. The mean and variance can be obtained as follows:

$$E\left[X_t^{(k)}\right] = \frac{1}{\sqrt{k}} \sum_{j=1}^n E[I_j] = 0$$

$$V\left(X_t^{(k)}\right) = \frac{1}{k} \sum_{j=1}^n E[I_j^2] = \frac{n}{k}$$

where $t = n/k$, $n = 1, 2, \dots, k$. Since $X_{n/k}^{(k)}$ is defined by the sum of IID random variables, it has

- *Independent increments:* $X_{n_1/k}^{(k)}$ and $X_{n_2/k}^{(k)} - X_{n_1/k}^{(k)}$ are independent, for all $n_1, n_2 \in \{0, 1, \dots, k\}$ with $n_1 < n_2$.
- *Stationary increments:* $X_{n_2/k}^{(k)} - X_{n_1/k}^{(k)} \stackrel{d}{=} X_{(n_2-n_1)/k}^{(k)}$ for all $n_1, n_2 \in \{0, 1, \dots, k\}$ with $n_1 < n_2$.

Moreover, the distribution of $X_t^{(k)}$ will approach the normal distribution due to the central limit theorem. Consequently, we have found all the defining properties of a Brownian motion in this simple approximating process, that is, the process $(X_t^{(k)})_{0 \leq t \leq 1}$ converges in distribution to the standard Brownian motion $(W_t)_{0 \leq t \leq 1}$.

In the context of financial applications, there are two main variants of the standard Brownian motion which have to be mentioned: the arithmetic and the geometric Brownian motion. Both are obtained as a function of the standard Brownian motion.

Arithmetic Brownian Motion

Given a Brownian motion $(W_t)_{t \geq 0}$ and two real constants μ and σ , the arithmetic Brownian motion $(X_t)_{t \geq 0}$ is obtained as:

$$X_t = \mu t + \sigma W_t$$

The process $(X_t)_{t \geq 0}$ consists of the sum of a purely deterministic linear trend function μt and a rescaled Brownian motion σW_t . The latter has the property that at time t , σW_t is normally distributed with mean 0 and variance $\sigma^2 t$. The paths will therefore randomly jitter around the deterministic trend with a variance proportional to the point in time t under consideration. The arithmetic Brownian motion is a simple but popular model for financial asset returns.

Geometric Brownian Motion

Given a Brownian motion $(W_t)_{t \geq 0}$, two real constants μ and σ , and a starting value $S_0 > 0$, the geometric Brownian motion $(S_t)_{t \geq 0}$ is obtained as:

$$S_t = S_0 e^{\mu t + \sigma W_t}$$

The process $(S_t)_{t \geq 0}$ is just the exponential of an arithmetic Brownian motion multiplied by a factor. Therefore $\log(S_t/S_0)$ is normally distributed and

$$E[S_t/S_0] = e^{\mu t + \frac{1}{2}\sigma^2 t}$$

TIME-CHANGED BROWNIAN MOTION

If a pure jump process $T = (T_t)_{t \geq 0}$ is non-decreasing, that is, $T_t \geq 0$ a.s. for $t > 0$, and $T_t \geq T_s$ a.s. for $s \leq t$, then the process T is referred to as the subordinator or intrinsic time process. Intuitively, it can be thought of as the cumulative trading volume process for a financial asset which measures the cumulative volume of all the transitions up to physical time t (Rachev and Mitnik, 2000).

The Poisson, gamma, and inverse Gaussian processes are non-decreasing, and hence they are subordinators. Moreover, for the case where

$0 < \alpha < 1$, the support of the α -stable distribution $S_\alpha(\alpha, 1, 0)$ is the positive real line. Hence, the α -stable process with parameters $(\frac{\alpha}{2}, \sigma, 1, 0)$ and $0 < \alpha < 2$ is a subordinator and referred to as α -stable subordinator. If we can consider an additional assumption that $E[T_t] = t$, this would mean that the expected intrinsic time is the same as physical time.

If we take an arithmetic Brownian motion and change the physical time to a subordinator, then we obtain the *time-changed Brownian motion*. That is, take an arithmetic Brownian motion with drift μ and volatility σ as follows:

$$\mu t + \sigma W_t$$

and consider a subordinator $T = (T_t)_{t \geq 0}$ independent to the standard Brownian motion $(W_t)_{t \geq 0}$. Then substituting $t = T_t$ in the arithmetic Brownian motion, we have a new process $X = (X_t)_{t \geq 0}$ with

$$X_t = \mu T_t + \sigma W_{T_t}$$

which is the time-changed Brownian motion.

If T_t is fixed, then the conditional probability of X_t with a fixed variable T_t follows a normal distribution, that is

$$\begin{aligned} \mathbf{P}(X_t < y | T_t) &= \mathbf{P}(\mu T_t + \sigma W_{T_t} < y | T_t) \\ &= \frac{1}{\sqrt{2\pi\sigma^2 T_t}} \int_{-\infty}^y e^{-\frac{(x-\mu T_t)^2}{2\sigma^2 T_t}} dx \end{aligned}$$

Using properties of the conditional probability and independence between W_t and T_t , the distribution function F_{X_t} and the probability density function f_{X_t} of X_t are obtained by

$$\begin{aligned} F_{X_t}(y) &= \mathbf{P}(X_t < y) \\ &= \int_{-\infty}^y \int_0^\infty \frac{1}{\sqrt{2\pi\sigma^2 s}} e^{-\frac{(y-\mu s)^2}{2\sigma^2 s}} f_{T_t}(s) ds dx \end{aligned}$$

and

$$f_{X_t}(y) = \frac{d}{dy} F_{X_t}(y) = \int_0^\infty \frac{1}{\sqrt{2\pi\sigma^2 s}} e^{-\frac{(y-\mu s)^2}{2\sigma^2 s}} f_{T_t}(s) ds$$

respectively, where f_{T_t} is the probability density function of T_t . Moreover, we can derive the characteristic function ϕ_{X_t} as follows:

$$\phi_{X_t}(u) = \phi_{T_t} \left(\mu u + \frac{i u^2 \sigma^2}{2} \right) \tag{7}$$

where ϕ_{T_t} is the characteristic function of T_t . Using the time-changed Brownian motion, we can define various processes.

The time-changed Brownian motion construction is well known from the theory of stochastic processes and is referred to as the Skorokhod embedding problem. Theoretically, every Lévy process can be defined as the time-changed Brownian motion. More in general, a process can be embedded in a Brownian motion if and only if it is a local semimartingale, as proved by Monroe (1978).

Although the representation via Brownian subordination is a nice property, we do not know a general constructive method to find the process T_t such that $X_t = \mu T_t + \sigma W_{T_t}$. This means that given a semimartingale X_t , the time process T_t is not always of known form. Thus, this approach can be applied only for some particular Lévy processes.

Variance Gamma Process

By considering the gamma process as the subordinator of the Brownian motion, we obtain the VG process. That is, the VG process is defined by $X = (X_t)_{t \geq 0}$ with

$$X_t = \mu G_t + \sigma W_{G_t}$$

where $G = (G_t)_{t \geq 0}$ is the gamma process with parameter (c, λ) . In order to reduce the number of parameters, we consider the assumption $E[G_t] = t$. Since we have $E[G_t] = \frac{ct}{\lambda}$, the assumption is satisfied if $c = \lambda$. Then the characteristic function of X_t is equal to

$$\phi_{X_t}(u) = \left(\frac{c}{c - i\mu u + \frac{u^2 \sigma^2}{2}} \right)^{ct} = \left(\frac{\frac{2c}{\sigma^2}}{\frac{2c}{\sigma^2} - \frac{2\mu}{\sigma^2} ui + u^2} \right)^{ct} \quad (8)$$

by (7) and the characteristic function of G_t given in (4) with $c = \lambda$. Inserting into (8) the parametrization

$$\begin{aligned} \lambda_- - \lambda_+ &= \frac{2\mu}{\sigma^2} \\ \lambda_+ \lambda_- &= \frac{2c}{\sigma^2} \\ C &= c \end{aligned}$$

we obtain the form given by (6).

Normal Inverse Gaussian Process

By considering the inverse Gaussian process as the subordinator of the Brownian motion, we obtain the NIG process.

Define a process $X = (X_t)_{t \geq 0}$ with

$$X_t = \mu T_t + \sigma W_{T_t}$$

where $T = (T_t)_{t \geq 0}$ is the inverse Gaussian process with parameter (c, λ) , satisfying $E[T_t] = t$. The condition $E[T_t] = t$ holds if $c = \lambda$. Then the characteristic function of X_t is equal to

$$\begin{aligned} \phi_{X_t}(u) &= \exp \left(-kt(\sqrt{k^2 - 2i\mu u + 2\sigma^2 u^2} - k) \right) \\ &= \exp \left(-\sqrt{2}k\sigma t \left(\sqrt{\frac{k^2}{2\sigma^2} - \frac{\mu}{\sigma^2} iu + u^2} - \sqrt{\frac{k^2}{2\sigma^2}} \right) \right) \quad (9) \end{aligned}$$

by (7) and the characteristic function of T_t given in (5) with $k := c = \lambda$. Inserting into (9) the parametrization

$$\begin{aligned} \lambda^2 - \beta^2 &= \frac{k^2}{2\sigma^2} \\ \beta &= \frac{\mu}{2\sigma^2} \\ c &= \sqrt{2}k\sigma \end{aligned}$$

we obtain the NIG process with parameter $(c, \lambda, \beta, \frac{c\beta}{\sqrt{\lambda^2 - \beta^2}})$.

Normal Tempered Stable Process

Assume Lévy measure ν is equal to

$$\nu(dx) = \frac{ce^{-\theta x}}{x^{\alpha/2+1}} 1_{x>0} dx \quad (10)$$

where $\alpha \in (0, 2)$, $c > 0$, and $\theta > 0$, and consider the pure jump process $T = (T_t)_{t \geq 0}$ defined by ν and γ , where

$$\gamma = \int_0^1 x\nu(dx)$$

Since $\nu(A) = 0$ for all $A \subset (-\infty, 0)$ and $\mu \geq 0$, the process T is a nondecreasing process. Hence it is a subordinator and referred to as the tempered stable subordinator with parameters

(α, c, θ) . Using equation (2), the characteristic function ϕ_{T_t} of T_t is equal to

$$\phi_{T_t}(u) = \exp \left(tc \int_0^\infty (e^{iux} - 1) \frac{e^{-\theta x}}{x^{\alpha/2+1}} dx \right)$$

Solving the integration in the last equation, we can obtain the following formula,

$$\phi_{T_t}(u) = \exp \left(tc \Gamma \left(-\frac{\alpha}{2} \right) ((\theta - iu)^{\frac{\alpha}{2}} - \theta^{\frac{\alpha}{2}}) \right) \quad (11)$$

The mean of T_t is computed by the first cumulant, that is,

$$E[T_t] = \frac{1}{i} \frac{\partial}{\partial u} \log \phi_{T_t}(u)|_{u=0} = tc \Gamma \left(1 - \frac{\alpha}{2} \right) \theta^{\frac{\alpha}{2}-1}$$

Hence, the condition $E[T_t] = t$ holds if $c = (\Gamma(1 - \frac{\alpha}{2}) \theta^{\frac{\alpha}{2}-1})^{-1}$.

By considering the tempered stable subordinator as the subordinator of the Brownian motion, we obtain the NTS process. That is, define a process $X = (X_t)_{t \geq 0}$ with

$$X_t = \mu T_t + \sigma W_{T_t}$$

where $T = (T_t)_{t \geq 0}$ is the tempered stable subordinator with parameter $(\alpha, (\Gamma(1 - \frac{\alpha}{2}) \theta^{\frac{\alpha}{2}-1})^{-1}, \theta)$. The characteristic function of X_t is equal to

$$\begin{aligned} \phi_{X_t}(u) &= \exp \left(\frac{t \Gamma(-\frac{\alpha}{2})}{\Gamma(1 - \frac{\alpha}{2}) \theta^{\frac{\alpha}{2}-1}} \left(\left(\theta - i \left(\mu u + \frac{i \sigma^2 u^2}{2} \right) \right)^{\frac{\alpha}{2}} - \theta^{\frac{\alpha}{2}} \right) \right) \\ &= \exp \left(\frac{-2t}{\alpha \theta^{\frac{\alpha}{2}-1}} \left(\left(\theta - i \left(\mu u + \frac{i \sigma^2 u^2}{2} \right) \right)^{\frac{\alpha}{2}} - \theta^{\frac{\alpha}{2}} \right) \right) \quad (12) \end{aligned}$$

by (7) and (11) with $c = (\Gamma(1 - \frac{\alpha}{2}) \theta^{\frac{\alpha}{2}-1})^{-1}$. The last equation can be changed to the following expression:

$$\begin{aligned} \phi_{X_t}(u) &= \exp \left(\frac{t \Gamma(-\frac{\alpha}{2}) \left(\frac{\sigma^2}{2} \right)^{\frac{\alpha}{2}}}{\Gamma(1 - \frac{\alpha}{2}) \theta^{\frac{\alpha}{2}-1}} \left(\left(\frac{2\theta}{\sigma^2} + \left(\frac{\mu}{\sigma^2} \right)^2 \right. \right. \right. \\ &\quad \left. \left. \left. - \left(\frac{\mu}{\sigma^2} + iu \right)^2 \right)^{\frac{\alpha}{2}} - \left(\frac{2\theta}{\sigma^2} \right)^{\frac{\alpha}{2}} \right) \right) \quad (13) \end{aligned}$$

Inserting into (13) the parametrization

$$\begin{aligned} \lambda &= \sqrt{\frac{2\theta}{\sigma^2} + \left(\frac{\mu}{\sigma^2} \right)^2} \\ \beta &= \frac{\mu}{\sigma^2} \\ C &= \frac{\sqrt{2\sigma^\alpha}}{\sqrt{\pi} \Gamma \left(1 - \frac{\alpha}{2} \right) \theta^{\frac{\alpha}{2}-1}} \end{aligned}$$

we obtain the NTS process with parameter $(\alpha, C, \lambda, \beta, m)$ where

$$m = -2^{-\frac{\alpha+1}{2}} C \sqrt{\pi} \Gamma \left(\frac{\alpha}{2} \right) \beta (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-1}$$

LÉVY PROCESS

A stochastic process $X = (X_t)_{t \geq 0}$ is called a *Lévy process* if the following five conditions are satisfied :

1. $X_0 = 0$ a.s.
2. X has independent increments.
3. X has stationary increment.
4. X is stochastically continuous that is, $\forall t \geq 0$ and $a > 0$,

$$\lim_{s \rightarrow t} \mathbf{P}[|X_s - X_t| > a] = 0$$

5. X is right continuous and has left limits (cadlag).

The standard Brownian motion, arithmetic Brownian motions, and pure jump processes are all Lévy processes. Moreover, a Lévy process can be decomposed by a Brownian motion and a pure jump process $(Z_t)_{t \geq 0}$ independent to the Brownian motion, that is

$$X_t = \sigma W_t + Z_t$$

Hence we obtain the characteristic function of X_t as follows:

$$\begin{aligned} \phi_{X_t}(u) &= \phi_{\sigma W_t}(u) \phi_{Z_t}(u) \\ &= \exp \left(-\frac{t}{2} \sigma^2 u^2 \right) \exp \left(i \gamma u t + t \int_{-\infty}^\infty (e^{iux} - 1 - iux \mathbf{1}_{|x| \leq 1}) \nu(dx) \right) \\ &= \exp \left(i \gamma u t - \frac{t}{2} \sigma^2 u^2 + t \int_{-\infty}^\infty (e^{iux} - 1 - iux \mathbf{1}_{|x| \leq 1}) \nu(dx) \right) \end{aligned}$$

where $\phi_{\sigma W_t}(u)$ is the characteristic function of $N(0, \sigma^2 t)$, and $\phi_{Z_t}(u)$ given by (2). Therefore,

if $X = (X_t)_{t \geq 0}$ is a Lévy process, then for any $t \geq 0$, X_t is an infinitely divisible random variable. Conversely, if Y is an infinitely divisible random variable, then there exists uniquely a Lévy process $(X_t)_{t \geq 0}$ such that $X_1 = Y$, as proved by Sato (1999, p. 38).

KEY POINTS

- Continuous-time stochastic processes are the building block of financial modeling and they are usually used to explain the uncertain behavior of financial assets. Some results of probability theory can be usefully applied to financial derivatives pricing and risk management.
- Given any infinitely divisible random variable X_1 , it is possible to define a stochastic process with independent and stationary increments such that for all $t > s$, the increment $X_t - X_s$ has characteristic function $\exp((t - s) \log \phi_{X_1}(u))$. These processes are known as Lévy processes.
- Brownian motion and Poisson processes are Lévy processes. All Lévy processes can be constructed by changing the deterministic time t of the Brownian motion W_t with a stochastic time T_t . This construction is called Brownian subordination and the increasing process T_t is a subordinator.
- There are two main variants of the standard Brownian motion used in financial applications: the arithmetic and the geometric Brownian motion.
- The Poisson process is a fundamental example of a stochastic process with discontinuous trajectories, and a building block for constructing more complex jump processes.
- Pure jump processes include also the gamma process, the inverse Gaussian process, the variance gamma process, the α -stable process, and the tempered stable process.

Abstract: The current price of an option is obtained by the conditional expectation of the payoff function under the risk-neutral measure. The risk-neutral measure is the measure equivalent to the real market measure under which the discounted price process of the underlying stock becomes a martingale. In the Black-Scholes model, the risk-neutral measure can be obtained by the Girsanov theorem. The Esscher transform has been used to find the risk-neutral measure for the continuous Lévy process models. The general theory of the Esscher transform is applied to find the risk-neutral measure under tempered stable Lévy process models.

In this entry, we present some issues in stochastic processes. We begin by defining events of a probability space mathematically, and then discuss the concept of conditional expectation. We then explain two important notions for stochastic processes: martingale properties and Markov properties. The former relates to the fair price in a market and

the latter describes the efficiency of a market. Finally, “change of measures” for processes are discussed. Change of measures for tempered stable processes are important for determining no-arbitrage pricing for assets. Further details about no-arbitrage pricing with the change of measure is discussed in Rachev et al. (2011).

Dr. Bianchi acknowledges that the views expressed in this entry are his own and do not necessarily reflect those of the Bank of Italy.

EVENTS, σ -FIELDS, AND FILTRATION

A set of possible outcomes in a given sample space Ω is called an event. An event is mathematically defined as a subset of Ω . If we have one event A , then the set of outcomes that are not included in A is also an event. For example, if we consider an event that the return of the stock of Disney tomorrow will be positive, then the set of outcomes that Disney's return tomorrow will be negative is also an event. Moreover, if we have two events A and B , then a set of outcomes included in both A and B is also an event. For instance, consider two events, the first event being that Disney's stock return tomorrow will be positive, and the other event that IBM's stock return tomorrow will be positive. Then a set of outcomes that both stock returns will be positive tomorrow is an event.

The class of events is described mathematically by the σ -field. The σ -field, denoted by \mathcal{F} , is the class of the subsets of Ω that satisfy the following properties:

Property 1. $\emptyset \in \mathcal{F}$ and $\Omega \in \mathcal{F}$.

Property 2. If $A \in \mathcal{F}$, then $A^c = \{x \in \Omega \mid x \notin A\} \in \mathcal{F}$.

Property 3. If $A_1, A_2, A_3, \dots \in \mathcal{F}$, then $\bigcup_{n=1}^{\infty} A_n \in \mathcal{F}$.

Let \mathcal{G} denote a class of subsets contained in Ω . Then the smallest σ -field containing \mathcal{G} is referred to as the σ -field generated by \mathcal{G} , and is denoted by $\sigma(\mathcal{G})$. For a given random variable X , consider the class $\mathcal{G} = \{A \subseteq \Omega : A = X^{-1}(I), \text{ for all open interval } I \text{ in } \mathbb{R}\}$, where X^{-1} is the inverse image of X . Then the σ -field generated by \mathcal{G} is referred to as the σ -field generated by X , and denoted by $\sigma(X)$. If there is a σ -field \mathcal{F} such that $\sigma(X) \subseteq \mathcal{F}$, then we say that X is \mathcal{F} -measurable.

The probability \mathbf{P} is a map from a given σ -field \mathcal{F} to the unit interval $[0, 1]$. If $A \subseteq N \in \mathcal{F}$ and $P(N) = 0$, then the set A is referred to as a null set with respect to $(\Omega, \mathcal{F}, \mathbf{P})$. Let \mathcal{N} be the class of all null sets with respect to $(\Omega, \mathcal{F}, \mathbf{P})$. The space $(\Omega, \tilde{\mathcal{F}}, \tilde{\mathbf{P}})$ is referred to as a comple-

tion of $(\Omega, \mathcal{F}, \mathbf{P})$ if $\tilde{\mathcal{F}} = \sigma(\mathcal{F} \cup \mathcal{N})$ and $\tilde{\mathbf{P}}(A \cup N) = \mathbf{P}(A)$ for all $A \in \mathcal{F}$ and $N \in \mathcal{N}$. All probability spaces in this entry are assumed to be completions of spaces, that is, all null sets are contained in given σ -fields, and probabilities are defined on completed σ -fields.

Let $(\mathcal{F}_t)_{t \geq 0}$ be a sequence of σ -field with continuous index $t \geq 0$ (or discrete index $t = 0, 1, 2, \dots$). If $\mathcal{F}_s \subseteq \mathcal{F}_t$ for all $0 \leq s \leq t$, then $(\mathcal{F}_t)_{t \geq 0}$ is referred to as a filtration. \mathcal{F}_t can be interpreted as the "information" available to all market agents at time t . The filtration describes increasing information for time t .

Consider a stochastic process $X = (X_t)_{t \geq 0}$. If X_t is \mathcal{F}_t -measurable for all $t \geq 0$, then X is referred to as a $(\mathcal{F}_t)_{t \geq 0}$ -adapted process. If X_t is \mathcal{F}_{t-1} -measurable for all discrete index $t = 0, 1, 2, \dots$, then X is referred to as a $(\mathcal{F}_t)_{t \geq 0}$ -predictable process.

For a given process $X = (X_t)_{t \geq 0}$, we can generate a filtration $(\mathcal{F}_t)_{t \geq 0}$ by

$$\mathcal{F}_t = \sigma(X_s; 0 \leq s \leq t)$$

where $\sigma(X_s; 0 \leq s \leq t)$ is the smallest σ -field containing all $\sigma(X_s)$ with $0 \leq s \leq t$. Then the process X is $(\mathcal{F}_t)_{t \geq 0}$ -adapted and this filtration is referred to as a filtration generated by X .

CONDITIONAL EXPECTATION

The *conditional expectation* is a value of the expectation of a random variable under some restricted events. Let g be a Borel function, X be a random variable on a space (Ω, \mathbf{P}) with $E[g(X)] < \infty$, and A be an event. The conditional expectation $E[g(X)|A]$ is defined by

$$E[g(X)|A] = \frac{E[g(X)1_A]}{P(A)}$$

where

$$1_A(\omega) = \begin{cases} 0 & \text{if } \omega \notin A \\ 1 & \text{if } \omega \in A \end{cases}$$

Consider a Borel function g , a stochastic process $X = (X_t)_{t \geq 0}$ adapted to filtration $(\mathcal{F}_t)_{t \geq 0}$. We can define the conditional expectation on \mathcal{F}_t as

a random variable. That is, the conditional expectation $E[g(X_T)|\mathcal{F}_t]$ for $t \leq T$ is a random variable, such that

$$E[g(X_T)|\mathcal{F}_t](\omega) = E[g(X_T)|A_\omega], \quad \omega \in \Omega$$

where A_ω is the smallest event in \mathcal{F}_t with $\omega \in A_\omega$, or $A_\omega = \cap_{\omega \in B_\omega \in \mathcal{F}_t} B_\omega$. Moreover, if g and h are Borel functions, and $0 \leq s \leq t \leq T \leq T^*$, then we have the following properties:

- $E[g(X_t)|\mathcal{F}_0] = E[g(X_t)]$ where $\mathcal{F}_0 = \{\emptyset, \Omega\}$.
- $E[E[g(X_T)|\mathcal{F}_t]|\mathcal{F}_s] = E[g(X_T)|\mathcal{F}_s]$.
- $E[g(X_t)h(X_T)|\mathcal{F}_t] = g(X_t)E[h(X_T)|\mathcal{F}_t]$.
- $E[ag(X_T) + bh(X_{T^*})|\mathcal{F}_t] = aE[g(X_T)|\mathcal{F}_t] + bE[h(X_{T^*})|\mathcal{F}_t]$, for $a, b \in \mathbb{R}$.

We write $E[g(X_T)|X_t]$ instead of $E[g(X_T)|\mathcal{F}_t]$ when $\mathcal{F}_t = \sigma(X_t)$. Hence we have:

- $E[E[g(X_T)|X_t]|X_s] = E[g(X_T)|X_s]$.
- $E[g(X_t)h(X_T)|X_t] = g(X_t)E[h(X_T)|X_t]$.
- $E[ag(X_T) + bh(X_{T^*})|X_t] = aE[g(X_T)|X_t] + bE[h(X_{T^*})|X_t]$, for $a, b \in \mathbb{R}$.

If a (\mathcal{F}_t) -adapted process $X = (X_t)_{t \geq 0}$ satisfies the condition

$$E[g(X_T)|\mathcal{F}_t] = E[g(X_T)|X_t]$$

for all $0 \leq t \leq T$ and Borel function g , then the process X is referred to as a Markov process.

In finance, a Markov process is used to explain the efficient market hypothesis. Suppose X is a price process of an asset, and consider a forward contract on the asset with maturity T . The σ -field \mathcal{F}_t contains all market information until time t . Hence, $F_t = E[X_T|\mathcal{F}_t]$ is the expected price of the forward contract based on the information up to t . If the market is efficient, all information until t is impounded into the current price X_t . Hence, the expected price of the forward contract can be obtained by $F_t = E[X_T|X_t]$.

If a (\mathcal{F}_t) -adapted process $X = (X_t)_{t \geq 0}$ satisfies the condition

$$X_t = E[X_T|\mathcal{F}_t]$$

for all $0 \leq t \leq T$, then the process X is referred to as a martingale process. The process $X = (X_t)_{t \geq 0}$

with $X_t = \sigma W_t$ is a martingale process, where $\sigma > 0$ and $(W_t)_{t \geq 0}$ is the standard Brownian motion. Since X_t is \mathcal{F}_t -measurable, we have

$$\begin{aligned} E[X_T|\mathcal{F}_t] &= E[X_T - X_t + X_t|\mathcal{F}_t] \\ &= E[X_T - X_t|\mathcal{F}_t] + X_t \end{aligned}$$

Since X has stationary and independent increments,

$$\begin{aligned} E[X_T - X_t|\mathcal{F}_t] &= E[X_T - X_t] = E[X_{T-t}] \\ &= E[\sigma W_{T-t}] = 0 \end{aligned}$$

Hence the process X is a martingale.

In finance, a martingale process describes the fair price or no-arbitrage price for an asset. For example, consider one share of a stock and a forward contract that required delivery of one share of that stock to the forward contract holder at the maturity date. Suppose $(S_t)_{t \geq 0}$ is a stock price process and $(F_t)_{0 \leq t \leq T}$ is the price process for the forward contract with maturity T . The forward price at time $t < T$ is given by the conditional expectation of S_T based on the information until time t , that is, $F_t = E[S_T|\mathcal{F}_t]$. Moreover, we can see that $F_t = S_t$ for all t with $0 \leq t \leq T$ by the following argument. Suppose $F_t > S_t$. Then we obtain the difference $F_t - S_t > 0$ at time t by purchasing one share of the stock at price S_t and selling the forward contract at price F_t . We invest the proceeds in a money market account with interest rate r . At time T , by delivering the stock to the holder of the forward contract, we will then have $e^{r(T-t)}(F_t - S_t)$, which is an arbitrage profit. If $F_t > S_t$, then another arbitrage opportunity can be found by selling (i.e., shorting) one share of the stock and purchasing the forward contract. Therefore, to eliminate arbitrage opportunities, F_t should be equal to S_t ; that is, the stock price process should be a martingale.

CHANGE OF MEASURES

In this section, we will present *change of measure* for random variables and Lévy processes. Change of measure is an important method

to determine no-arbitrage prices of assets and derivatives.

Equivalent Probability Measure

Consider two probability measures \mathbf{P} and \mathbf{Q} on a sample space Ω and σ -field \mathcal{F} . If they satisfy the condition

$$\mathbf{Q}(A) = 0 \Rightarrow \mathbf{P}(A) = 0,$$

then we say that \mathbf{P} is absolutely continuous with respect to \mathbf{Q} , and denote $\mathbf{P} \ll \mathbf{Q}$. Moreover, if $\mathbf{P} \ll \mathbf{Q}$ and $\mathbf{Q} \ll \mathbf{P}$, that is,

$$\mathbf{Q}(A) = 0 \Leftrightarrow \mathbf{P}(A) = 0,$$

then we say that \mathbf{P} and \mathbf{Q} are equivalent.

If $\mathbf{Q} \ll \mathbf{P}$, then there exists a positive random variable ξ with $\int_{\Omega} \xi d\mathbf{P} = 1$ and

$$\mathbf{Q}(A) = \int_A \xi d\mathbf{P} \quad (1)$$

for any $A \in \mathcal{F}$. In this case, ξ is referred to as the Radon-Nikodym derivative, and denotes

$$\xi = \frac{d\mathbf{Q}}{d\mathbf{P}}$$

Conversely, if there is a positive random variable ξ with $\int_{\Omega} \xi d\mathbf{P} = 1$ and \mathbf{Q} is defined by equation (1), then \mathbf{Q} is also a probability measure and $\mathbf{Q} \ll \mathbf{P}$.

Let X be a random variable on a probability measure \mathbf{P} , and $f(x) = \frac{\partial}{\partial x} \mathbf{P}(X \leq x)$ be the probability density function (p.d.f.) of X . Suppose \mathbf{Q} is a probability measure and the probability density function of X on \mathbf{Q} is given by $g(x) = \frac{\partial}{\partial x} \mathbf{Q}(X \leq x)$. If \mathbf{P} and \mathbf{Q} are equivalent, then the Radon-Nikodym derivative is equal to

$$\frac{d\mathbf{Q}}{d\mathbf{P}} = \frac{g(X)}{f(X)}$$

For example, $X \sim N(0, 1)$ is normally distributed on \mathbf{P} . If we take the Radon-Nikodym derivative by

$$\xi_1 = \frac{e^{-\frac{(x-\mu)^2}{2\sigma^2}} / \sqrt{2\pi\sigma^2}}{e^{-\frac{x^2}{2}} / \sqrt{2\pi}},$$

then the measure \mathbf{Q}_1 defined by $\mathbf{Q}_1(A) = \int_A \xi_1 d\mathbf{P}$ for $A \in \mathcal{F}$ is equivalent to \mathbf{P} and $X \sim N(\mu, \sigma^2)$ on the measure \mathbf{Q}_1 . On the other hand, if we take the Radon-Nikodym derivative by

$$\xi_2 = \frac{h(X)}{e^{-\frac{x^2}{2}} / \sqrt{2\pi}}$$

where

$$h(x) = \frac{\sigma}{\pi((x-\mu)^2 + \sigma^2)}$$

which is the probability density function of the Cauchy distribution, then the measure \mathbf{Q}_2 , defined by $\mathbf{Q}_2(A) = \int_A \xi_2 d\mathbf{P}$ for $A \in \mathcal{F}$ is equivalent to \mathbf{P} and $X \sim S_1(\sigma, 0, \mu)$ on the measure \mathbf{Q}_2 .

Consider a finite discrete process $(X_t)_{t \in \{1, 2, \dots, T\}}$ of independent and identically distributed (IID) real random variables on both probability measures \mathbf{P} and \mathbf{Q} , where T is a positive integer. By the independent property of the process on \mathbf{P} , we have

$$\begin{aligned} & \mathbf{P}[X_1 \in \mathbb{R}, \dots, X_{t-1} \in \mathbb{R}, X_t < x, \\ & \quad X_{t+1} \in \mathbb{R}, \dots, X_T \in \mathbb{R}] \\ &= \mathbf{P}[X_1 \in \mathbb{R}] \cdots \mathbf{P}[X_{t-1} \in \mathbb{R}] \cdot \mathbf{P}[X_t < x] \\ & \quad \cdot \mathbf{P}[X_{t+1} \in \mathbb{R}] \cdots \mathbf{P}[X_T \in \mathbb{R}] \\ &= \mathbf{P}[X_t < x] \end{aligned}$$

By the same argument, we have

$$\begin{aligned} & \mathbf{Q}[X_1 \in \mathbb{R}, \dots, X_{t-1} \in \mathbb{R}, X_t < x, \\ & \quad X_{t+1} \in \mathbb{R}, \dots, X_T \in \mathbb{R}] = \mathbf{Q}[X_t < x] \end{aligned}$$

Since X_t 's are identically distributed on \mathbf{P} and \mathbf{Q} , respectively, we have $\mathbf{P}[X_t < x] = \mathbf{P}[X_s < x]$ and $\mathbf{Q}[X_t < x] = \mathbf{Q}[X_s < x]$ for all $t, s \in \{1, 2, \dots, T\}$. Suppose that for all $t \in \{1, 2, \dots, T\}$ the probability density functions of X_t are given by $f(x)$ and $g(x)$ on probability measures \mathbf{P} and \mathbf{Q} , respectively. That is

$$f(x) = \frac{\partial}{\partial x} \mathbf{P}[X_t < x]$$

and

$$g(x) = \frac{\partial}{\partial x} \mathbf{Q}[X_t < x]$$

If the domain of the function f is the same as the domain of the function g , then \mathbf{P} and \mathbf{Q} are

equivalent and the Radon-Nikodym derivative is equal to

$$\frac{d\mathbf{Q}}{d\mathbf{P}} = \frac{g(X_1)g(X_2)\cdots g(X_T)}{f(X_1)f(X_2)\cdots f(X_T)}$$

However, that method cannot be used for either continuous-time processes or infinite-discrete processes. In the next section, we discuss the change of measure for continuous-time processes using Girsanov's theorem and the extended Girsanov's theorem.

Change of Measure for Continuous-Time Processes

A continuous-time process is a function from the sample space to the set of appropriate functions. Hence, the change of measure for processes is more complex than the change of measure for a random variable.

Brownian motion is a function from the sample space to the set of continuous functions. For Brownian motion, we can find an equivalent measure using the following theorem, which is referred to as *Girsanov's theorem*.¹

Theorem 1. Let $W = (W_t)_{t \geq 0}$ be a standard Brownian motion under measure \mathbf{P} and $(\mathcal{F}_t)_{t \geq 0}$ be a filtration generated by W . Consider a process $(\xi_t)_{t \geq 0}$ defined by

$$\xi_t = e^{-\theta W_t - \frac{\theta^2}{2}t}$$

Then the probability measure \mathbf{Q} given by

$$\mathbf{Q}(A) |_{\mathcal{F}_t} = \int_A \xi_t d\mathbf{P}, \quad A \in \mathcal{F}_t$$

is equivalent to $\mathbf{P}|_{\mathcal{F}_t}$ for all $t \geq 0$, and the process $\tilde{W} = (\tilde{W}_t)_{t \geq 0}$ with $\tilde{W}_t = \theta t + W_t$ is a standard Brownian motion under the measure \mathbf{Q} .

Girsanov's theorem shows how stochastic processes change under the change of measure. For example, let a process $X = (X_t)_{t \geq 0}$ be an arithmetic Brownian motion under measure \mathbf{P} such that

$$X_t = \mu t + \sigma W_t$$

where $(W_t)_{t \geq 0}$ is the standard Brownian motion. The process X is not martingale on the measure \mathbf{P} , but we can obtain a measure where X is a martingale by Girsanov's theorem. Indeed, we define a measure \mathbf{Q} equivalent to \mathbf{P} such that

$$\mathbf{Q}(A) |_{\mathcal{F}_t} = \int_A e^{-\frac{\mu W_t}{\sigma} - \frac{\mu^2}{2\sigma^2}t} d\mathbf{P}, \quad A \in \mathcal{F}_t$$

Then the process X becomes $X_t = \sigma \tilde{W}_t$ with $\tilde{W}_t = \frac{\mu t}{\sigma} + W_t$ and the process $(\tilde{W}_t)_{t \geq 0}$ is a standard Brownian motion on the measure \mathbf{Q} . Therefore, the process X is a martingale on the measure \mathbf{Q} .

A Lévy process is a function from the sample space to the set of right continuous functions with left limits at any point of the domain.² Girsanov's theorem can be extended for Lévy processes by the following theorem:

Theorem 2. Suppose a process $X = (X_t)_{t \geq 0}$ is a Lévy process with Lévy triplets (σ^2, ν, γ) under measure \mathbf{P} . If there is a real number θ satisfying $\int_{|x| \geq 1} e^{\theta x} \nu(dx) < \infty$, then we can find the equivalent measure \mathbf{Q} whose Radon-Nikodym derivative is given by

$$\frac{d\mathbf{Q}}{d\mathbf{P}} |_{\mathcal{F}_t} = \xi_t = \frac{e^{\theta X_t}}{E_{\mathbf{P}}[e^{\theta X_t}]} = e^{\theta X_t - l(\theta)t}$$

where $l(\theta) = \log E_{\mathbf{P}}[e^{\theta X_1}]$. That is,

$$\mathbf{Q}(A) |_{\mathcal{F}_t} = \int_A \xi_t d\mathbf{P}, \quad A \in \mathcal{F}_t$$

is equivalent to $\mathbf{P}|_{\mathcal{F}_t}$ for all $t \geq 0$. Moreover, the process X is a Lévy process with Lévy triplets $(\sigma^2, \tilde{\nu}, \tilde{\gamma})$ under the measure \mathbf{Q} , where $\tilde{\nu}(dx) = e^{\theta x} \nu(dx)$ and $\tilde{\gamma} = \gamma + \int_{|x| \leq 1} x(e^{\theta x} - 1) \nu(dx)$.

The change of measure using Theorem 2 is referred to as the *Esscher transform*. The most general theorem of change of measure for Lévy processes is given by the following theorem (see Sato, 1999):

Theorem 3. Suppose a process $X = (X_t)_{t \geq 0}$ has Lévy triplets (σ^2, ν, γ) and $(\tilde{\sigma}^2, \tilde{\nu}, \tilde{\gamma})$ under measures \mathbf{P} and \mathbf{Q} , respectively.

1. In the case where $\sigma^2 \neq 0$ and $\tilde{\sigma}^2 \neq 0$, $\mathbf{P}|_{\mathcal{F}_t}$ and $\mathbf{Q}|_{\mathcal{F}_t}$ are equivalent for all $t > 0$ if and only if

the Lévy triplets satisfy

$$\sigma^2 = \tilde{\sigma}^2 > 0 \tag{2}$$

and

$$\int_{-\infty}^{\infty} (e^{\psi(x)/2} - 1)^2 \nu(dx) < \infty \tag{3}$$

where $\psi(x) = \ln \left(\frac{d\tilde{\nu}}{d\nu} \right)$.

2. In the case where $\sigma^2 = \tilde{\sigma}^2 = 0$, $\mathbf{P}|_{\mathcal{F}_t}$ and $\mathbf{Q}|_{\mathcal{F}_t}$ are equivalent for all $t \geq 0$ if and only if the Lévy triplets satisfy (3) and

$$\tilde{\gamma} - \gamma = \int_{|x| \leq 1} x(\tilde{\nu} - \nu)(dx) \tag{4}$$

When \mathbf{P} and \mathbf{Q} are equivalent, the Radon-Nikodym derivative is

$$\frac{d\mathbf{Q}}{d\mathbf{P}} \Big|_{\mathcal{F}_t} = e^{\xi t}$$

where $\xi = (\xi_t)_{t \geq 0}$ is a Lévy process with Lévy triplet $(\sigma_\xi^2, \nu_\xi, \gamma_\xi)$ given by

$$\begin{cases} \sigma_\xi^2 = \sigma^2 \eta^2 \\ \nu_\xi = \nu \circ \psi^{-1} \\ \gamma_\xi = -\frac{\sigma^2 \eta^2}{2} - \int_{-\infty}^{\infty} (e^y - 1 - y1_{|y| \leq 1}) \nu_\xi(dy) \end{cases} \tag{5}$$

and η is such that

$$\tilde{\gamma} - \gamma - \int_{|x| \leq 1} x(\tilde{\nu} - \nu)(dx) = \begin{cases} \sigma^2 \eta & \text{if } \sigma > 0 \\ 0 & \text{if } \sigma = 0 \end{cases}$$

Change of Measure in Tempered Stable Processes

In this section, we present the change of measure for six tempered stable processes: the classical tempered stable (CTS) process, Kim-Rachev tempered stable (KRTS) process, modified tempered stable (MTS) process, normal tempered stable (NTS) process, and rapidly decreasing tempered stable (RDTS) process. The six processes are defined as follows:

- Let $\alpha \in (0, 2)$, $C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. A Lévy process $(X_t)_{t \geq 0}$ is referred to as the classical tempered stable (CTS) process³ if the charac-

teristic function of X_t is given by

$$\begin{aligned} \phi_{X_t}(u) = \exp(iumt - iutC\Gamma(1 - \alpha)(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1}) \\ + tC\Gamma(-\alpha)((\lambda_+ - iu)^\alpha - \lambda_+^\alpha \\ + (\lambda_- + iu)^\alpha - \lambda_-^\alpha)) \end{aligned}$$

If we take a special parameter C defined by

$$C = (\Gamma(2 - \alpha)(\lambda_+^{\alpha-2} + 2\lambda_-^{\alpha-2}))^{-1} \tag{6}$$

and $m = 0$ then $E[X_t] = 0$ and $V(X_t) = t$. In this case, X is called the standard CTS process with parameters $(\alpha, \lambda_+, \lambda_-)$.

- A Lévy process $(X_t)_{t \geq 0}$ is referred to as the generalized tempered stable (GTS) process if the characteristic function of X_t is given by

$$\begin{aligned} \phi_{X_t}(u) = \exp(iumt - iut\Gamma(1 - \alpha)(C_+\lambda_+^{\alpha-1} \\ - C_-\lambda_-^{\alpha-1}) \\ + tC_+\Gamma(-\alpha_+)((\lambda_+ - iu)^{\alpha_+} - \lambda_+^{\alpha_+}) \\ + tC_-\Gamma(-\alpha_-)((\lambda_- + iu)^{\alpha_-} - \lambda_-^{\alpha_-})), \end{aligned} \tag{7}$$

where $\alpha_+, \alpha_- \in (0, 1) \cup (1, 2)$, $C_+, C_-, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. If we substitute

$$C_+ = \frac{p\lambda_+^{2-\alpha_+}}{\Gamma(2 - \alpha_+)}, \quad C_- = \frac{(1 - p)\lambda_-^{2-\alpha_-}}{\Gamma(2 - \alpha_-)} \tag{8}$$

where $p \in (0, 1)$, and $m = 0$ then $E[X_t] = 0$ and $V(X_t) = t$. In this case, X is called the standard GTS process with parameters $(\alpha_+, \alpha_-, \lambda_+, \lambda_-, p)$.

- Let $\alpha \in (0, 2) \setminus \{1\}$, $k_+, k_-, r_+, r_- > 0$, $p_+, p_- \in \{p > -\alpha \mid p \neq -1, p \neq 0\}$, and $m \in \mathbb{R}$. A Lévy process $(X_t)_{t \geq 0}$ is referred to as the Kim-Rachev (KR) process⁴ if the characteristic function of X_t is given by

$$\begin{aligned} \phi_{X_t}(u) = \exp(iumt - iut\Gamma(1 - \alpha) \\ \times \left(\frac{k_+r_+}{p_+ + 1} - \frac{k_-r_-}{p_- + 1} \right) \\ + tk_+H(iu; \alpha, r_+, p_+) \\ + tk_-H(-iu; \alpha, r_-, p_-)) \end{aligned}$$

where

$$H(x; \alpha, r, p) = \frac{\Gamma(-\alpha)}{p} ({}_2F_1(p, -\alpha; 1 + p; rx) - 1)$$

where ${}_2F_1$ is the hypergeometric function.⁵ If p_+ and p_- approach to the infinite, then the

KR process converges to the CTS process. If we substitute

$$k_+ = C \frac{\alpha + p_+}{r_+^\alpha}$$

$$k_- = C \frac{\alpha + p_-}{r_-^\alpha}$$

where

$$C = \frac{1}{\Gamma(2-\alpha)} \left(\frac{\alpha + p_+}{2 + p_+} r_+^{2-\alpha} + \frac{\alpha + p_-}{2 + p_-} r_-^{2-\alpha} \right)^{-1} \quad (9)$$

and $m = 0$ then $E[X_t] = 0$ and $V(X_t) = t$. In this case, X is called the standard KRTS process with parameters $(\alpha, r_+, r_-, p_+, p_-)$.

- Let $\alpha \in (0, 2) \setminus \{1\}$, $C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. A Lévy process $(X_t)_{t \geq 0}$ is referred to as the modified tempered stable (MTS) process⁶ if the characteristic function of X_t is given by

$$\begin{aligned} \phi_{X_t}(u) = & \exp(iumt + tC(G_R(u; \alpha, C, \lambda_+) \\ & + G_R(u; \alpha, C, \lambda_-)) \\ & + iutC(G_I(u; \alpha, \lambda_+) - G_I(u; \alpha, \lambda_-))) \end{aligned}$$

where for $u \in \mathbb{R}$,

$$\begin{aligned} G_R(x; \alpha, \lambda) = & 2^{-\frac{\alpha+3}{2}} \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \\ & \times ((\lambda^2 + x^2)^{\frac{\alpha}{2}} - \lambda^\alpha) \end{aligned}$$

and

$$\begin{aligned} G_I(x; \alpha, \lambda) = & 2^{-\frac{\alpha+1}{2}} \Gamma\left(\frac{1-\alpha}{2}\right) \lambda^{\alpha-1} \\ & \times \left[{}_2F_1\left(1, \frac{1-\alpha}{2}; \frac{3}{2}; -\frac{x^2}{\lambda^2}\right) - 1 \right] \end{aligned}$$

If we substitute

$$C = 2^{\frac{\alpha+1}{2}} \left(\sqrt{\pi} \Gamma\left(1 - \frac{\alpha}{2}\right) (\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}) \right)^{-1} \quad (10)$$

and $m = 0$ then $E[X_t] = 0$ and $V(X_t) = t$. In this case, X is called the standard MTS process with parameters $(\alpha, \lambda_+, \lambda_-)$.

- Let $\alpha \in (0, 2)$, $C, \lambda > 0$, $|\beta| < \lambda$, and $m \in \mathbb{R}$. A Lévy process $(X_t)_{t \geq 0}$ is referred to as the normal tempered stable (NTS) process⁷ if the

characteristic function of X_t is given by

$$\begin{aligned} \phi_{X_t}(u) = & \exp\left(iumt + iut2^{-\frac{\alpha+1}{2}} C \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \right. \\ & \times \alpha \beta (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-1} + 2^{-\frac{\alpha+1}{2}} t C \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \\ & \left. \times ((\lambda^2 - (\beta + iu)^2)^{\frac{\alpha}{2}} - (\lambda^2 - \beta^2)^{\frac{\alpha}{2}}) \right) \end{aligned}$$

If we substitute

$$C = 2^{\frac{\alpha+1}{2}} \left(\sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) \alpha (\lambda^2 - \beta^2)^{\frac{\alpha}{2}-2} \right. \\ \left. \times (\alpha \beta^2 - \lambda^2 - \beta^2) \right)^{-1} \quad (11)$$

and $m = 0$ then $E[X_t] = 0$ and $V(X_t) = t$. In this case, X is called the standard NTS process with parameters (α, λ, β) .

- Let $\alpha \in (0, 2) \setminus \{1\}$, $C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. A Lévy process $(X_t)_{t \geq 0}$ is referred to as the rapidly decreasing tempered stable (RDTS) process⁸ if the characteristic function of X_t is given by

$$\begin{aligned} \phi_{X_t}(u) = & \exp(iumt + tC(G(iu; \alpha, \lambda_+) \\ & + G(-iu; \alpha, \lambda_-))) \end{aligned}$$

where

$$\begin{aligned} G(x; \alpha, \lambda) = & 2^{-\frac{\alpha}{2}-1} \lambda^\alpha \Gamma\left(-\frac{\alpha}{2}\right) \left(M\left(-\frac{\alpha}{2}, \frac{1}{2}; \frac{x^2}{2\lambda^2}\right) - 1 \right) \\ & + 2^{-\frac{\alpha}{2}-\frac{1}{2}} \lambda^{\alpha-1} x \Gamma\left(\frac{1-\alpha}{2}\right) \\ & \times \left(M\left(\frac{1-\alpha}{2}, \frac{3}{2}; \frac{x^2}{2\lambda^2}\right) - 1 \right) \end{aligned}$$

and M is the confluent hypergeometric function. See Andrews (1998). If we take a special parameter C defined by

$$C = 2^{\frac{\alpha}{2}} \left(\Gamma\left(1 - \frac{\alpha}{2}\right) (\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}) \right)^{-1} \quad (12)$$

and $m = 0$ then $E[X_t] = 0$ and $V(X_t) = t$. In this case, X is called the standard RDTS process with parameters $(\alpha, \lambda_+, \lambda_-)$.

The six tempered stable processes are pure jump Lévy processes with Lévy triplet $(0, \nu, \gamma)$, where $\gamma = m - \int_{|x|>1} x \nu(dx)$ and Lévy measures are presented in Table 1.

Table 1 Lévy Measures for Tempered Stable Processes

	Lévy Measure $\nu(dx)$
CTS	$C \left(\frac{e^{-\lambda_+ x}}{x^{1+\alpha}} 1_{x>0} + \frac{e^{-\lambda_- x }}{ x ^{1+\alpha}} 1_{x<0} \right) dx$
GTS	$\left(\frac{C_+ e^{-\lambda_+ x}}{x^{1+\alpha_+}} 1_{x>0} + \frac{C_- e^{-\lambda_- x }}{ x ^{1+\alpha_-}} 1_{x<0} \right) dx$
MTS	$\left(\frac{C_+ (\lambda_+ x)^{\frac{\alpha+1}{2}} K_{\frac{\alpha+1}{2}}(\lambda_+ x)}{x^{1+\alpha}} 1_{x>0} + \frac{C_- (\lambda_- x)^{\frac{\alpha+1}{2}} K_{\frac{\alpha+1}{2}}(\lambda_- x)}{ x ^{1+\alpha}} 1_{x<0} \right) dx$
NTS	$\frac{C e^{\beta x} (\lambda x)^{\frac{\alpha+1}{2}} K_{\frac{\alpha+1}{2}}(\lambda x)}{ x ^{1+\alpha}} dx$
KRTS	$\left(\frac{k_+ r_+^{-p_+}}{x^{1+\alpha}} \int_0^{r_+} e^{-x/s} s^{\alpha+p_+-1} ds 1_{x>0} + \frac{k_- r_-^{-p_-}}{ x ^{1+\alpha}} \int_0^{r_-} e^{- x /s} s^{\alpha+p_- -1} ds 1_{x<0} \right) dx$
RDTs	$\left(\frac{C_+ e^{-\frac{\lambda_+ x^2}{2}}}{x^{1+\alpha}} 1_{x>0} + \frac{C_- e^{-\frac{\lambda_- x ^2}{2}}}{ x ^{1+\alpha}} 1_{x<0} \right) dx$

Let $X = (X_t)_{t \geq 0}$ be one tempered stable process among the six tempered stable processes. Then $E[X_t] = mt$ and X has stationary and independent increments. Therefore, we have

$$\begin{aligned} E[X_T | \mathcal{F}_t] &= E[X_T - X_t | \mathcal{F}_t] + X_t \\ &= E[X_{T-t}] + X_t = m(T-t) + X_t \end{aligned}$$

and hence X is a martingale when $m = 0$.

The properties of tempered stable processes change under the change of measure using the Esscher transform. For example, let a process $X = (X_t)_{t \geq 0}$ be a symmetric CTS process under measure \mathbf{P} (that is $\lambda_+ = \lambda_- = \lambda$). Then the Lévy measure $\nu(dx)$ of X is given by

$$\nu(dx) = C \left(\frac{e^{-\lambda x}}{x^{1+\alpha}} 1_{x>0} + \frac{e^{-\lambda |x|}}{|x|^{1+\alpha}} 1_{x<0} \right) dx$$

Since we have $\int_{|x| \geq 1} e^{\theta x} \nu(dx) < \infty$ for some real number θ with $-\lambda \leq \theta \leq \lambda$, we can define a measure \mathbf{Q} equivalent to \mathbf{P} such that

$$\mathbf{Q}(A) |_{\mathcal{F}_t} = \int_A e^{\theta X_t - I(\theta)t} d\mathbf{P}, \quad A \in \mathcal{F}_t$$

where

$$\begin{aligned} I(\theta) &= \log E_{\mathbf{P}}[e^{\theta X_1}] = C \Gamma(-\alpha) ((\lambda - \theta)^\alpha \\ &\quad + (\lambda + \theta)^\alpha - 2\lambda^\alpha) \end{aligned}$$

Moreover, the Lévy measure $\tilde{\nu}(dx)$ of X under \mathbf{Q} is given by

$$\begin{aligned} \tilde{\nu}(dx) &= e^{\theta x} \nu(dx) \\ &= C \left(\frac{e^{-(\lambda-\theta)x}}{x^{1+\alpha}} 1_{x>0} + \frac{e^{-(\lambda+\theta)|x|}}{|x|^{1+\alpha}} 1_{x<0} \right) dx \end{aligned}$$

By the same argument, we discuss the relation between the symmetric MTS and NTS process. That is, let a process $X = (X_t)_{t \geq 0}$ be a symmetric MTS process under measure \mathbf{P} . Then the Lévy measure $\nu(dx)$ of X is given by

$$\nu(dx) = C (\lambda |x|)^{\frac{\alpha+1}{2}} K_{\frac{\alpha+1}{2}}(\lambda |x|) dx$$

Since we have $\int_{|x| \geq 1} e^{-\beta x} \nu(dx) < \infty$ for some real number β with $-\lambda \leq \beta \leq \lambda$, we can define a measure \mathbf{Q} equivalent to \mathbf{P} such that

$$\mathbf{Q}(A) |_{\mathcal{F}_t} = \int_A e^{-\beta X_t - I(-\beta)t} d\mathbf{P}, \quad A \in \mathcal{F}_t,$$

where

$$\begin{aligned} I(x) &= \log E_{\mathbf{P}}[e^{x X_1}] \\ &= C 2^{-\frac{\alpha+1}{2}} \sqrt{\pi} \Gamma\left(-\frac{\alpha}{2}\right) ((\lambda^2 + x^2)^{\frac{\alpha}{2}} - \lambda^\alpha) \end{aligned}$$

Moreover, the Lévy measure $\tilde{\nu}(dx)$ of X under \mathbf{Q} is given by

$$\tilde{\nu}(dx) = e^{-\beta x} \nu(dx) = C e^{-\beta x} (\lambda |x|)^{\frac{\alpha+1}{2}} K_{\frac{\alpha+1}{2}}(\lambda |x|) dx$$

which is the Lévy measure for the NTS process.

Table 2 Condition for Equivalent between **P** and **Q**

$(X_t)_{t \geq 0}$	Parameters under Measure P	Parameters under Measure Q	Equivalent Condition
CTS process	$(\alpha, C, \lambda_+, \lambda_-, m)$	$(\tilde{\alpha}, \tilde{C}, \tilde{\lambda}_+, \tilde{\lambda}_-, \tilde{m})$	$C = \tilde{C}, \alpha = \tilde{\alpha}$, and $\tilde{m} - m = C\Gamma(1 - \alpha)(\tilde{\lambda}_+^{\alpha-1} - \tilde{\lambda}_-^{\alpha-1} - \lambda_+^{\alpha-1} + \lambda_-^{\alpha-1})$
GTS process	$\left(\begin{matrix} \alpha_+, \alpha_-, C_+, C_- \\ \lambda_+, \lambda_-, m \end{matrix} \right)$	$\left(\begin{matrix} \tilde{\alpha}_+, \tilde{\alpha}_-, \tilde{C}_+, \tilde{C}_- \\ \tilde{\lambda}_+, \tilde{\lambda}_-, \tilde{m} \end{matrix} \right)$	$\alpha_+ = \tilde{\alpha}_+, \alpha_- = \tilde{\alpha}_-, C_+ = \tilde{C}_+, C_- = \tilde{C}_-$, and $\tilde{m} - m = C_+\Gamma(1 - \alpha_+)(\tilde{\lambda}_+^{\alpha_+-1} - \tilde{\lambda}_-^{\alpha_+-1}) - C_-\Gamma(1 - \alpha_-)(\lambda_+^{\alpha_+-1} + \lambda_-^{\alpha_+-1})$
MTS process	$(\alpha, C, \lambda_+, \lambda_-, m)$	$(\tilde{\alpha}, \tilde{C}, \tilde{\lambda}_+, \tilde{\lambda}_-, \tilde{m})$	$C = \tilde{C}, \alpha = \tilde{\alpha}$, and $\tilde{m} - m = 2^{-\frac{\alpha+1}{2}}C\Gamma\left(\frac{1-\alpha}{2}\right)(\tilde{\lambda}_+^{\alpha-1} - \tilde{\lambda}_-^{\alpha-1} - \lambda_+^{\alpha-1} + \lambda_-^{\alpha-1})$
NTS process	$(\alpha, C, \lambda, \beta, m)$	$(\tilde{\alpha}, \tilde{C}, \tilde{\lambda}, \tilde{\beta}, \tilde{m})$	$C = \tilde{C}, \alpha = \tilde{\alpha}$, and $\tilde{m} - m = \kappa(\tilde{\beta}(\tilde{\lambda}^2 - \tilde{\beta}^2)^{\frac{\alpha}{2}-1} - \beta(\lambda^2 - \beta^2)^{\frac{\alpha}{2}-1})$, where $\kappa = 2^{-\frac{\alpha-1}{2}}\sqrt{\pi}C\Gamma\left(1 - \frac{\alpha}{2}\right)$
KRTS process	$\left(\begin{matrix} \alpha_1, k_{1,+}, k_{1,-}, r_{1,+} \\ r_{1,-}, p_{1,+}, p_{1,-}, m_1 \end{matrix} \right)$	$\left(\begin{matrix} \alpha_2, k_{2,+}, k_{2,-}, r_{2,+} \\ r_{2,-}, p_{2,+}, p_{2,-}, m_2 \end{matrix} \right)$	$\begin{cases} p_{j,\pm} > 1/2 - \alpha_j \text{ and } p_{j,\pm} \neq 0, & \alpha_j \in (0, 1) \\ p_{j,\pm} > 1 - \alpha_j \text{ and } p_{j,\pm} \neq 0, & \alpha_j \in (1, 2) \end{cases}$, for $j = 1, 2$ $\alpha := \alpha_1 = \alpha_2$ $\frac{k_{1,+} + r_{1,+}^\alpha}{\alpha + p_{1,+}} = \frac{k_{2,+} + r_{2,+}^\alpha}{\alpha + p_{2,+}}, \frac{k_{1,-} + r_{1,-}^\alpha}{\alpha + p_{1,-}} = \frac{k_{2,-} + r_{2,-}^\alpha}{\alpha + p_{2,-}}$, and $m_2 - m_1 = \Gamma(1 - \alpha) \sum_{j=1,2} (-1)^j \left(\frac{k_{j,+} + r_{j,+}}{p_{j,+} + 1} - \frac{k_{j,-} + r_{j,-}}{p_{j,-} + 1} \right)$
RDTs process	$(\alpha, C, \lambda_+, \lambda_-, m)$	$(\tilde{\alpha}, \tilde{C}, \tilde{\lambda}_+, \tilde{\lambda}_-, \tilde{m})$	$C = \tilde{C}, \alpha = \tilde{\alpha}$, and $\tilde{m} - m = 2^{-\frac{\alpha+1}{2}}C\Gamma\left(\frac{1-\alpha}{2}\right)(\tilde{\lambda}_+^{\alpha-1} - \tilde{\lambda}_-^{\alpha-1} - \lambda_+^{\alpha-1} + \lambda_-^{\alpha-1})$

We can apply Theorem 3 to tempered stable processes. For example, let $X = (X_t)_{t \geq 0}$ be a CTS process with parameters $(\alpha, C, \lambda_+, \lambda_-, m)$ on measure **P** and a CTS process with parameters $(\tilde{\alpha}, \tilde{C}, \tilde{\lambda}_+, \tilde{\lambda}_-, \tilde{m})$ on measure **Q**. Then **P** and **Q** are equivalent if and only if $C = \tilde{C}, \alpha = \tilde{\alpha}$, and

$$\tilde{m} - m = C\Gamma(1 - \alpha)(\tilde{\lambda}_+^{\alpha-1} - \tilde{\lambda}_-^{\alpha-1} - \lambda_+^{\alpha-1} + \lambda_-^{\alpha-1}) \tag{13}$$

When **P** and **Q** are equivalent, the Radon-Nikodym derivative is $\left. \frac{d\mathbf{Q}}{d\mathbf{P}} \right|_{\mathcal{F}_t} = e^{U_t}$ where $U = (U_t)_{t \geq 0}$ is a Lévy process with Lévy triplet $(\sigma_U^2, \nu_U, \gamma_U)$ given by

$$\begin{aligned} \sigma_U^2 &= 0, \quad \nu_U = \nu \circ \psi^{-1}, \\ \gamma_U &= -\int_{-\infty}^{\infty} t(e^y - 1 - y1_{|y| \leq 1})(\nu \circ \psi^{-1})(dy) \end{aligned} \tag{14}$$

In equation (14), ν is the CTS Lévy measure given by

$$\nu(dx) = C \left(\frac{e^{-\lambda_+x}}{x^{1+\alpha}} 1_{x>0} + \frac{e^{-\lambda_-|x|}}{|x|^{1+\alpha}} 1_{x<0} \right) dx$$

and $\psi(x) = (\lambda_+ - \tilde{\lambda}_+)x1_{x>0} - (\lambda_- - \tilde{\lambda}_-)x1_{x<0}$. Proofs can be obtained by Theorem 3, but we will not discuss the proofs here.⁹

We can apply the same argument to the GTS, MTS, NTS, KRTS, and RDTs processes.¹⁰ The necessary and sufficient equivalent condition for change of measures for the six tempered stable distributions are presented in Table 2. Radon-Nikodym derivatives are omitted in the table.

By applying change of measures, we can obtain a martingale process from a CTS process. Let a process $X^0 = (X_t^0)_{t \geq 0}$ be a CTS process with

Table 3 Change of Measures for Standard TS Processes: $Y_t = \mu t + X_t$

$(X_t)_{t \geq 0}$ under Measure P	$(Y_t)_{t \geq 0}$ under Measure Q	Relations of Parameters
Standard CTS process with parameters $(\alpha, \lambda_+, \lambda_-)$	Standard CTS process with parameters $(\alpha, \tilde{\lambda}_+, \tilde{\lambda}_-)$	$\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2} = \tilde{\lambda}_+^{\alpha-2} + \tilde{\lambda}_-^{\alpha-2},$ $\mu = \frac{\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1} - \tilde{\lambda}_+^{\alpha-1} + \tilde{\lambda}_-^{\alpha-1}}{(1-\alpha)(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})}$
Standard GTS process with parameters $(\alpha_+, \alpha_-, \lambda_+, \lambda_-, p)$	Standard GTS process with parameters $(\alpha_+, \alpha_-, \tilde{\lambda}_+, \tilde{\lambda}_-, \tilde{p})$	$p\lambda_+^{2-\alpha_+} = \tilde{p}\tilde{\lambda}_+^{2-\alpha_+}$ $(1-p)\lambda_-^{\alpha_- - 2} = (1-\tilde{p})\tilde{\lambda}_-^{\alpha_- - 2}$ $\mu = p \frac{\lambda_+^{\alpha_+ - 1} - \tilde{\lambda}_+^{\alpha_+ - 1}}{(1-\alpha_+)\lambda_+^{\alpha_+ - 1}} + (1-p) \frac{\tilde{\lambda}_-^{\alpha_- - 1} - \lambda_-^{\alpha_- - 1}}{(1-\alpha_-)\lambda_-^{\alpha_- - 1}}$
Standard MTS process with parameters $(\alpha, \lambda_+, \lambda_-)$	Standard MTS process with parameters $(\alpha, \tilde{\lambda}_+, \tilde{\lambda}_-)$	$\tilde{\lambda}_+^{\alpha-2} + \tilde{\lambda}_-^{\alpha-2} = \lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}$ $\mu = \frac{\Gamma(\frac{1-\alpha}{2})(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1} - \tilde{\lambda}_+^{\alpha-1} + \tilde{\lambda}_-^{\alpha-1})}{\sqrt{\pi}\Gamma(1-\frac{\alpha}{2})(\tilde{\lambda}_+^{\alpha-2} + \tilde{\lambda}_-^{\alpha-2})}$
Standard NTS process with parameters (α, λ, β)	Standard NTS process with parameters $(\alpha, \tilde{\lambda}, \tilde{\beta})$	$\frac{\alpha\beta^2 - \lambda^2 - \beta^2}{(\lambda^2 - \beta^2)^{2-\frac{\alpha}{2}}} = \frac{\alpha\tilde{\beta}^2 - \tilde{\lambda}^2 - \tilde{\beta}^2}{(\tilde{\lambda}^2 - \tilde{\beta}^2)^{2-\frac{\alpha}{2}}}$ $\mu = \frac{\beta(\lambda^2 - \beta^2)^{\frac{\alpha}{2}-1} - \tilde{\beta}(\tilde{\lambda}^2 - \tilde{\beta}^2)^{\frac{\alpha}{2}-1}}{(\lambda^2 - \beta^2)^{\frac{\alpha}{2}-2}(\alpha\beta^2 - \lambda^2 - \beta^2)}$
Standard KRTS process with parameters $(\alpha, r_{1,+}, r_{1,-}, p_{1,+}, p_{1,-})$	Standard KRTS process with parameters $(\alpha, r_{2,+}, r_{2,-}, p_{2,+}, p_{2,-})$	$r_{2,+}, r_{2,-} > 0$ $\frac{\alpha + p_{1,+}}{2 + p_{1,+}} r_{1,+}^{2-\alpha} + \frac{\alpha + p_{1,-}}{2 + p_{1,-}} r_{1,-}^{2-\alpha} + \frac{\alpha + p_{2,+}}{2 + p_{2,+}} r_{2,+}^{2-\alpha} + \frac{\alpha + p_{2,-}}{2 + p_{2,-}} r_{2,-}^{2-\alpha}$ $\mu = \sum_{j=1,2} (-1)^j c_j \left(\frac{p_{j,+} + \alpha}{p_{j,+} + 1} r_{j,+}^{1-\alpha} - \frac{p_{j,-} + \alpha}{p_{j,-} + 1} r_{j,-}^{1-\alpha} \right)$
Standard RDTS process with parameters $(\alpha, \lambda_+, \lambda_-)$	Standard RDTS process with parameters $(\alpha, \tilde{\lambda}_+, \tilde{\lambda}_-)$	$\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2} = \tilde{\lambda}_+^{\alpha-2} + \tilde{\lambda}_-^{\alpha-2},$ $\mu = \frac{\Gamma(\frac{1-\alpha}{2})(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1} - \tilde{\lambda}_+^{\alpha-1} + \tilde{\lambda}_-^{\alpha-1})}{\sqrt{2}\Gamma(1-\frac{\alpha}{2})(\tilde{\lambda}_+^{\alpha-2} + \tilde{\lambda}_-^{\alpha-2})}$

parameters $(\alpha, C, \lambda_+, \lambda_-, 0)$ on measure **P** and let $X = (X_t)_{t \geq 0}$ be a process with $X_t = mt + X_t^0$. Then X becomes the CTS process with parameters $(\alpha, C, \lambda_+, \lambda_-, m)$ on the measure **P**. The process X is not a martingale on the measure **P**, but we can obtain a measure where X is a martingale by the change of measures for CTS processes. We assume that $\tilde{\lambda}_+$ and $\tilde{\lambda}_-$ are positive real numbers such that

$$0 - m = C\Gamma(1-\alpha)(\tilde{\lambda}_+^{\alpha-1} - \tilde{\lambda}_-^{\alpha-1} - \lambda_+^{\alpha-1} + \lambda_-^{\alpha-1})$$

and we define a measure **Q** equivalent to **P** such that

$$\mathbf{Q}(A) |_{\mathcal{F}_t} = \int_A e^{U_t} d\mathbf{P}, \quad A \in \mathcal{F}_t$$

where $(U_t)_{t \geq 0}$ is the Lévy process with Lévy triplet $(\sigma_U^2, \nu_U, \gamma_U)$ given by equation (14). Then

the process X becomes the CTS process with parameters $(\alpha, C, \tilde{\lambda}_+, \tilde{\lambda}_-, 0)$ on the measure **Q**. Therefore, the process X is a martingale on measure **Q**.

Furthermore, by applying change of measures to the standard CTS process, we obtain the following result. Let $(X_t)_{t \geq 0}$ be a standard CTS process with parameters $(\alpha, \lambda_+, \lambda_-)$ under a measure **P**, and $\tilde{\lambda}_+, \tilde{\lambda}_- > 0$ and real number μ satisfy the following:

$$\begin{cases} \lambda_+^{\alpha-2} + \lambda_-^{\alpha-2} = \tilde{\lambda}_+^{\alpha-2} + \tilde{\lambda}_-^{\alpha-2} \\ \mu = \frac{\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1} - \tilde{\lambda}_+^{\alpha-1} + \tilde{\lambda}_-^{\alpha-1}}{(1-\alpha)(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2})} \end{cases} \quad (15)$$

Then we can find a measure **Q** equivalent to **P** such that a process $(Y_t)_{t \geq 0}$ with $Y_t = \mu t + X_t$ is a standard CTS process with parameters $(\alpha, \tilde{\lambda}_+, \tilde{\lambda}_-)$ under a measure **Q**.

We apply the same argument to the standard GTS, standard MTS, standard NTS, standard KRIS, and standard RDIS processes. The relations of parameters between standard tempered stable process $(X_t)_{t \geq 0}$ under \mathbf{P} and standard tempered stable process $(Y_t)_{t \geq 0}$ with $Y_t = \mu t + X_t$ under \mathbf{Q} are presented in Table 3.

KEY POINTS

- The information available to all market agents at one time interprets the filtration.
- Conditional expectation is the best approximation of the price of assets, portfolios, and derivatives under information until the current time.
- Markov processes are used to explain the efficient market hypothesis in finance.
- Martingale processes describe the fair price or no-arbitrage price for an asset in finance.
- Change of measure on the Brownian motion process is achieved by Girsanov's theorem, while change of measure on the Lévy process is achieved by the Esscher transform or the generalized Girsanov theorem.
- Using the generalized Girsanov theorem, the tempered stable process becomes a martingale process.

NOTES

1. The general form of the Girsanov's theorem is presented in many articles including Karatzas and Shreve (1991), Oksendal (2000), and Klebaner (2005). The Black-Scholes option pricing formula is derived by applying Girsanov's theorem in Harrison and Pliska (1981).

Change of Time Methods

ANATOLIY SWISHCHUK, PhD

Professor of Mathematics and Statistics, University of Calgary

Abstract: Change of time can be used in financial modeling to introduce stochastic volatility or solve many stochastic differential equations. The main idea of the change of time method is to change time from t to a nonnegative process $T(t)$ with nondecreasing sample paths (e.g., subordinator). Many Lévy processes may be written as time-changed Brownian motion. Lévy processes can also be used as a time change for other Lévy processes (subordinators). Using change of time, we can get an option pricing formula for an asset following geometric Brownian motion (e.g., Black-Scholes formula) and obtain an explicit option pricing formula for an asset following the mean-reverting process (e.g., continuous-time GARCH process).

In this entry, we provide an overview on *change of time* methods (CTM), and show how to solve many *stochastic differential equations* (SDEs) in finance (geometric Brownian motion [GBM], Ornstein-Uhlenbeck [OU], Vasiček, continuous-time GARCH, etc.) using the change of time method. As applications of CTM we present two different models: geometric Brownian motion (GBM) and *mean-reverting models*. The solutions of these two models are different. But the nice thing is that they can be solved by CTM like many other models mentioned in this entry. And moreover, we can use these solutions to find easy option pricing formulas: One is classic-Black-Scholes and another one is new for a mean-reverting asset. These formulas can be used in practice (for example, in the energy market) because they all are explicit.¹

This includes:

- CTM in *martingale* and *semimartingale* setting
- CTM in SDEs setting
- Subordination as a change of time

We present two applications of CTM:

- Black-Scholes formula
- *Explicit option pricing formula* for a mean-reverting asset

CHANGE OF TIME METHOD

The main idea of the change of time method is to change time from t to a nonnegative process $T(t)$ with nondecreasing sample paths. One example is subordinator: If $X(t)$ and $T(t) > 0$ are some processes, then $X(T(t))$ is subordinated to

$X(t); T(t)$ is a change of time. Another example is time-changed Brownian motion: $M(t) = B(T(t))$, where $B(t)$ is a Brownian motion and $T(t)$ is a subordinator (e.g., variance-gamma process² $V(t) = B(T(t))$, where $T(t)$ is a gamma process).

Bochner (1949) introduced the notion of change of time (time-changed Brownian motion). Clark (1973) introduced Bochner's change of time into financial economics. Feller (1966) introduced subordinated process $X(T(t))$ with Markov process $X(t)$ and $T(t)$ as a process with independent increments ($T(t)$ was called randomized operational time). Johnson (1979) introduced the time-changed *stochastic volatility* model (SVM) in continuous time. Johnson and Shanno (1987) studied the pricing of options using the time-changed stochastic volatility (SV) model. Ikeda and Watanabe (1981) introduced and studied change of time for the solution of SDEs. Barndorff-Nielsen, Nicolato, and Shephard (2003) studied the relationship between subordination and SVM using change of time ($T(t)$ -chronometer). Carr, Geman, Madan, and Yor (2003) used subordinated processes to construct SV for Lévy processes ($T(t)$ -business time).

The change of time method is closely associated with the embedding problem: To embed a process $X(t)$ in Brownian motion is to find a Wiener process $W(t)$ and an increasing family of stopping times $T(t)$ such that $W(T(t))$ has the same joint distribution as $X(t)$. Skorokhod (1965) first treated the embedding problem, showing that the sum of any sequence of independent random variables (r.v.) with mean zero and finite variation could be embedded in Brownian motion using stopping times. Dambis (1965) and Dubins and Schwartz (1965) independently showed that every continuous martingale could be embedded in Brownian motion. Knight (1971) discovered the multivariate extension of Dambis (1965) and Dubins and Schwartz's (1965) result. Huff (1969) showed that every process of pathwise bounded variation could be embedded in Brownian motion. Monroe (1972) proved that every right continu-

ous martingale could be embedded in a Brownian motion. Monroe (1978) proved that a process can be embedded in Brownian motion if and only if this process is a local semimartingale. Meyer (1971) and Papangelou (1972) independently discovered Knight's (1971) result for point processes.

Rosiński and Woyczyński (1986) considered time changes for integrals over stable Lévy processes. Kallenberg (1992) considered time change representations for stable integrals.

Lévy processes can also be used as a time change for other Lévy processes (subordinators). Madan and Seneta (1990) introduced the variance gamma (VG) process (Brownian motion with drift time changed by a gamma process). Geman, Madan, and Yor (2001) considered time changes for Lévy processes (business time). Carr, Geman, Madan, and Yor (2003) used change of time to introduce stochastic volatility into a Lévy model to achieve leverage effect and a long-term skew. Kallsen and Shiryaev (2001) showed that the Rosiński-Woyczyński-Kallenberg statement cannot be extended to any other Lévy process but symmetric α -stable. Swishchuk (2004, 2007) applied change of time method for options and swaps pricing for Gaussian models.³

The General Theory of Time Changes

The general theory of change of time for martingale and semimartingale theories⁴ is well known. In this entry we give a brief description of the change of time method in the following settings: martingales and stochastic differential equations.

Martingale and Semimartingale Settings of Change of Time

Let (Ω, \mathcal{F}, P) be a given probability space with a right continuous filtration $(\mathcal{F}_t)_{t \geq 0}$. Suppose M_t is a square integrable local continuous martingale such that $\lim_{t \rightarrow +\infty} \langle M \rangle(t) = +\infty$

almost sure (a.s.), where $\tau_t := \inf\{\mu : \langle M \rangle(u) > t\}$ and $\tilde{\mathcal{F}}_t = \mathcal{F}_{\tau_t}$. Then the time-changed process $B(t) := M(\tau_t)$ is an $\tilde{\mathcal{F}}_t$ -Brownian motion. Also, $M(t) = B(\langle M \rangle(t))$. Here, $\langle \cdot \rangle$ defines predictable quadratic variation.

If ϕ_t is a change of time process (i.e., any continuous \mathcal{F}_t -adapted process such that $\phi_0 = 0$, $t \rightarrow \phi_t$ is strictly increasing and $\lim_{t \rightarrow +\infty} \phi_t = +\infty$ a.s.) and if X_t is an \mathcal{F}_t -adapted semimartingale, then the process $\tilde{X}_t := X_{\tau_t}$ is an $\tilde{\mathcal{F}}_t$ -adapted semimartingale, where $\tau_t := \inf\{u : \phi_u > t\}$, and $\tilde{\mathcal{F}}_t := \mathcal{F}_{\tau_t}$. \tilde{X}_t is called the time change of X_t by ϕ_t .

Geman, Madan, and Yor (2001) consider pure jump Lévy processes (which are semimartingales) of finite variation with an infinite arrival rate of jumps as models for the logarithm of asset prices. These processes also may be written as time-changed Brownian motion. Their paper exhibits the explicit time change for each of a wide class of Lévy processes and shows that the time change is a weighted price move measure of time.

Stochastic Differential Equations Setting of Change of Time

The change of time method is used to solve the following SDE:

$$dX_t = \alpha(t, X_t)dB(t)$$

with $B(t)$ being a Brownian motion and $\alpha(t, x)$ being a "good" function of $t \geq 0$ and $x \in R$. Having solved the equation we can also solve the general SDE

$$dX_t = \beta(t, X_t)dt + \gamma(t, X_t)dB(t)$$

with drift $\beta(t, X_t)$ using the method of transformation of drift (the Girsanov transformation).⁵

Subordinators as Time Changes

Subordinators

Feller (1966) introduced a subordinated process X_{τ_t} for a Markov process X_t and τ_t a process with independent increments. τ_t was called a

randomized operational time. Increasing Lévy processes can also be used as a time change for other Lévy processes.⁶ Lévy processes of this kind are called subordinators. They are very important ingredients for building Lévy-based models in finance.⁷ If S_t is a subordinator, then its trajectories are almost surely increasing, and S_t can be interpreted as a "time deformation" and used to "time change" other Lévy processes. Roughly, if $(X_t)_{t \geq 0}$ is a Lévy process and $(S_t)_{t \geq 0}$ is a subordinator independent of X_t , then the process $(Y_t)_{t \geq 0}$ defined by $Y_t := X_{S_t}$ is a Lévy process.⁸ This time scale has the financial interpretation of business time,⁹ that is, the integrated rate of information arrival.

Subordinators and Stochastic Volatility

The time change method was used to introduce stochastic volatility into a Lévy model to achieve the leverage effect and a long-term skew.¹⁰ In the Bates (1996) model the leverage effect and long-term skew were achieved using correlated sources of randomness in the price process and the instantaneous volatility. The sources of randomness are thus required to be Brownian motions. In the Barndorff-Nielsen et al. (2001, 2002) model the leverage effect and long-term skew are generated using the same jumps in the price and volatility without a requirement for the sources of randomness to be Brownian motions. Another way to achieve the leverage effect and long-term skew is to make the volatility govern the time scale of the Lévy process driving jumps in the price. Carr et al. (2003) suggested the introduction of stochastic volatility into an exponential-Lévy model via a time change. The generic model here is $S_t = \exp(X_t) = \exp(Y_{\nu_t})$, where $\nu_t := \int_0^t \sigma_s^2 ds$. The volatility process should be positive and mean-reverting (i.e., an Ornstein-Uhlenbeck or Cox-Ingersoll-Ross process). Barndorff-Nielsen et al. (2003) reviewed and placed in context some of their recent work on stochastic volatility models including the relationship between subordination and stochastic volatility.

The main difference between the change of time method and the subordinator method is that in the former case the change of time process ϕ_t depends on the process X_t , but in the latter case, the subordinator S_t and Lévy process X_t are independent.

APPLICATIONS OF CHANGE OF TIME METHOD

The change of time method may be applied to get Black-Scholes formula for GBM, explicit option pricing formula for a mean-reverting asset, and to price swaps in financial models with stochastic volatility.

Black-Scholes by Change of Time Method

In the early 1970s, Black et al. (1973) made a major breakthrough by deriving a pricing formula for vanilla option written on a stock. Their model and its extensions assume that the probability distribution of the underlying cash flow at any given future time is lognormal. There are many proofs of their result, including partial differential equation and the martingale approach.¹¹

One of the aims of this entry is to give an idea of how to get the Black-Scholes result by the change of time method.

An Option Pricing Formula for a Mean-Reverting Asset Model Using a Change of Time Method

Some commodity prices, like oil and gas, exhibit mean reversion. This means that they tend over time to return to some long-term mean. This mean-reverting model is a one-factor version of the two-factor model made popular in the context of energy modeling by Pilipovic (1997). Black's model (1976) and Schwartz's model (1997) have become standard tools to price options on commodities. These models have the advantage that they give rise to closed-

form solutions for some types of option.¹² We note that the recent book by Geman (2005) discusses hard and soft commodities (that is, energy, agriculture, and metals) and also presents an analysis of economic and geopolitical issues in commodities markets. Here, we show how to get an explicit option pricing formula for a continuous-time GARCH asset price model using change of time.

One of the aims of this entry is to get an explicit option pricing formula for a mean-reverting asset using change of time method.

Swaps by Change of Time Method: Heston Model

One of the applications of change of time method is to value variance, volatility, covariance, and correlation swaps for Heston's (1993) model. Change of time method for pricing of different types of swaps for Heston's model and pricing of options has been considered in Swishchuk (2004, 2007, 2008c). Applications of change of time method to Lévy-based stochastic volatility models, interest rates, and energy derivatives have been considered in Swishchuk (2008a, 2008b, 2010a, 2010b).

In this section, we apply the change of time method to get the Black-Scholes formula and to obtain an explicit option pricing formula for a mean-reverting asset.

Change of Time Method

In this section we give a brief description of the *change of time method* for the martingales and stochastic differential equations. Throughout this entry we consider $(\Omega, \mathcal{F}, \mathcal{F}_t, P)$ to be a probability space with a right continuous filtration $(\mathcal{F}_t)_{t \geq 0}$

Change of Time Method in Martingale Setting

In this section, we describe the change of time method for a martingale $M(t) \in \mathcal{M}_2^{c,loc}$, the space of local square integrable continuous martingales.¹³

If $M(t) \in \mathcal{M}_2^{c,loc}$, $\lim_{t \rightarrow +\infty} \langle M \rangle (t) = +\infty$ a.s., $\tau_t := \inf\{u : \langle M \rangle (u) > t\}$ and $\tilde{\mathcal{F}}_t := \mathcal{F}_{\tau_t}$, then the following process with changed time

$$W(t) := M(\tau_t)$$

is an $\tilde{\mathcal{F}}_t$ -Brownian motion (or standard Wiener process).

Consequently, we can express a local martingale $M(t)$ using an $\tilde{\mathcal{F}}_t$ -Brownian motion $W(t)$ and an $\tilde{\mathcal{F}}_t$ -stopping time. (since $\{\langle M \rangle (t) \leq u\} = \{\tau_u \geq t\} \in \mathcal{F}_{\tau_u} = \tilde{\mathcal{F}}_u$)

$$M(t) = W(\langle M \rangle (t))$$

Change of Time Method in a Stochastic Differential Equation Setting

We consider the following generalization of the previous results to an SDE of the following form (without a drift)

$$dX(t) = \alpha(t, X(t))dW(t)$$

where $W(t)$ is a Brownian motion and $\alpha(t, X)$ is a continuous and measurable by t and X function on $[0, +\infty) \times R$.

The reason we consider this equation is if we solve the equation, then we can solve a more general equation with a drift $\beta(t, X)$ using the Girsanov transformation.¹⁴ The following result is used frequently to find a solution of an SDE using change of time method. The following theorem is due to Ikeda and Watanabe (1981).¹⁵

Let $\tilde{W}(t)$ be a one-dimensional \mathcal{F}_t -Wiener process with $\tilde{W}(0) = 0$, given on a probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t>0}, P)$ and let $X(0)$ be an \mathcal{F}_0 -adopted random variable. Define a continuous process $V = V(t)$ by

$$V(t) = X(0) + \tilde{W}(t)$$

Let ϕ_t be the change of time process:

$$\phi_t = \int_0^t \alpha^{-2}(\phi_s, X(0) + \tilde{W}(s))ds$$

If

$$X(t) := V(\phi_t^{-1}) = X(0) + \tilde{W}(\phi_t^{-1})$$

and $\tilde{\mathcal{F}}_t := \mathcal{F}_{\phi_t^{-1}}$, then there exists $\tilde{\mathcal{F}}_t$ -adopted Wiener process $W = W(t)$ such that $(X(t), W(t))$ is a solution of the initial equation on probability space $(\Omega, \mathcal{F}, \tilde{\mathcal{F}}_t, P)$.¹⁶

We note that the solution of the following SDE

$$dX(t) = a(X(t))dW(t)$$

may be presented in the following form (which follows from the previous theorem)

$$X(t) = X(0) + \tilde{W}(\phi_t^{-1})$$

where $a(X)$ is a continuous measurable function, $\tilde{W}(t)$ is an n -dimensional \mathcal{F}_t -Wiener process with $\tilde{W}(0) = 0$, given on a probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0}, P)$ and $X(0)$ is an \mathcal{F}_0 -adopted random variable. In this case¹⁷

$$\phi_t = \int_0^t a^{-2}(X(0) + \tilde{W}(s))ds$$

and

$$\phi_t^{-1} = \int_0^t a^2(X(0) + \tilde{W}(\phi_s^{-1}))ds$$

Examples: Solutions of Some SDEs¹⁸

1. *Solution for Ornstein-Uhlenbeck (OU) Process Using Change of Time.*

Let S_t satisfy the following SDE:

$$dS_t = -\alpha S_t dt + \sigma dW_t$$

Then S_t may be presented in the following form using the change of time method:

$$S_t = e^{-\alpha t}[S_0 + \tilde{W}(\phi_t^{-1})]$$

where ϕ_t^{-1} satisfies

$$\phi_t^{-1} = \sigma^2 \int_0^t (e^{\alpha s}(S_0 + \tilde{W}(\phi_s^{-1})))^2 ds$$

2. *Solution for Vasićek Process Using Change of Time.*

Let S_t satisfy the following SDE:

$$dS_t = \alpha(b - S_t)dt + \sigma dW_t$$

Then S_t may be presented in the following form using the change of time method

$$S_t = e^{-\alpha t}[S_0 - b + \tilde{W}(\phi_t^{-1})]$$

where ϕ_t^{-1} satisfies

$$\phi_t^{-1} = \sigma^2 \int_0^t (e^{\alpha s} (S_0 - b + \tilde{W}(\phi_s^{-1})) + b)^2 ds$$

The above theorem may also be applied to solve the Cox-Ingersoll-Ross (1985) equation, mean-reversion equation for commodity price (Pilipovic, 1997) and geometric Brownian motion equation (Black-Scholes, 1973).¹⁹

Black-Scholes Formula by Change of Time Method

Let $(\Omega, \mathcal{F}, \mathcal{F}_t, P)$ be a probability space with a sample space Ω , σ -algebra of Borel sets \mathcal{F} and probability P . The filtration $\mathcal{F}_t, t \in [0, T]$ is the natural filtration of a standard Brownian motion $W_t, t \in [0, T]$, and $\mathcal{F}_T = \mathcal{F}$.

Black-Scholes Formula

The well-known Black-Scholes (1973) formula states if we have (B, S) -security market consisting of riskless asset $B(t)$ with interest rate r as a constant

$$dB(t) = rB(t)dt, \quad B(0) > 0, \quad r > 0 \quad (1)$$

and risky asset (stock) $S(t)$

$$dS(t) = \mu S(t)dt + \sigma S(t)dW(t), \quad S(0) > 0 \quad (2)$$

where $\mu \in R$ is an appreciation rate, $\sigma > 0$ is a volatility, then the option price formula for European call option with pay-off function $f(T) = \max(S(T) - K, 0)$ ($K > 0$ is a strike price) has the following look

$$C(T) = S(0)\Phi(y_+) - e^{-rT}K\Phi(y_-) \quad (3)$$

where

$$y_{\pm} := \frac{\ln\left(\frac{S(0)}{K}\right) + \left(r \pm \frac{\sigma^2}{2}\right)T}{\sigma\sqrt{T}} \quad (4)$$

and

$$\Phi(y) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^y e^{-\frac{x^2}{2}} dx \quad (5)$$

Solution of SDE for Geometric Brownian Motion using Change of Time Method

The solution of equation (2) has the following look:

$$S(t) = e^{\mu t} (S(0) + \tilde{W}(\phi_s^{-1})) \quad (6)$$

where $\tilde{W}(t)$ is a one-dimensional Wiener process,

$$\phi_t^{-1} = \sigma^2 \int_0^t [S(0) + \tilde{W}(\phi_s^{-1})]^2 ds$$

and

$$\phi_t = \sigma^{-2} \int_0^t [S(0) + \tilde{W}(s)]^{-2} ds$$

Black-Scholes Formula by Change of Time Method

In a risk-neutral world the dynamic of stock price $S(t)$ has the following look:

$$dS(t) = rS(t)dt + \sigma S(t)dW^*(t) \quad (7)$$

where

$$W^*(t) := W(t) + \frac{\mu - r}{\sigma} t \quad (8)$$

From (6) we have the solution of equation (7)

$$S(t) = e^{rt} [S(0) + \tilde{W}^*(\phi_t^{-1})] \quad (9)$$

where

$$\tilde{W}^*(\phi_t^{-1}) = S(0)(e^{\sigma W^*(t) - \frac{\sigma^2 t}{2}} - 1) \quad (10)$$

and $W^*(t)$ is defined in (8).

Let E_{P^*} be an expectation under risk-neutral measure (or martingale measure) P^* (i.e., process $e^{-rT}S(t)$ is a martingale under the measure P^*).

Then the option pricing formula for European call option with payoff function

$$f(T) = \max[S(T) - K, 0]$$

has the following look

$$\begin{aligned} C(T) &= e^{-rT} E_{P^*}[f(T)] \\ &= e^{-rT} E_{P^*}[\max(S(T) - K, 0)] \end{aligned} \quad (11)$$

Using change of time method we have the following representation for the process $S(t)$ (see (9))

$$S(t) = e^{rt}[S(0) + \tilde{W}^*(\phi_t^{-1})]$$

where $\tilde{W}^*(\phi_t^{-1})$ is defined in (10). From (7)–(11), after substitution $\tilde{W}^*(\phi_t^{-1})$ into (9) and $S(T)$ into (11), it follows that

$$\begin{aligned} C(T) &= e^{-rT} E_{P^*}[\max(S(T) - K, 0)] \\ &= e^{-rT} \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \max[S(0)e^{\sigma u\sqrt{T} + (r - \frac{\sigma^2}{2})T} \\ &\quad - K, 0] e^{-\frac{u^2}{2}} du \end{aligned} \quad (12)$$

Let y_0 be a solution of the following equation

$$S(0)e^{\sigma y\sqrt{T} + (r - \sigma^2/2)T} = K$$

namely,

$$y_0 = \frac{\ln\left(\frac{K}{S(0)}\right) - (r - \sigma^2/2)T}{\sigma\sqrt{T}}.$$

Then (12) may be presented in the following form

$$\begin{aligned} C(T) &= e^{-rT} \frac{1}{\sqrt{2\pi}} \int_{y_0}^{+\infty} (S(0)e^{\sigma u\sqrt{T} + (r - \frac{\sigma^2}{2})T} - K) \\ &\quad \times e^{-\frac{u^2}{2}} du \end{aligned} \quad (13)$$

Finally, straightforward calculation of the integral in the right-hand side of (13) gives us the

Black-Scholes result:²⁰

$$\begin{aligned} C(T) &= \frac{1}{\sqrt{2\pi}} \int_{y_0}^{+\infty} S(0)e^{\sigma u\sqrt{T} - \frac{\sigma^2 T}{2}} e^{-u^2/2} du \\ &\quad - Ke^{-rT}[1 - \Phi(y_0)] \\ &= \frac{S(0)}{\sqrt{2\pi}} \int_{y_0 - \sigma\sqrt{T}}^{+\infty} e^{-u^2/2} du - Ke^{-rT}[1 - \Phi(y_0)] \\ &= S(0)[1 - \Phi(y_0 - \sigma\sqrt{T})] - Ke^{-rT}[1 - \Phi(y_0)] \\ &= S(0)\Phi(y_+) - Ke^{-rT}\Phi(y_-) \end{aligned} \quad (14)$$

where y_{\pm} and $\Phi(y)$ are defined in (4) and (5).

Explicit Option Pricing Formula for Mean-Reverting Asset Model (MRAM) by Change of Time Method

In this section, we consider a risky asset S_t following the mean-reverting stochastic process given by the following stochastic differential equation

$$dS_t = a(L - S_t)dt + \sigma S_t dW_t \quad (15)$$

where W_t is an \mathcal{F}_t -measurable one-dimensional standard Wiener process, $\sigma > 0$ is the volatility, constant L is called the long-term mean of the process, to which it reverts over time, and $a > 0$ measures the “strength” of mean reversion. We find explicit solution of the equation (15) using the change of time method, give some properties of the mean-reverting asset S_t , and present an explicit option pricing formula for the European call option for this mean-reverting asset model of commodity price.

Explicit Solution of SDE for MRAM Equation

$$dS_t = a(L - S_t)dt + \sigma S_t dW_t$$

in (15) has the following solution

$$S_t = e^{-at}[S_0 - L + \tilde{W}(\phi_t^{-1})] + L$$

where $\tilde{W}(\phi_t^{-1})$ is a one-dimensional Wiener process and

$$\phi_t^{-1} = \sigma^2 \int_0^t (S_0 - L + \tilde{W}(\phi_s^{-1}) + e^{as}L)^2 ds$$

which follows from the substitution

$$V_t := e^{at}(S_t - L)$$

and theorem above.

Explicit Option Pricing Formula for European Call Option under Risk-Neutral Measure

In this section, we are going to obtain an explicit option pricing formula for a European call option under risk-neutral measure P^* using the change of time method.

Mean-Reverting Risk-Neutral Asset Model

Consider the model given by (15)

$$dS_t = a(L - S_t)dt + \sigma S_t dW_t$$

We want to find a probability P^* equivalent to P , under which the process $e^{-rt}S_t$ is a martingale, where $r > 0$ is a constant interest rate.

In a risk-neutral world the model in (15) takes the following look:

$$dS_t = a^*(L^* - S_t)dt + \sigma S_t dW_t^* \quad (16)$$

where

$$a^* := a + \lambda\sigma, \quad L^* := \frac{aL}{a + \lambda\sigma} \quad (17)$$

$$W_t^* = W_t + \lambda \int_0^t S(u)du \quad (18)$$

and $\lambda \in R$ is a market price of risk, which follows from the Girsanov theorem.²¹

Now, we are going to apply our method of changing of time to the model (16) to obtain the explicit option pricing formula.

Explicit Solution for Mean-Reverting Risk-Neutral Asset Model

Applying the above results to our model (16) we obtain the explicit solution (19) for our risk-neutral model (16). The explicit solution for the risk-neutral model given by (16) has the following look

$$S_t = e^{-a^*t} [S_0 - L^* + \tilde{W}^*((\phi_t^*)^{-1})] + L \quad (19)$$

where $\tilde{W}^*(t)$ is an \mathcal{F}_t -measurable standard one-dimensional Wiener process in (18) under measure P^* , $(\phi_t^*)^{-1}$ is an inverse function to ϕ_t^* :

$$\phi_t^* = \sigma^{-2} \int_0^t (S_0 - L^* + \tilde{W}^*(s) + e^{a^*s} L^*)^{-2} ds \quad (20)$$

We note that

$$(\phi_t^*)^{-1} = \sigma^2 \int_0^t (S_0 - L^* + \tilde{W}^*((\phi_t^*)^{-1}) + e^{a^*s} L^*)^2 ds$$

where a^* and L^* are defined in (17).

Explicit Option Pricing Formula for European Call Option under Risk-Neutral Measure

The payoff function f_T for the European call option equals

$$f_T = (S_T - K)^+ := \max(S_T - K, 0)$$

where S_T is an asset price, T is an expiration time (maturity), and K is a strike price.

In this way (see (19)),

$$\begin{aligned} f_T &= [e^{-a^*T}(S_0 - L^* + \tilde{W}^*(\phi_T^{-1})) + L^* - K]^+ \\ &= [S(0)e^{-a^*T} e^{\sigma W^*(T) - \frac{\sigma^2 T}{2}} \\ &\quad + a^* L^* e^{-a^*T} e^{\sigma W^*(T) - \frac{\sigma^2 T}{2}} \int_0^T e^{a^*s} e^{-\sigma W^*(s) \frac{\sigma^2 s}{2}} \\ &\quad \times ds - K]^+ \end{aligned} \quad (21)$$

The explicit option pricing formula for the European call option under a risk-neutral measure for mean-reverting asset $S(t)$ in (21) has the following look:

$$\begin{aligned} C_T^* &= e^{-(r+a^*)T} S(0) \Phi(y_+) - e^{-rT} K \Phi(y_-) \\ &\quad + L^* e^{-(r+a^*)T} [(e^{a^*T} - 1) - \int_0^{y_0} z F_T^*(dz)] \end{aligned} \quad (22)$$

where y_0 is the solution of the following equation

$$\begin{aligned} y_0 &= \frac{\ln\left(\frac{K}{S(0)}\right) + \left(\frac{\sigma^2}{2} + a^*\right)T}{\sigma\sqrt{T}} \\ &\quad - \frac{\ln\left(1 + \frac{a^*L^*}{S(0)} \int_0^T e^{a^*s} e^{-\sigma y_0 \sqrt{s} + \frac{\sigma^2 s}{2}} ds\right)}{\sigma\sqrt{T}} \end{aligned} \quad (23)$$

$$y^+ := \sigma\sqrt{T} - y_0 \quad \text{and} \quad y_- := -y_0,$$

$$a^* := a + \lambda\sigma, \quad L^* := \frac{aL}{a + \lambda\sigma} \quad (24)$$

λ is the market price of risk and $F_T^*(dz)$ is the distribution with characteristic function

$$\phi_\lambda^*(T) = e^{i\lambda(e^{a^*T}-1)}, \quad i := \sqrt{-1}, \quad \lambda \in \mathbb{C}$$

This result can be obtained from the following expression

$$\begin{aligned} C_T &:= e^{-rT} E_{P^*} f_T \\ &= e^{-rT} E_{P^*} [e^{-a^*T} (S_0 - L + \tilde{W}^*(\phi_T^{-1})) + L^* - K]^+ \\ &= \frac{1}{\sqrt{2\pi}} e^{-rT} \int_{-\infty}^{+\infty} \max[S(0)e^{-a^*T} e^{\sigma y \sqrt{T} - \frac{\sigma^2 T}{2}} \\ &\quad + aLe^{-a^*T} e^{\sigma y \sqrt{T} - \frac{\sigma^2 T}{2}} \int_0^T e^{a^*s} e^{-\sigma y \sqrt{s} + \frac{\sigma^2 s}{2}} ds \\ &\quad - K, 0] e^{-\frac{y^2}{2}} dy \end{aligned}$$

and above-mentioned results.

Connection with Black-Scholes Result: $L^* = 0$ and $a^* = -r$ and Black-Scholes formula follows!

If $L^* = 0$ and $a^* = -r$ then we obtain from (22)

$$C_T = S(0)\Phi(y_+) - e^{-rT}K\Phi(y_-) \quad (25)$$

where

$$y_+ := \sigma\sqrt{T} - y_0 \quad \text{and} \quad y_- := -y_0 \quad (26)$$

and y_0 is the solution of the following equation (see (23))

$$S(0)e^{-rT}e^{\sigma y_0 \sqrt{T} - \frac{\sigma^2 T}{2}} = K$$

or

$$y_0 = \frac{\ln\left(\frac{K}{S(0)}\right) + \left(\frac{\sigma^2}{2} - r\right)T}{\sigma\sqrt{T}} \quad (27)$$

and

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{y^2}{2}} dy$$

But (25)–(27) is exactly the well-known Black-Scholes result!

In this way, we can see that the option pricing formula in (22) for the mean-reverting asset $S(t)$ consists of a Black-Scholes part and an additional part due to mean reversion.

The results of this section may be also used to model and price variance and volatility swaps in energy and commodity markets for assets with stochastic volatility that are described

by a continuous-time mean-reverting GARCH model; see Swishchuk (2010a).

KEY POINTS

- The main idea of the change of time method is to change time from t to a nonnegative process $T(t)$ with nondecreasing sample paths (e.g., subordinator).
- Many Lévy processes may be written as time-changed Brownian motion.
- Lévy processes can also be used as a time change for other Lévy processes (subordinators).
- Change of time can be used to introduce stochastic volatility or solve many stochastic differential equations.
- Using change of time, we can get an option pricing formula for an asset following geometric Brownian motion such as the Black-Scholes formula.
- Using change of time, we can get an explicit option pricing formula for an asset following the mean-reverting process, such as continuous-time GARCH process.

Term Structure Modeling

The Concept and Measures of Interest Rate Volatility

ALEXANDER LEVIN, PhD

Director, Financial Engineering, Andrew Davidson & Co., Inc.

Abstract: The knowledge of interest rates and cash flows represents the basis for valuation of fixed income financial instruments. In reality, not only are future interest rates random, but the future cash flows of many securitized investments are also uncertain, as they depend (are “contingent”) on interest rates. Valuation of rate options and embedded option bonds, including MBS and ABS, requires sophisticated models of this randomness.

In this entry, we introduce the concepts of market volatility and discuss how it is measured. The dynamics of rates are subject to market forces, mean reversion, and combinations of diffusions and jumps.

BASIC DEFINITIONS AND FIRST FINDINGS

We can't tell in advance what interest rates will be. Investors may be either enriched or bankrupted from sudden changes in interest rates. Financial institutions devote considerable resources to risk management and hedging. Yet, if future interest rates were deterministic, there would be no need to hedge. Coping with uncertainty is a central feature of investment markets.

The pricing of options and embedded-options instruments utilizes a statistical concept to describe the magnitude of potential interest rates changes. The key notion is the volatility of interest rates. While this term conjures up images

of instability, flares of activity, and unpredictability, it is actually a very specific description of the range of possible outcomes. More precisely, volatility can be defined as the standard deviation of a rate's annualized daily increments. Table 1 provides an example for yields on the 10-year Treasury measured over 10 consecutive business days. As part of the measurement, we will be taking a daily time series and then transforming into “absolute returns” and “relative returns”—much like measuring portfolio performance.

The absolute rate changes are computed by taking the difference between the interest rates on successive days. The relative changes are computed by dividing the absolute change by the starting rate. For example, for the first day the absolute change is $5.00343 - 5.03234 = -0.0289$. The relative increment is $-0.0289 / 5.03234 = -0.0057$. In order to calculate the daily volatility, we just take the standard deviation of the daily absolute and relative change series. In the example above, the standard

Table 1 Example of Volatility Calculations

Date	Rate	Absolute Increments	Relative Increments
03-Jun-02	5.03234		
04-Jun-02	5.00343	-0.0289	-0.0057
05-Jun-02	5.04900	0.0456	0.0091
06-Jun-02	5.01176	-0.0372	-0.0074
07-Jun-02	5.06165	0.0499	0.0100
10-Jun-02	5.03885	-0.0228	-0.0045
11-Jun-02	4.97500	-0.0639	-0.0127
12-Jun-02	4.95004	-0.0250	-0.0050
13-Jun-02	4.90280	-0.0472	-0.0095
14-Jun-02	4.80276	-0.1000	-0.0204

deviations are 0.048 (absolute increments) and 0.00966 (relative increments). The former number is the standard deviation for daily absolute increments; the latter number represents that of the daily relative changes. To compute volatility, we place these daily measures on an annual basis scaling by the number of trading days in the year (approximately 260):

Relative Volatility

$$= \text{Daily Standard Relative Deviation} \times \sqrt{260}$$

$$= 0.00966 \times \sqrt{260} = 0.1557$$

Absolute Volatility

$$= \text{Daily Standard Absolute Deviation} \times \sqrt{260}$$

$$= 0.0480 \times \sqrt{260} = 0.773$$

Thus, in our example of the 10-day yield series, we would calculate the annual volatility as 77.3 basis points (absolute) or 15.57% (relative). The relative volatility times the average yield for the period $0.1557 \times 4.983 = 0.776$ is close to the absolute yield volatility of 0.773—as one would expect.

The second relevant clarification may damage a naïve understanding of volatility as the annual standard deviation. Volatility measures only the pace of uncertainty; this concept does not assume the daily-measured volatility remains constant over time, just as when driving in traffic with starts and stops there is a difference between instantaneous speed and the average velocity. Third, an important assumption for annualizing the daily volatilities is that

the *daily increments* are serially independent. If there is a relationship between rate changes on one day and another day, then we say there is serial correlation. The “square-root rule” will not be an accurate measure of the annual volatility if there is serial correlation in the random process. Figure 1 illustrates that volatility has been volatile.

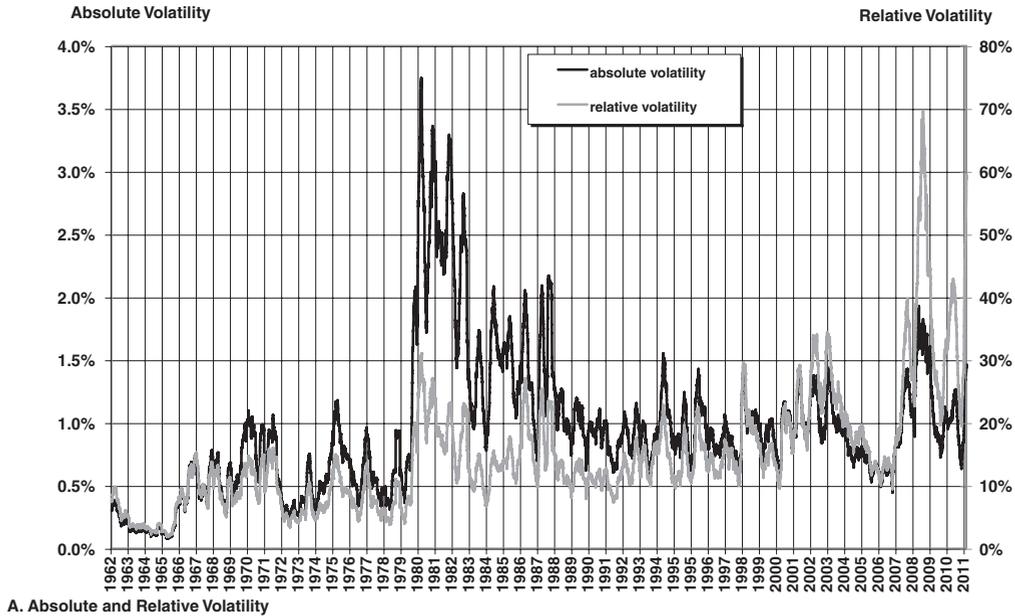

In the 1980s, both volatility measures exhibited instability, although the relative one appeared to be much more stable. However, since the 1990s, the absolute volatility measure has become more stable, oscillating around 1% (100 basis points). Based on these observations, it is not hard to understand why during different time periods, the relative volatility was moving inversely, and the absolute volatility directly, with respect to the rate level. Aside from the explicit level-related effect, both volatility measures seemingly synchronously react to economic disturbances. Pricing in the interest rate options market reflects these important findings.

Different points of the yield curve have differing volatility, too. This observation suggests that not only do the rates have a “term structure,” but their volatility has a term structure as well. A hump shape of such a volatility curve is often observed (see Figure 2). It can be attributed to (1) absence of change in the short rates unless regulators take actions and (2) the dampening force of the mean reversion. We will explain both factors further in the entry.

A DIFFUSIVE MODEL FOR RANDOMNESS

Can we describe the randomness mathematically? It is perhaps simpler than it sounds. In fact, having become acquainted with volatility, we did most of the task. A general diffusive model for an interest rate process that describes how interest rates will vary over time, $r(t)$, will have the following form:

$$dr = (\text{Drift})dt + (\text{Volatility})dz \quad (1)$$

A. Absolute and Relative Volatility

B. Rate Level

Figure 1 History of Volatility for the 10-year Treasury Yield

What does this mean? Notations dr and dt refer to small increments measured over infinitesimally short time. Variable dz represents small changes in $z(t)$ which is called *Brownian motion*, also known as the Wiener process. It is the source of randomness. We cannot control the exact value of this variable. *Drift* and *volatility*

describe how the changes in rates are related to changes in time and the random variable dz . Mathematical model (1) can be thought of in the following way: The change in interest rate over a small time period is the result of a number representing systematic drift times the amount of time change plus a random shock scaled by

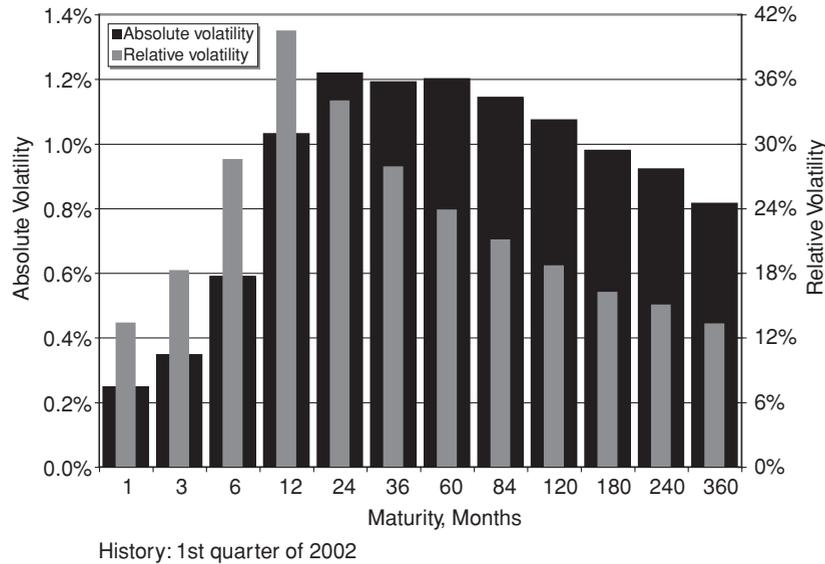

Figure 2 Historical Volatility Term Structure for the Swap Rates

the amount of volatility.

$$\Delta r = (\text{Drift})(\text{Passage of time}) + (\text{Volatility}) \times (\text{Random shock})$$

A Brief Excursion to Brownian Motion

Brownian motion:

- Is continuous
- Is normally distributed
- Has a zero mean (“centered”)
- Has time increments that are serially independent
- Has its own volatility scaled to 1

Therefore, $z(t)$ has a standard deviation of \sqrt{t} (for the same reason that a square root appears in the annualization of daily volatility). Any particular function $z(t)$ is said to be a “realization” or a “sample path” of the Brownian motion. The Brownian motion, therefore, can be thought of as a container of random paths subject to the conditions described above. Figure 3 depicts a sample path and the single- and double-standard deviation zones.

With the use of *volatility* multiples, we can scale the rate process to any volatility level. The *drift* variable simulates a systematic, nonrandom tendency. For example, it can model a central tendency function known as *mean reversion*. Equation (1) is called the *stochastic differential equation*. Both multiples, *drift* and *volatility* do not have to be constants. They can be functions of time, t , and rate, r . Any particular specification of $drift(t,r)$ and $volatility(t,r)$ leads to a specific rate model, but not necessarily a good one. At this stage, it is enough to understand that a good model can be a strong quantitative pricing tool. Although we cannot know what the random variable $z(t)$ is going to do, we, at least, can simulate its behavior with a large number of random scenarios. The Monte Carlo method draws on this idea. On the other hand, we may be able to do some intelligent analytical work making the brute-force simulations unnecessary. We could also make sure that the model is consistent with (“calibrated to”) prices of widely traded interest rate instruments; then we will feel more confident applying it to the exotic options or the market for mortgage-backed securities (MBSs) and asset-backed securities (ABSs).

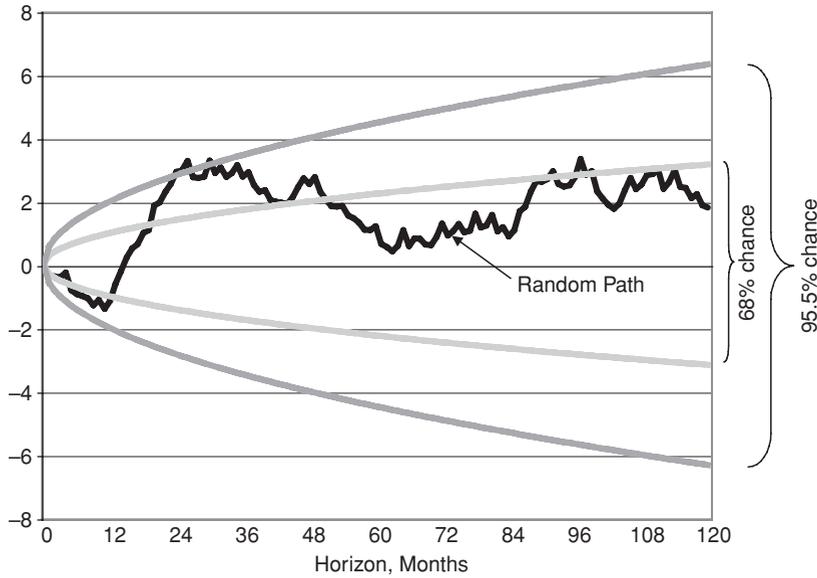

Figure 3 Brownian Motion's Sample Path with Deviation Zones

MEAN REVERSION AND MARKET STABILITY

Consider the following special form of equation (1): $dr = 5r dt + \sigma dz$. Can this equation model an actual interest rate? Since the formula shows that the change in interest rate increases with changes in time, the average rate will continue to grow. Utilizing calculus, we note that the solution to this equation will not only grow with time, but will grow exponentially as it contains an e^{5t} term. Since interest rates cannot increase exponentially forever (at least, they never have), we need to dismiss this formula as inappropriate for the job.

How about $dr = \sigma dz$? The drift is chosen to be zero, and provided that the initial value $r(0)$ is known, the process will randomly evolve around this value, on average. Whether the initial rate is high or low, the model will stay centered around it. The standard deviation, as we already know, will grow as \sqrt{t} . This may not be a very good thing either. A century from now, the magnitude of the standard deviation will be huge, at ten times annual volatility. Figure 1B demonstrated that interest rates tend to stay within a range.

Both models briefly reviewed above suffer with the same disease: They are unstable. Observable objects in economy, finance, engineering, or physics tend to be stable; otherwise, they would not be able to exist long enough to be observed. The feature making financial markets stable is known as mean reversion. It is simply a properly chosen specification of the drift term that would ensure the dampening effect (also known as central tendency). If the rate randomly has grown too high or fallen too low, the drift term will help "return" it back. Here is an example:

$$dr = a(r_{\infty} - r)dt + \sigma dz \tag{2}$$

where mean reversion parameter $a > 0$. This time, the solution will contain e^{-at} , a decaying component that indicates stability. The mean converges to parameter r_{∞} , the long-term equilibrium (now we see the point for this strange notation). The standard deviation will grow with time as

$$\sigma \sqrt{(1 - e^{-2at})/2a}$$

and converges to

$$\sigma/\sqrt{2a}$$

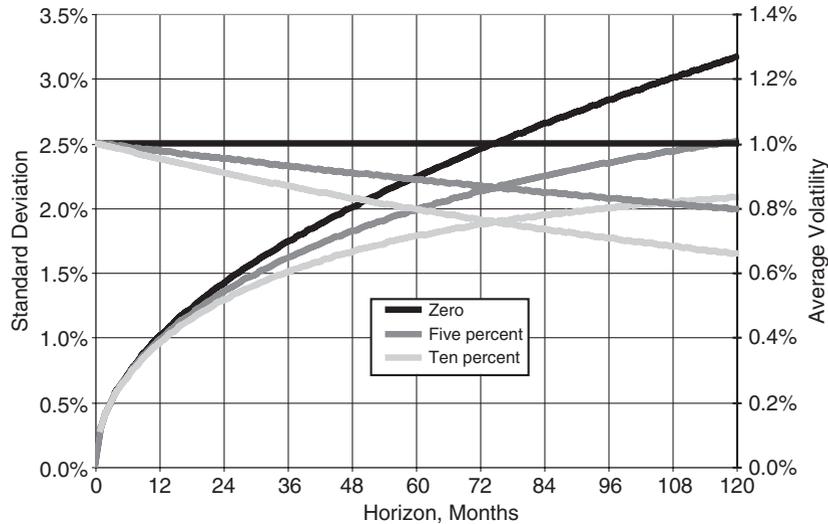

Figure 4 Standard Deviation and Average Volatility for Different Values of a

as the horizon extends. Figure 4 compares the standard deviation (lines launching from the origin) and equivalent (“average”) volatility for different levels of mean reversion including the zero one ($\sigma = 1\%$ was assumed).

Mean reversion, therefore, stabilizes the market. It also explains why volatility is typically measured on a daily basis; in the presence of mean reversion, the average volatility measured over a time horizon generally depends on this horizon. For example, if $a = 10\%$, only 95% of actual volatility is seen in annual increments.

If $r(t)$ in (2) is the short market rate, then every other rate (the 5-year, the 10-year, etc.) can be derived as a function of it. In particular, for mean-reverting models, volatility of *long rates* should eventually fade with maturity of the rate, and it does happen as seen in Figure 2. Mathematically, it is a direct consequence of the mean reversion: The *short rate's* uncertainty gets limited going forward, thereby making long-term bonds less volatile now. Economically, discount rates for very remote cash flows should be almost certain; otherwise their present values would be infinitely risky.

Does it seem that model (2) makes sense? Well, Vasicek (1977) noticed it, as one of the first interest rate models. It is been popular and

important since and was a basis for many of the models that are used today.

THE RATE DISTRIBUTION

Equation (2) is a linear stochastic differential equation disturbed by a Brownian motion. The math tells us that the output of this equation, rate $r(t)$, is going to be normally distributed. Although it makes the model tractable, the negative rates are not precluded, which may or may not be a problem. Arguably, the actual rates should stay positive—at least, they almost always have been. When using process (2), odds of negative rates grow with future time, as the present value falls. In addition, mortgages and related securities are amortizing and may have small balances and cash flows years from now. Levin (2004) provided a quantitative support for the use of normal distribution by showing it does not distort options’ value materially.

The fact that a Brownian motion is normally distributed does not require that the rate process be such. For example, considering exponential transformation $R = \exp(r)$ and using R as the rate, rather than r , we ensure that the rate

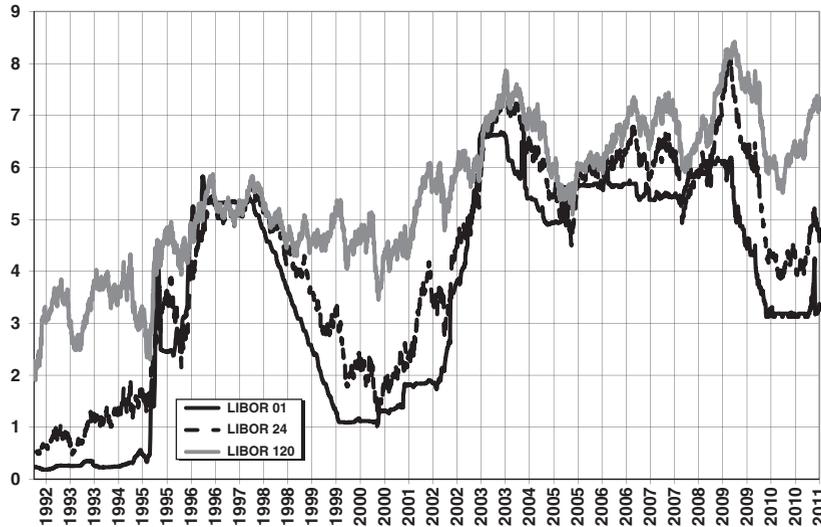

Figure 5 Jumpy and Continuous Interest Rates

remains positive. Such a process is said to have lognormal distribution. The mean and standard deviation for this known distribution is explicitly stated through the mean μ and the standard deviation σ of the original variable, $r(t)$:

$$E(R) = \exp\left(\mu + \frac{1}{2}\sigma^2\right)$$

$$std(R) = \exp\left(\mu + \frac{1}{2}\sigma^2\right)\sqrt{\exp(\sigma^2) - 1}$$

Another popular example is the squared transformation, $R = r^2$, that also guarantees that rate R stays positive; the distribution of such defined rate is known as noncentral χ^2 . For the squared transformation,

$$E(R) = \mu^2 + \sigma^2$$

$$std(R) = \sigma\sqrt{2\sigma^2 + 4\mu^2}$$

INTEREST RATE JUMPS

Stochastic differential equation (1) is not the most general mathematical form of a random process. It applies only to *diffusions*, that is, continuous random processes. Stochastic calculus considers many other forms of randomness; an important one is called random *jumps* or random events. To appreciate this type of random-

ness, let us consider the history of three rates, the 1-month London Interbank Offered Rate (LIBOR) (“LIBOR 01”), the 2-year swap (“LIBOR 24”), and the 10-year swap rate (“LIBOR 120”), depicted in Figure 5.

Both swap rates change almost continuously, day after day, and little by little, at times randomly oscillating, in response to the market forces. The 1-month rate was changing in a suspiciously smooth fashion between sudden jumps featuring apparent and prolonged plateaus that are not seen for the swap rates. For example, in 2002 to 2004, it had been barely changing for a while, and then plunged responding to the Fed’s actions. Furthermore, whereas the visual dynamics for all three rates seem to resemble one another, statistical measurements of correlation between daily increments overwhelmingly reject such a conclusion. For this 18-year-long history (over 4,500 observations) we computed a small 7% correlation between daily increments of the 1-month and the 2-year rates, and an even smaller 4% correlation between 1-month and 10-year rates. What if we measure correlations between increments in monthly averages (216 observations), thereby filtering out the disparity between daily dynamics? Then the 7% goes way up to 46% and

Table 2 Empirical Correlations between Periodic Increments, 1992–2010 History

	Daily	Monthly	Quarterly	Semiannually	Annually
2-year to 1-month	7%	46	65	81	90
10-year to 1-month	4	24	40	51	71
Total observations	4,527	216	71	35	17

the 4% to 24%, and the interrater correlations continue to improve steadily as we extend the averaging period (Table 2).

These objective facts suggest that a stochastic diffusive model suitable for swap rates may be not perfectly appropriate for short rates. A random jump component may be necessary to explain the actual short-rate behavior and associated option pricing. One popular mathematical form of jumps is the *Poisson* process. It is simply a random occurrence of events described by a single parameter λ called frequency or intensity. The average number of events to occur during a time interval of t is equal to λt ; curiously enough the variance of this number is equal to λt too. Probability that we will have exactly j events during this time interval is equal to $e^{-\lambda t}(\lambda t)^j/j!$. It is only the period's length that really matters, not when the period starts—for this reason, the Poisson process can't be used to describe, say, human deaths or bulb failures when the attained age is a strong factor. However, it is plausible to assume that the Poisson jumps describe some events in financial markets.

Aside from the jumps' arrival, the size of jumps can be also random. Merton (1976) introduced an option-pricing model when the underlying process includes Poisson jumps with normally distributed magnitude. Using mathematical notations, we can express the model as

$$dr = (\text{Drift})dt + (\text{Volatility})dz + (\text{Jump Volatility})dN \quad (3)$$

where N is the Poisson-Merton jump variable. When jump occurs, dN is drawn from the standard normal distribution $N[0,1]$; it stays 0 oth-

erwise. In a less strict notations,

$$\begin{aligned} \Delta r = & (\text{Drift})(\text{Passage of time}) \\ & + (\text{Volatility})(\text{Random shock}) \\ & + (\text{Jump volatility})(\text{Random jump}) \end{aligned}$$

The practical difference between random shock and random jump is that, for a small time interval, the former is small, but nonzero, whereas the latter is mostly zero and rarely finite. Hence, equation (3) describes a more general stochastic process combining diffusion and jumps ("jump-diffusion"). Notably, mathematical variance of the Poisson process $N(t)$ is too proportional to the time horizon t . This fact allows aligning interpretations of $\sigma_d \equiv \text{Volatility}$ and $\sigma_j \equiv \text{Jump Volatility}$: for very small t , the standard deviation of $r(t)$ is equal to

$$t\sqrt{\sigma_d^2 + \lambda\sigma_j^2}$$

meaning that the mixed volatility will be simply

$$\sigma = \sqrt{\sigma_d^2 + \lambda\sigma_j^2}$$

Furthermore, if we generalize the linear mean-reverting Vasicek model given by (2) by adding a jump term, then expressions for the mean and the standard deviation of $r(t)$ won't change; it will be enough to replace σ .

At first, it is tempting to interpret a jump-diffusion process as diffusion with another volatility scale. In reality, probability distributions of these two stochastic patterns are different. Inclusion of jumps "fattens" the distribution's tail (see Table 3) and is much more suitable for modeling and pricing rare events like a corporation's defaults or credit downgrade, a financial crisis, reaching a very remote option's strike, or change in the short rate over a fairly short horizon.

Table 3 Comparison of Distribution's Tails for Poisson-Merton Jump Processes

Value of λt	$\text{Prob}(r < \mu - 4\sigma)$	$\text{Prob}(r < \mu - 3\sigma)$	$\text{Prob}(r < \mu - 2\sigma)$	$\text{Prob}(r < \mu - 1\sigma)$
0.2	0.789%	1.777%	3.505%	6.022%
1	0.158	0.753	3.357	12.568
5	0.027	0.303	2.559	14.732
Infinite (normal)	0.003	0.135	2.275	15.866

Models with Poisson-Merton processes converge to normal when the value of λt is large (frequent jumps are similar to diffusion), but may produce significantly different results when it is small.

Stochastic differential equations (1) and (3) can be viewed as building blocks for the interest rate modeling. Some models used today in the financial industry are multifactor with the short rate $r(t)$ defined not as the solution to equations (1) or (3), but as their sum. When modeling LIBOR, neither the jump arrivals have to be Poissonian, nor the magnitude has to be normal. For example, Chan et al. (2003) developed a model with rate jumps timed to periodic Fed meetings, and the magnitude being a random multiple of 25 bps. There exist other modeling views at interest rate dynamics that we don't cover in this entry including continuous randomness with stochastic volatility levels; see James and Webber (2000) for a comprehensive overview.

KEY POINTS

- The most common way of simulating interest rates' uncertainty is employing stochastic differential equations containing drift and volatility terms.
- In older times, absolute volatility was directionally related to the rate's level; this relationship has gradually disappeared.

- The drift term must contain a mean reversion, that is, stabilization force.
- Actual short rates (LIBOR) have been historically jumpy and require adding random jumps to diffusions.

Short-Rate Term Structure Models

ALEXANDER LEVIN, PhD

Director, Financial Engineering, Andrew Davidson & Co., Inc.

Abstract: Market randomness makes the fair value of a financial instrument an expectation. It also requires a rigorous quantification of the dynamics of interest rates; that is, a well-defined interest rate model. Prices of interest rate options and options embedded in bonds such as corporate or agency callable debts, mortgage-backed securities, and asset-backed securities will firmly depend on this modeling work. Contemporary interest rate models employ the available information about currently observed forward rates and vanilla European options and are “calibrated” to them. The relationships between bond rates should preclude arbitrage. Some analytically tractable models ensure these properties explicitly. Selecting the “best” term structure model is becoming more a conscientious task and less a matter of taste. Measuring “volatility skew” for widely traded swaptions is a simple technique that yields rich results. Another method is computing volatility indexes produced by different models and tracking their stability. Recent trading history confirms normalization of the swaption market making the Hull-White model, the extended Cox-Ingersoll-Ross model, or the squared Gaussian model more attractive than formerly popular lognormal models. Single-factor models cannot value accurately curve options or some exotic derivatives that are exposed to the yield curve shape and require multifactor modeling work. The affine theory offers a systematic method of constructing such models. It also allows for jump-diffusion extensions that may be necessary to explain volatility smile; that is, an excessive convexity of the Black volatility as a function of strike.

This entry introduces a family of models for stochastic behavior of interest rates and the principles of their design widely used by market participants.

THE CONCEPT OF SHORT-RATE MODELING

Why do we call interest rate models term-structure models? Aren't there too many rates for one model? The tree-based valuation ex-

amples found in many books and research papers show us that we can value an any-maturity bond and thereby reconstruct the entire term structure using only dynamics of one-period rate (see, for example, Davidson et al., 2003 [Chapter 12], and Fabozzi, 1994). Interest rate models operating with the short (one-period) rate $r(t)$ as their main object are commonly referred to as “short-rate models.” They are different by construction from so-called “forward rate models,” such as the Heath-Jarrow-Morton model (Heath, Jarrow,

and Morton, 1992) or the Brace-Gatarek-Musiela model (Brace, Gatarek, and Musiela, 1997). Both types of interest rate modeling are designed to solve the same problems and are widely used for valuation of fixed income options and embedded option bonds, but operate with different objects. Unlike the short-rate modeling family, forward rate models employ and randomly evolve the entire forward curve of the short rate, $f(t, T)$, in which the t is time and T is the forward time, to which the short rate applies.

We restrict our attention solely to the short-rate modeling. This term does not assume that any short-rate term structure model is a one-factor model or depends only on the short rate.

The Arbitrage-Free Interrate Relationship

Let us assume that we have a stochastic process, possibly multifactor, describing the short rate dynamics $r(t)$. Let us denote $P_T(t)$ to be the market price observed at time t of a T -maturity zero-coupon bond; that is, a bond paying \$1 at $t + T$. This price is exponential to the yield to maturity ("rate") $r_T(t)$ of this bond: $P_T(t) = \exp[-r_T(t)T]$. However, we can use the arbitrage argument claiming that, once prices of instruments reflect rate expectations and risks, there should exist no advantage or disadvantage in investing in the zero-coupon bond over continuous reinvesting into the short rate. Hence, the same price should be equal to

$$P_T(t) = E \left[\exp \left[- \int_t^{t+T} r(\tau) d\tau \right] \right]$$

where E denotes the arbitrage-free expectation.

Equating these two expressions, we get

$$r_T(t) = -\frac{1}{T} \text{Ln} E \left[\exp \left[- \int_t^{t+T} r(\tau) d\tau \right] \right] \quad (1)$$

Formula (1) allows us to compute any-maturity zero-coupon rates via some expectation involving random behavior of the short rate. Of course, once we establish the entire zero-coupon curve, we can restore a yield for any other bond including a coupon-paying one. To compute the expectation in (1), we must know two things: stochastic equation (or equations) for $r(\tau)$ and initial (time t) conditions. The latter represents public information about the market at time t and includes every factor affecting the short rate. Therefore, it would be correct to state that an any-maturity rate can be recovered using only factors that determine the evolution of the short rate. In particular, if only one Brownian motion drives the short rate dynamics, it will define the entire yield curve as well.

Consistency with the Initial Yield Curve

Let us apply the interrater relationship (1) to the initial point of time, $t = 0$:

$$r_T(0) = -\frac{1}{T} \text{Ln} E \left[\exp \left[- \int_0^T r(\tau) d\tau \right] \right] \quad (2)$$

The left-hand side of this formula is known from today's term structure of interest rates. Hence, the short rate dynamics $r(t)$ must be such as to ensure (2) holds. In practical terms, adjusting a rate process to fit the initial yield curve is part of a more general task often termed "calibration." Without this necessary step, an interest rate model can't be used to value even simple, option-free bonds. Computation of expectation in formulas (1) and (2) can be done numerically or, in some models, analytically.

Consistency with European Option Values

If a term structure model is built to value complex derivative instruments, it must value, at minimum, simple European options. Suppose

we have an option that is exercised at a future point of time t and generates a cash flow that we denote $g[r(t)]$; that is, some nonlinear function of the short rate observed at t . Note that the actual option's exercise may be triggered by a long, rather than the short, rate; nevertheless, it will depend either on $r(t)$ (single-factor models) or all market factors (*multifactor models*) known at t . The value of the option is going to be

$$\text{option} = E \left[g[r(t)] \exp \left[- \int_0^t r(\tau) d\tau \right] \right] \quad (3)$$

where E denotes the same expectation as before.

We may now demand that the short rate process $r(t)$ produces options values (3) that match market prices. Most commonly, term structure models are calibrated to LIBOR caps, or European options on swaps (swaptions), or both. These are standard, widely traded European options. For example, a call option on a T -maturity swap will generate cash flow equal to $g[r(t)] = A_T(t)[K - c_T(t)]^+$ where A denotes annuity, c denotes the swap rate, both measured at t , and superscript “+” indicates that only a positive value is taken. Another standard derivative is the LIBOR cap made of “caplets,” that is, European calls on some relatively short rate. A T -maturity LIBOR caplet ($T = 3$ months for standard caps) expiring at t pays $[r_T(t) - K]^+$ at $t + T$. To recognize the time difference T between the caplet's expiry and the actual pay, we can move the payoff from $t + T$ to t and express it as $g[r(t)] = [r_T(t) - K]^+ / (1 + Tr_T(t))$. We then have to make sure that formula (3) yields correct values for the caplets. Note that the cap market does not usually quote caplets directly; however, their values can be assessed by bootstrapping.

SINGLE-FACTOR SHORT-RATE MODELS

In this section, we describe several different single-factor models, which employ the

short rate as the only factor. We also give some evidence on the relative performance of the models. For each of the models, we emphasize three key aspects: the model's formulation, its arbitrage-free calibration, and the interrate relationship that recovers the entire term structure contingent on the dynamics of the short rate.

The Hull-White/Vasicek Model

The Hull-White (HW) model (Hull and White, 1994) describes the dynamics of the short rate $r(t)$ in the form given by

$$dr = a(t)(\theta(t) - r)dt + \sigma(t)dz \quad (4)$$

Here, $a(t)$ denotes *mean reversion*, $\sigma(t)$ stands for volatility; both can be time-dependent. Function $\theta(t)$ is sometimes referred to as “arbitrage-free” drift. This terminology is caused by the fact that, by selecting proper $\theta(t)$, we can match any observed yield curve. The HW model was preceded by the Vasicek model having $\theta(t) = 0$. The short rate is normally distributed in this model, so the volatility represents absolute rather than relative changes.

This can be seen mathematically as (4) is a linear equation disturbed by the Brownian motion (a normally distributed variable); the short rate is normally distributed as well. Therefore, its integral is normally distributed too, and the expectation found in the right-hand side of formulas (1), (2), and, in some cases, (3) can be computed in a closed form. Without going through the math we provide here the analytical *calibration* results to the observed short forward curve $f(t)$ for the constant-parameter case:

$$\theta(t) = f(t) + \frac{1}{a} \frac{df(t)}{dt} + \frac{\sigma^2}{2a^2} (1 - e^{-2at}) \quad (5)$$

The short rate's expectation is found as

$$E[r(t)] = f(t) + \frac{\sigma^2}{2a^2} (1 - e^{-at})^2 \quad (6)$$

The last term in (6) is called the convexity adjustment; that is, the difference between mathematically expected short rates in the future and

the forward short rates. This adjustment is proportional to volatility squared; for zero mean reversion, it is simply equal to $\frac{1}{2}\sigma^2t$. It is therefore up to financial engineers to make sure the convexity adjustment is properly implemented in a pricing system; it is very volatility sensitive.

The expected value for any long, T -maturity, zero-coupon rate is proven to be in the same form: forward rate + convexity adjustment. This time, the exact formula for this relation is

$$E[r_T(t)] = f_T(t) + \frac{\sigma^2}{4a^3T}(1 - e^{-aT})[2(1 - e^{-at})^2 + (1 - e^{-2at})(1 - e^{-aT})] \quad (7)$$

Any long zero-coupon rate is normally distributed too and proven to be linear in the short rate; deviations from their respective mean levels are related as

$$\frac{\Delta r_T}{\Delta r} \equiv \frac{r_T(t) - E[r_T(t)]}{r(t) - E[r(t)]} = \frac{1 - e^{-aT}}{aT} \equiv B_T \quad (8)$$

The function B_T of maturity T plays an important role in the HW model. It helps, for example, to link the *short-rate volatility* to the long-rate one and explicitly calibrate it to the market. If $a = 0$, this function becomes identical to 1, regardless the maturity T . This important special case allows for a pure parallel change in the entire curve (every point moves by the same amount). This particular specification can be suitable for standardized risk measurement tests.

The HW model is a very tractable arbitrage-free model, which allows for the use of analytical solutions as well as Monte Carlo simulation. The volatility σ and mean reversion a can be analytically calibrated to European options on zero-coupon bonds. Most commonly, the HW model is calibrated to either a set of short-rate options (LIBOR caps) or swaptions. In the later case, very good approximations can be constructed (see Levin, 2001; Musiela and Rutkowski, 2000). The model's chief drawback is that it produces negative interest rates. However, with mean reversion, the effect of negative

rates is reduced. The rate history of the 1990s and 2000s supports this type of formulation of a term structure model.

The Cox-Ingersoll-Ross Model

The Cox-Ingersoll-Ross model (CIR model) is a unique example of a model supported by the general equilibrium arguments (see Cox, Ingersoll, and Ross, 1985). CIR argued that the fixed income investment opportunities should not be dominated by neither expected return (the rate), nor the risk. The latter was associated with the return variance, thus suggesting that volatility-squared should be of the same magnitude as the rate:

$$dr = a(t)(\theta(t) - r)dt + \sigma(t)\sqrt{r} dz \quad (9)$$

Equation (9) is actually a no-arbitrage extension to the "original CIR" that allows fitting the initial rate and volatility curves. Since the volatility term is proportional to the square root of the short rate, the latter is meant to remain positive. The extended CIR model is analytically tractable, but to a lesser extent than the HW model. Perhaps the most important result of CIR is that the long zero-coupon rates are also proven linear in the short rate—in line with (8). However, the slope function has now a quite different form; it depends on both maturity T and time t and is found as $B_T(t) = -b(t, t + T)/T$. Function $b(t, T)$ used in this expression solves a Ricatti-type differential equation, considered for any fixed maturity T :

$$\frac{db(t, T)}{dt} = a(t)b(t, T) - \frac{1}{2}\sigma^2(t)b^2(t, T) + 1 \quad (10)$$

subject to terminal condition $b(T, T) = 0$.

If the mean reversion a and "CIR volatility" σ are constant (the "original CIR"), equation (10) allows for an explicit solution. In this case, $b(t, T)$ is a function of $T - t$ only, and B_T is appeared to be time-independent:

$$B_T = \frac{2(e^{\gamma T} - 1)}{(\gamma T + aT)(e^{\gamma T} - 1) + 2\gamma T} \quad (11)$$

where $\gamma = \sqrt{a^2 + 2\sigma^2}$.

Without a mean reversion, this formula reduces to a more concise

$$B_T = \frac{\tanh(\gamma T/2)}{(\gamma T/2)}$$

Note that this ratio is always less than 1. This means that the long rates are less volatile than the short one, even without a mean reversion. This is in contrast to the HW model where, with $a = 0$, the yield curve would experience a strictly parallel reaction to a short rate shock.

Generally speaking, calibration to the currently observed short forward curve $f(T)$ cannot be done as elegantly and explicitly as in the HW model. Once the $b(t, T)$ function is found, the calibrating function $\theta(t)$ satisfies an integral equation:

$$-f(T) = \int_0^T \frac{db(t, T)}{dT} \theta(t) a(t) dt + \frac{db(0, T)}{dT} r_0 \tag{12}$$

Numerical methods, well developed for integral equations, should be employed.

It is established that all zero-coupon rates, under the CIR model, have noncentral χ^2 distributions and remain positive. Economic rationale, nonnegative rates, and analytic tractability have made the CIR model deservedly popular; it is one of the most attractive and useful interest rate models. It is also consistent with the Japanese market and some periods of the U.S. rate history when rates were very low.

The Squared Gaussian Model

To describe the squared Gaussian model (SqG model, and also known as the quadratic model), we employ a linear differential equation (4) only to define an auxiliary variable $x(t)$; we then define the short rate in a form of its square:

$$\begin{aligned} dx &= -a(t)xdt + \sigma(t)dz \\ r(t) &= [R(t) + x(t)]^2 \end{aligned} \tag{13}$$

For convenience, we removed previously used *arbitrage-free* function $\theta(t)$ from the first

equation and introduced a deterministic calibrating function $R(t)$ to the second equation serving the same purpose. Note that we could have introduced the HW model similarly by defining the short rate as $r(t) = R(t) + x(t)$. Ito's lemma allows us to convert model (13) to a single stochastic differential equation for the short rate:

$$\begin{aligned} dr &= [2R'\sqrt{r} - 2a(r - R\sqrt{r}) + \sigma^2]dt \\ &\quad + 2\sigma\sqrt{r} dz \end{aligned} \tag{14}$$

where R' stands for dR/dt . The SqG model has an apparent similarity to the CIR model in that its volatility term is proportional to the square root of the short rate, too. However, comparing stochastic equations (14) and (9) we see that they have different drift terms.

The SqG model has been studied by Beaglehole and Tenney (1991), Jamshidian (1996), and Pelsser (1997), among others. The most notable fact established for the SqG model is that any zero-coupon rate $r_T(t)$ is quadratic in $x(t)$ that is linear in the short rate $r(t)$ and its square root $\sqrt{r(t)}$:

$$\begin{aligned} (T - t)r_T(t) &= A(t, T) - B(t, T)\sqrt{r(t)} \\ &\quad - C(t, T)r(t) \end{aligned} \tag{15}$$

Functions A , B , and C satisfy a system of ordinary differential equations:

$$A' = BR' + \sigma^2(\frac{1}{2}B^2 + C) + aRB \tag{16a}$$

with $A(T, T) = 0$

$$B' = aB - 2CR' - 2aCR - 2\sigma^2BC \tag{16b}$$

with $B(T, T) = 0$

$$C' = 1 + 2aC - 2\sigma^2C^2 \tag{16c}$$

with $C(T, T) = 0$

where, for brevity, A' and the like denote derivatives with respect to time t and the dependence of all functions on t and T is omitted. Note that all the terminal conditions are set to zero. Indeed, once t is equal to T , both sides of the relationship (15) must become zero for any value of r ; this is possible if and only if functions A , B , and C turn to zero. Much like

in the CIR model, equation (16c) for the linear term's slope, this time denoted via C , is of a Riccati type (see Boyle, Tian, and Guan, 2002) and can be solved in a closed-end form. In fact, it is identical to already solved equation (10) except it operates with a doubled mean reversion and a doubled volatility. Other equations in (16) and calibration to the initial yield curve can be solved numerically.

The short rate has a noncentral χ^2 distribution with 1 degree of freedom. Long rates are mixtures of normal and χ^2 deviates. Like the CIR model, the SqG model ensures positive rates; the square-root specification of volatility is suitable for many options. Due to some analytical tractability and known form for long rates, the volatility function and mean reversion can be quite accurately calibrated to traded options.

The Black-Karasinski Model

Once a very popular model, the Black-Karasinski model (BK model) expresses the short rate as $r(t) = R(t)\exp[x(t)]$, where, as in the previous case, random process $x(t)$ is normally distributed (see Black and Karasinski, 1991). The short rate is, therefore, lognormally distributed. Assuming the same process for $x(t)$ we can write the stochastic differential equation for the short rate as

$$dr = r \left(\frac{R'}{R} + \frac{1}{2}\sigma^2 - a \ln \frac{r}{R} \right) dt + r\sigma dz \quad (17)$$

The rate's absolute volatility is therefore proportional to the rate's level. Although the entire short-rate distribution is known (including the mean and variance), no closed-form pricing solution is available. This is because the cumulative discount rate, the integral of r , has an unknown distribution. Traditionally, the BK model is implemented on a tree. Calibration to the yield curve and volatility curve can be done using purely numeric procedures. For example, one could iterate to find $R(t)$ period-by-period until all the coupon bonds or zero-coupon bonds (used as input) are priced

exactly. Alternatively, one could find approximate formulas and build a faster, but approximate scheme.

Despite its past popularity, the BK model's main assumption, the rate's *lognormality*, is not supported by the recent rate history. The volatility parameter σ entering the BK model is not the same as the *Black volatility* typically quoted for swaptions or LIBOR caps. For example, selecting $\sigma = 0.15$, $a = 0$ does not ensure 15% volatility even for European options on short rates (caplets). Hence, calibration of the model to volatilities found in the option market is not an easy task.

The Flesaker-Hughston Model

The Flesaker-Hughston model (FH) is an interesting model because it is different from all previously described ones in that it allows for computing the coupon rates analytically (see Flesaker and Hughston, 1996). The model starts with defining a random process $M(t)$, which is any martingale starting from 1, and two deterministic positive functions $A(t)$ and $B(t)$, decreasing with time t . Then, at any point of time t , a zero-coupon bond maturing at T has its price in a rational functional form of $M(t)$:

$$P(t, T) = \frac{A(T) + B(T)M(t)}{A(t) + B(t)M(t)} \quad (18)$$

Taking the natural logarithm of this expression, changing the sign, and dividing it by $T - t$ gives us, of course, the zero-coupon rate. In order to derive a coupon rate $c(t, T)$, let us recall that a coupon-bearing bond generates periodic payments at a rate of c and returns the principal amount (\$1) at maturity. Let us denote the time- t value of this bond as $P^c(t, T)$:

$$P^c(t, T) = \sum_{i=1}^n cP(t, t_i) + P(t, T)$$

where t_i are the timings of coupon payments, with $t_n = T$. To express the par coupon rate c , let us equate this $P^c(t, T)$ to 1 and substitute

postulated expression (18) for all discount factors:

$$c(t, T) = \frac{A(t) - A(T) + [B(t) - B(T)]M(t)}{\sum_{i=1}^n [A(t_i) + B(t_i)M(t)]}$$

$$r(t) = -\frac{A'(t) + B'(t)M(t)}{A(t) + B(t)M(t)} \quad (19)$$

Hence, all coupon rates and the short rate are too rational functions of $M(t)$. If we select a positive martingale process $M(t)$; for example, a lognormal one, $dM = \sigma M dz$, then all rates will stay positive. Functions $A(t)$ and $B(t)$ can fit the initial term structure of rates and volatilities. (See Flesaker and Hughston, 1996, or James and Webber, 2000, for additional details.)

Other Single-Factor Models

There exists a fair amount of “named” models not mentioned in this entry thus far. They differ in specifications of drift and volatility functions. They include the Ho-Lee model, the Black-Derman-Toy model, and the Brennan-Schwartz model. We will briefly review some of them.

A predecessor to the HW model, the Ho-Lee model (HL model) was offered as a discrete-time, arbitrage-free, model (see Ho and Lee, 1986). Its continuous version is equivalent to the HW model with zero mean reversion. Hence, all analytical statements made for the HW model are valid for the HL model.

The Black-Derman-Toy model (BDT model) is a lognormal short-rate model with endogenously defined mean reversion term equal to $\sigma'(t)/\sigma(t)$ (see Black, Derman, and Toy, 1990). This specification means that a constant volatility leads to a zero mean reversion; a growing *short-rate volatility* function $\sigma(t)$ causes a negative mean reversion, thereby destabilizing the process. Once very popular in financial industry, BDT was replaced by the BK model; both of these models are now recognized as outdated.

The Brennan-Schwartz model is a proportional volatility, mean-reverting, short-rate model (see Brennan and Schwartz, 1979). Introduced in 1979 as an equilibrium model, it has some similarity in its volatility specification

to lognormal models; however, rates are not lognormally distributed.

Calibration Issues

The Vasicek model and the original Cox-Ingersoll-Ross model laid the foundation of term structure modeling. Despite their unquestionable historical importance, traders almost never employ them today. The reason is fairly simple: Built with constant parameters, these models can't be calibrated to the market accurately enough. The extensions, known as the Hull-White (“extended Vasicek”) model and the extended CIR model, allow for selecting time-dependent functions $a(t)$, $\sigma(t)$, and $\theta(t)$ so that the model produces exact or very close prices for a large set of widely traded fixed income instruments, ranging from option-free bonds (or swaps) to European (“vanilla”) options on them and more. In particular, function $\theta(t)$ [or $R(t)$] is normally selected to fit the entire option-free yield curve as formula (5) demonstrates. In contrast, functions $a(t)$, $\sigma(t)$ are usually found to match prices of European options. For example, using just a pair of constants (a, σ) one can match exactly prices of two options, for example, a 1-year swaption on the 2-year swap and 10-year swap. Clearly, we can match many more expiration points if we make $a(t)$, $\sigma(t)$ time dependent. In some systems, volatility function is allowed to be time dependent, but mean reversion remains a positive constant. This way, one can fit options' expiration curve only on average, but the model remains stable and robust. Note that a negative mean reversion may destabilize the dynamic process.

As we pointed out, single-factor models possess various degrees of *analytical tractability*. When using the HW model, a large portion of calibration work can be done analytically—starting from formula (5). The CIR model and the SqG model are somewhat analytical, but, practically speaking, require numerical solutions to ordinary differential equations. The BK model has no known solution

at all. A lack of analytical tractability doesn't preclude using numerical methods or efficient analytical approximations that are beyond this entry.

Single-factor models can't be calibrated to all market instruments. For example, each of the models we have considered thus far creates certain dependence of a European option's value (hence the implied volatility) on an option's strike known as *volatility skew*. Once a model is selected, luckily or not (see the next section), the skew implied by it cannot be changed by the model's parameters. Another problem is that all rates are perfectly correlated in any single-factor model. Hence, none of them can replicate values of "spread options" or "curve options," that is, special derivatives that are exercised when the yield curve flattens or steepens. The solution may lie in using multifactor models as discussed further in this entry.

WHICH MODEL IS BETTER?

The HW model, the CIR model, the SqG model, and the BK model are special cases of a more general class of "CEV models" introduced in 1980s:

$$dr = (\text{Drift})dt + \sigma r^\gamma dz \quad (20)$$

Parameter γ is called constant elasticity of variance (CEV). For $\gamma = 0$ we may have the HW model; for $\gamma = 0.5$, the CIR model or the SqG model; for $\gamma = 1$, the BK model. There exist no specific economic arguments supporting the r^γ functional form for volatility. Often, the CEV constant lies between 0 and 1, but it is not necessary.

Measuring Volatility Skew

Blyth and Uglum (1999) linked the CEV constant to the volatility skew; that is, its dependence of the *Black volatility* (also called implied volatility) on the option's strike, found in the swaption market. They argue that market participants should track the Black volatility ac-

ording to the following simple formula:

$$\frac{\sigma_K}{\sigma_F} \approx \left(\frac{F}{K} \right)^{\frac{1-\gamma}{2}} \quad (21)$$

where σ_K is the Black volatility for the option struck at K , σ_F is the Black volatility for the "at-the-money" option struck at today's forward rate, F . Importantly, one can recover the best CEV constant to use in the model by simply measuring the observed skew.

The skew measured for the 5-year option on the 10-year swap quoted for the period of 1998 to 2004 suggests $\gamma = 0.14$ being optimal, on average. This means that the most suitable model lies between the HW model and the CIR/SqG model (Figure 1). It is also seen that low-struck options are traded with a close-to-normal volatility, while high-struck options are traded with a square-root volatility profile. This fact may be a combination of the "smile" effect discussed at the end of this entry and the broker commission demand. As shown a little further, the square-root volatility specification becomes very suitable in a low-rate environment.

The most recent tendency has been clearly toward $\gamma = 0$, that is, *normality* (Figure 2), thereby making the HW model the best single-factor model choice currently. Note that neither the rate history of the 20-year period from 1991 to 2010, nor the available swaption volatility skew data support lognormality, although earlier rate history did appear to support $\gamma > 1$.

Using the Volatility Index

To compare rate models, it is useful to design a market *volatility index*—a single number reflecting the overall level of option volatility deemed relevant to the interest rate market. Levin (2004) describes a method of constructing such an index by first designating a family of at-the-money (ATM) swaptions ("surface"); that is, options on swaps struck exactly at current forward rate. Then, assuming zero *mean reversion*, one can optimize for the single short-rate volatility constant σ (*volatility index*) best matching the swaptions' volatility surface, on average. This

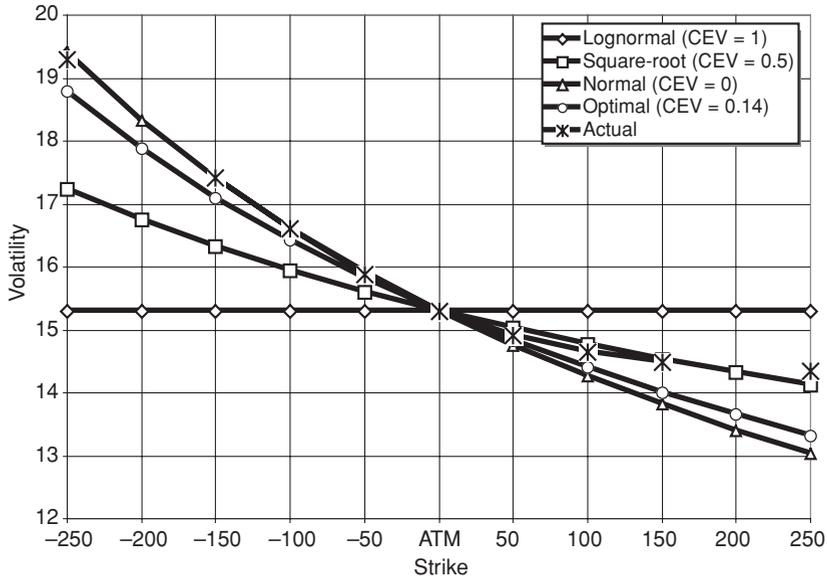

Figure 1 Implied Volatility Skew on 5-Year-into-10-Year Swap (1998–2004 Average)
 *Source of actual volatility: Bank of America; volatility for 200 bps ITM/OTM was not quoted.

measure is model-specific; unlike some other volatility indexes, it is not a simple average of swaption volatilities. The internal analytics of each model, exact or approximate, are used to translate the short rate volatility constant into swaption volatilities used for calibration. Note that this constant-volatility, zero mean rever-

sion setup is employed only to define the index; it is not a recommended setup for pricing complex instruments.

Figure 3 depicts the history of three volatility indexes (sigmas) computed from the beginning of 2000 for the HW model, the BK model, and the squared Gaussian model. Each index is

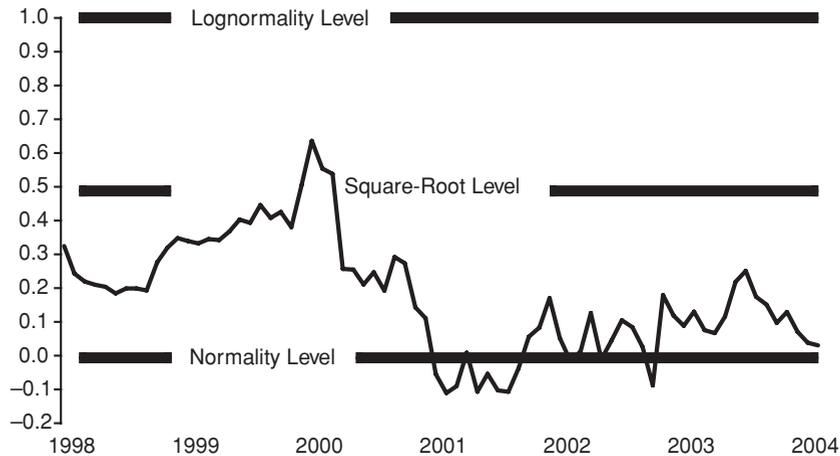

Figure 2 Historical CEV Values

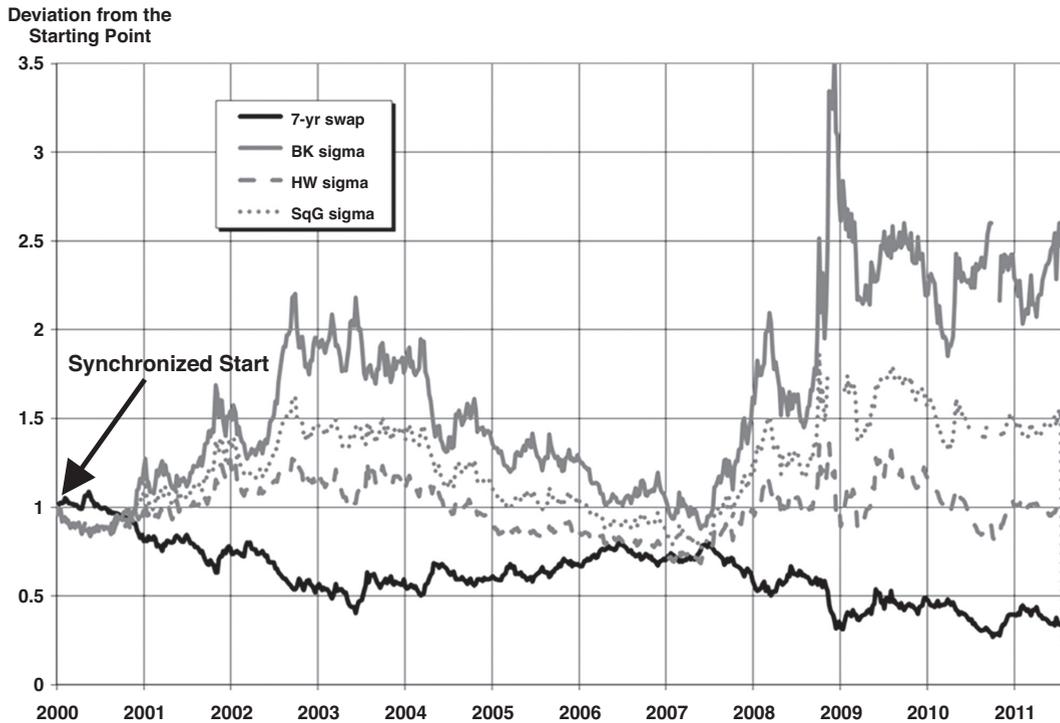

Figure 3 Which Volatility Index Is Most Stable?

calibrated to the same family of equally weighted ATM swaptions on the 2-year swap and the 10-year swap with expirations ranging from 6 months to 10 years. We add for comparison a line for the 7-year rate level, and scale all four lines so that they start from 1.0.

Figure 3 strongly confirms the normalization of the interest rate market; the volatility index constructed for the HW model has gradually become the most stable one. For example, the swap rate plunged a good 60% between January 2000 and June 2003, but the HW volatility index barely changed. The two other models produced volatility indexes that looked mirror-reflective of the rate level (the lognormal model does by far the worst job). A similar observation applies to the 2007–2010 period.

Interestingly enough, the SqG index was stable for most of 2003 and could handle the record-setting rate plunge. This confirms that the square root volatility pattern may outper-

form others when the rates are very low. These findings are consistent with the swaption skew measures we have discussed. This is not a coincidence at all. People who set the market for the ATM swaptions are the same ones who trade out-of- and in-the-money options.

In the sections to follow we will discuss how to extend the short-rate modeling framework to multifactor models and jump-diffusion models, which are often constructed in so-called affine analytical form.

ADDING A SECOND FACTOR TO SHORT-RATE MODELS

Let us consider a fixed income instrument that pays floating coupons indexed to some short rate (such as the 3-month LIBOR). The payer does not want to pay too much in case the curve inverts, so a cap is established equal to the level of some long, say 10-year, rate.

How much is this cap worth? Practically speaking, the curve's inversion is not so rare a phenomenon of the fixed income market. However, if the initial curve is steep, we will greatly undervalue the cap using any of the single-factor models described above. This example highlights the limitation of single-factor modeling: All rates change in unison. Instruments that contain "curve options," that is, asymmetric response to a curve's twist or butterfly moves, cannot be valued using single-factor term structures. Much more complex examples requiring multifactor modeling include American or Bermudan options, certain collateralized mortgage obligations (CMOs) that are much shorter or longer than the collateral itself.

Mathematically, a two-factor normal model can be constructed in a fairly simple way. Suppose that, instead of having one auxiliary Gaussian variable $x(t)$, we have two, $x_1(t)$ and $x_2(t)$, that follow linear stochastic differential equations:

$$\begin{aligned} dx_1 &= -a_1(t)x_1 dt + \sigma_1(t)dz_1 \\ dx_2 &= -a_2(t)x_2 dt + \sigma_2(t)dz_2 \end{aligned} \quad (22)$$

Brownian motions $z_1(t)$ and $z_2(t)$ may have correlated increments, $\text{corr}[dz_1, dz_2] = \rho$. Let us assume that ρ is equal to neither $+1$ nor -1 , and mean reversions $a_1(t)$ and $a_2(t)$ are positive and not identical to one another. These conditions ensure that the system (22) is stable and cannot be reduced to single-factor diffusion.

We now define the short rate simply as $r(t) = R(t) + x_1(t) + x_2(t)$ where deterministic function $R(t)$ is chosen to fit the initial yield curve. The short rate will be normally distributed; it can be shown that such a model possesses analytical tractability similar to the Hull-White single-factor model, see Levin (1998). In particular, the calibrating function $R(t)$ can be computed in a closed-end form given the forward curve, $f(t)$. The long zero-coupon rates are linear in $x_1(t)$ and $x_2(t)$,

$$r_T(t) = A(t, T) + B_{1T}(t)x_1(t) + B_{2T}(t)x_2(t)$$

Functions B 's depend on time t only if the mean reversions a 's do. If a 's are constant, then B 's depend only on maturity T and have a familiar form: $B_{iT} = (1 - e^{-a_i T})/a_i$, $i = 1$ or 2 .

The normal deviates, $x_1(t)$ and $x_2(t)$, bear no financial meaning. However, we can complement the short rate with an independent "slope" variable, $v = x_1 + \beta x_2$ with

$$\beta = -\sigma_1(\sigma_1 + \rho\sigma_2)/\sigma_2(\sigma_2 + \rho\sigma_1) \neq 1$$

The new variable has increments dv mathematically uncorrelated to dr ; it therefore can be interpreted as the driver of long rates independent of the short rate. The underlying processes, $x_1(t)$ and $x_2(t)$, can be transformed differently, thereby creating a pair of state variables with desired financial meanings, see Levin (2001). Levin (1998) developed a three-point calibration method that analytically computes parameters of the two-factor model using volatility of and correlation between the short rate and two arbitrary long rates. The method allows for constructing term structure models with inter-rate correlations selected by the user and maintained steadily over time. The latter property can be achieved by constructing a model with constant mean reversion parameters a_1 and a_2 , and a constant $\sigma_1(t)/\sigma_2(t)$ ratio.

Interestingly enough, all stable two-factor normal models having two real eigenvalues can be presented in the above-written form. Hull and White (1994) introduced a two-factor model that was designed in the form of a single-factor HW model for the short rate (factor 1) with a random long-term equilibrium rate (factor 2). Their approach draws on Brennan and Schwartz (1979). It is now clear that such an appeal to the financial meaning was unnecessary, and the general mathematical approach is as good or even better.

If we transform $x_1(t)$ and $x_2(t)$ nonlinearly, we will get multifactor versions of other previously considered models. For example, we could define the short rate as $r(t) = R(t)\exp[x_1(t) + x_2(t)]$, thereby creating a two-factor lognormal model. As one would expect, these models

inherit main properties of the single-factor parents, but add a greater freedom in changing the curve's shape and calibrating to volatility and correlation structures.

THE CONCEPT OF AFFINE MODELING

Affine modeling is a term introduced by Duffie and Kan (1996). It is a class of term structure models, often multifactor, where all zero-coupon rates are linear functions of factors. Therefore, the zero-coupon bond pricing has an exponential-linear form. Let us revisit the general stochastic model given by

$$dr = (\text{Drift})dt + (\text{Volatility})dz$$

Duffie and Kan showed that the model will be affine if drift and the square of volatility are both linear in rate r , or, more generally, in all market factors. In order to illustrate the main idea, let us denote the drift term as $\mu(x,t)$, the volatility term as $\sigma(x,t)$, and assume for the sake of simplicity that $r = x$, the lone market factor.

Every financial derivative satisfies a partial differential equation, see Duffie (1996). The left-hand side of this equation is equal to the investment's arbitrage-free expected return, which is the product of price (P) by the short rate (r). The right-hand side collects all the terms arising in the course of random behavior of $P(x,t)$: the decay, the drift, the diffusion, and cash received. In particular, a zero-coupon bond receives no cash; its equation is

$$rP(x,t) = \frac{\partial P(x,t)}{\partial t} + \mu(x,t) \frac{\partial P(x,t)}{\partial x} + \frac{1}{2} \sigma^2(x,t) \frac{\partial^2 P(x,t)}{\partial x^2} \quad (23)$$

subject to the terminal condition, $P(x,T) = 1$ (bond pays sure \$1 at maturity regardless of the market conditions). Suppose now that functions $\mu(x,t)$ and $\sigma^2(x,t)$ are linear in x :

$$\begin{aligned} \mu(x,t) &= \alpha_1(t) + \alpha_2(t)x; \\ \sigma^2(x,t) &= \beta_1(t) + \beta_2(t)x \end{aligned}$$

It turns out that the solution to equation (23) will have an exponential-linear form:

$$P(x,t) = \exp[a(t,T) + b(t,T)x]$$

To prove this conjecture, we place the above expressions into equation (23), take all derivatives, and observe that all the terms are either independent of x or linear in x . Collecting them, we get two ordinary differential equations defining unknown functions $a(t,T)$ and $b(t,T)$:

$$\begin{aligned} b'_i(t,T) &= -\alpha_2(t)b(t,T) - \frac{1}{2}\beta_2(t)b^2(t,T) + 1 \\ b(T,T) &= 0 \end{aligned} \quad (24)$$

$$\begin{aligned} a'_i(t,T) &= -\alpha_1(t)b(t,T) - \frac{1}{2}\beta_1(t)b^2(t,T) \\ a(T,T) &= 0 \end{aligned} \quad (25)$$

The terminal conditions for $a(t,T)$ and $b(t,T)$ are dictated by the terminal condition for the price function, $P(x,T) = 1$. Note that equation (24) defines function $b(t,T)$; once it is solved, we can solve (25) for $a(t,T)$.

It is clear that the HW model and the CIR model we considered earlier in the entry were affine. Indeed, in the HW model, β_2 is zero, α_2 is $-a$, β_1 is σ^2 , and (24) becomes a linear differential equation. In the CIR model, β_1 is zero, α_2 is again $-a$, and β_2 is σ^2 ; (24) becomes the Riccati equation (10). In fact, these two models cover all most important specifications of the affine modeling, for the single-factor case. The concept of affine modeling lets us build multifactor models systematically. The two-factor Gaussian model we introduced above was affine, too. Much more complex three-factor affine models were analyzed by Balduzzi et al. (1996) and by Dai and Singleton (2000). Among early works we should mention the model of Longstaff and Schwartz (1992). In their model, both the short rate and its volatility are affine in two factors that follow CIR-like processes.

The Jump-Diffusion Case

All term structure models considered thus far are based on *diffusion*—a continuous random

disturbance known as Brownian motion (Wiener process), $z(t)$. Short rates are somewhat jumpy and may require an addition of the Poisson process for modeling. The jump-diffusion extension to the affine modeling concept has been considered by many researchers (see Duffie and Kan, 1996; Das et al., 1996; and Das, 2000). The key point is that, under certain conditions, addition of jumps does not change the complexity of the problem; long rates remain affine in factors and even equation (24) for $b(t, T)$ remains unaffected.

Under the presence of *jumps*, the main stochastic differential equation for the short rate (or other market factors) gets an additional term as shown below:

$$dr = (\text{Drift})dt + (\text{Volatility})dz + (\text{Jump Volatility})dN$$

where N is the Poisson-Merton jump variable having intensity of λ . When a jump occurs, dN is drawn from the standard normal distribution $N_{[0,1]}$; it stays 0 otherwise. Continuing our affine-model notational style, let us denote the jump volatility term as $\sigma_j(t)$ and the jump intensity as $\lambda(x, t)$. Note that we allow jump's intensity, but not the size, to be factor dependent.

With jumps, the partial differential equation (23) will get one additional term to its right-hand side. If a jump of size δ occurs, the price of a zero-coupon bond, $P(x, t)$ before the jump, will become $P(x + \delta, t)$. The expected change of price can be written as

$$\int_{-\infty}^{\infty} [P(x + \delta, t) - P(x, t)]n_{[0, \sigma_j]}(\delta)d\delta$$

where, as usual, n denotes a normal density function. This expression captures the randomness of the jump's size, not the randomness of the jump's occurrence. Multiplying it by the probability of a jump to occur between t and $t + dt$ (that is, λdt) we get the cumulative expected effect of price change. Finally, dividing by dt we get the annualized return component caused by the jumps. Therefore, the partial-

differential equation (23) will now become a partial integral-differential equation:

$$\begin{aligned} rP(x, t) = & \frac{\partial P(x, t)}{\partial t} + \mu(x, t) \frac{\partial P(x, t)}{\partial x} + \frac{1}{2} \sigma^2(x, t) \frac{\partial^2 P(x, t)}{\partial x^2} \\ & + \lambda(x, t) \int_{-\infty}^{\infty} [P(x + \delta, t) - P(x, t)]n_{[0, \sigma_j]}(\delta)d\delta \end{aligned} \quad (26)$$

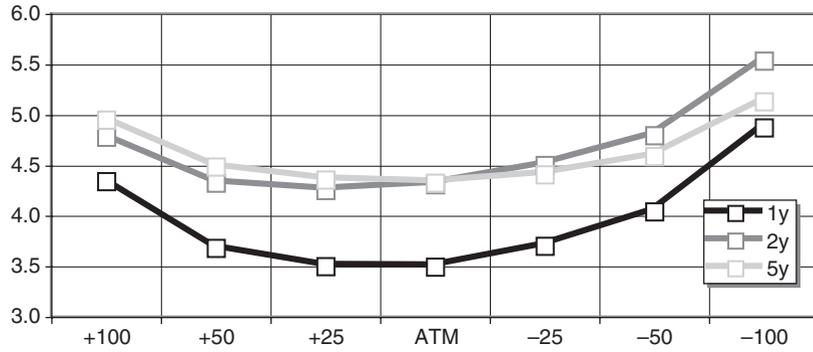

For the diffusion case, we required functions $\mu(x, t)$ and $\sigma^2(x, t)$ to be linear in x . Let us extend this condition to the jump's intensity: $\lambda(x, t) = \gamma_1(t) + \gamma_2(t)x$. It turns out that the exponential-linear form $P(x, t) = \exp[a(t, T) + b(t, T)x]$ still fits the equation. Again, collecting terms, we get two ordinary differential equations defining unknown functions $a(t, T)$ and $b(t, T)$:

$$\begin{aligned} b'_t(t, T) = & -\alpha_2(t)b(t, T) - \frac{1}{2}\beta_2(t)b^2(t, T) \\ & - \gamma_2(t)[e^{\frac{1}{2}b^2(t, T)\sigma_j^2(t)} - 1] + 1 \\ b(T, T) = & 0 \end{aligned} \quad (27)$$

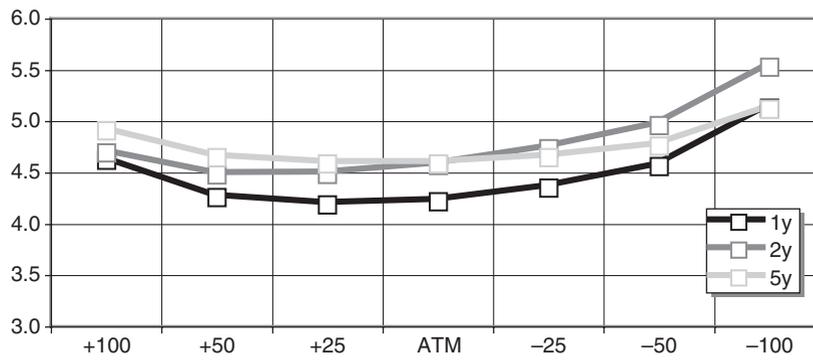

$$\begin{aligned} a'_t(t, T) = & -\alpha_1(t)b(t, T) - \frac{1}{2}\beta_1(t)b^2(t, T) \\ & - \gamma_1(t)[e^{\frac{1}{2}b^2(t, T)\sigma_j^2(t)} - 1] \\ a(T, T) = & 0 \end{aligned} \quad (28)$$

Notably, equation (27) defining function $b(t, T)$ will coincide with previously discussed equation (24) if $\gamma_2 = 0$. If we have a single-factor model, the linear relationship between long rates and the short rate will have a slope of $b(t, t + T)/T$. This slope, found for an affine diffusive model, won't change if we add jumps of factor-independent intensity and size. Hence, in such affine models, jumps and diffusions are equally propagated from the short rate to long rates. Knowing that actually observed long rates are chiefly diffusive and the short rate is notably jumpy, one can conclude that the jump-diffusive setting makes more practical sense within the frame of multifactor modeling.

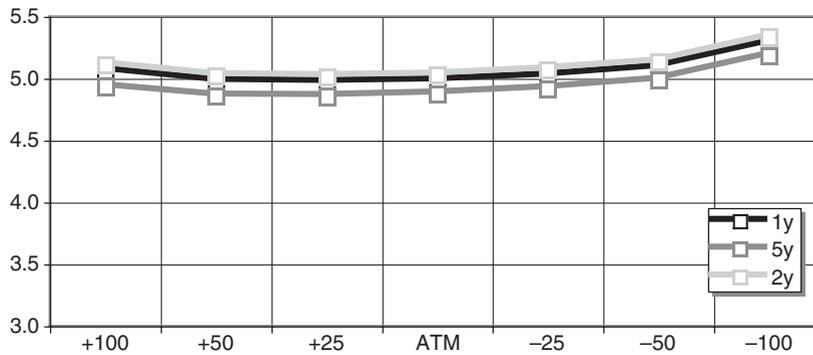

Using jump-diffusion models may be required when valuing options struck away from the current forward rate (that is, the ATM point). Aside from the *volatility skew*, option pricing features *volatility smile*, or simply an

A. 1-month Expiration on Various Swap Tenors

excessive convexity in σ_K . Revisiting Figure 1, one can notice that the actual dependence of volatility on the strike is more convex than even the optimal CEV model predicts. This is the smile effect, albeit fairly moderate for options on long rates. Smiles for options on shorter rates are very apparent, especially for short ex-

pirations. Figure 4 depicts swaption volatility measured in basis points per day, as a function of strike.

In this normalized scale, all panels of Figure 4 exhibit similar volatility skews, the ones close to normal (CEV = 0). However, the smile effect looks very different in panels A, B,

and C ; it clearly fades with maturity of the underlying rate and the option's expiry. The presence of jumps fattens the distribution tails and inflates out-of-the money or in-the money option values relatively to the ATM values. Therefore, jump modeling can capture the smile effect and explains its dependence on the swap's maturity and the option's expiry: Jumps allowed to occur over a longer time horizon look more like diffusion.

KEY POINTS

- The concept of short-rate modeling serves as a foundation for the fixed-income derivatives market.
- Short-rate models can be single- or multifactor, but their central object is a theoretical risk-free rate. Models employed in the financial markets have to be calibrated to the initial yield curve and simple options; some models let us solve this task analytically.
- There are a number of single-factor models that differ with respect to their distribution of rates, interrate relationships, and ability to fit the swaption market; the Hull-White (normal) model seems to fit the observed volatility skew the best.
- A two-factor normal model can be constructed by borrowing the recipes of so-called "affine" models; such a model can be used to price complex derivatives that are asymmetrically exposed to changes in the yield curve's shape.
- With jumps included, models can be employed to capture volatility "smile," that is, value options struck far out-of- or in-the-money.

Abstract: The term structure of interest rates represents the cost of (return from) borrowing (lending / investing) for different terms at any one moment in time. The term structure is most often specified for a specific market such as the U.S. Treasury market, the bond market for double-A rated financial institutions, the interest rate market for LIBOR and swaps, and so on. The term structure is usually specified via a rate or yield for a given term or the discount to a cash payment at some time in the future. These are often summarized mathematically through a wide variety of models. In addition, term structure models are fundamental to expressing value and risk, and establishing relative value across the spectrum of instruments found in the various interest-rate or bond markets. Static models of the term structure are characterizations that are devoted to relationships based on a given market and do not serve future scenarios where there is uncertainty. Standard static models include those known as the spot yield curve, discount function, par yield curve, and the implied forward curve. Instantiations of these models may be found in both a discrete- and continuous-time framework. An important consideration is establishing how these term structure models are constructed and how to transform one model into another.

The objective of this entry is to describe the principles and approaches for a deterministic model of the term structure of interest rates. This is done first in a discrete-time setting, followed by a more analytical development in a continuous-

time setting. We provide an eclectic mixture of ideas from the academic literature in concert with adaptations well known to practitioners.

Computational implementation of anything as complex as interest rate term structure

models naturally engenders the rigorous adherence to, yet clever application of, some arcane ideas from software/system engineering. These are beyond the scope of this introduction, but such topics include numerical recipes; mechanisms to ensure internal consistencies during development and build-up; tests for internal consistency, verification, and validation of completed applications (e.g., put-call parity, cash-and-carry arbitrage, and others); parameterization of models and applications from the markets; and the utility of advanced computer architectures.

A deterministic approach to the term structure of interest rates (or simply, the term structure) may be appropriately thought of as a static modeling approach. This is distinguished from a dynamic model of term structure. The chief distinction is that in a static term structure model, no accommodation is made of the course of interest rates over time. On the other hand, a dynamic model explicitly incorporates how *interest rates* change over time and therefore needs to admit a notion of uncertainty in considering the future course of interest rates. The following discussion will concentrate on static models. First, we address a taxonomy for term structure models in some additional detail.

INTRODUCTION TO TERM STRUCTURE MODELING

The *term structure of interest rates* (or term structure) is simply a price or yield relationship among a set of securities that differ only in the timing of their cash flows or their term until maturity. These securities invariably have a specified set of other attributes in common so that the study of the term relationship is meaningful.

It is common to think of the *term structure* as consisting of the current-coupon U.S. Treasury issues only. This restriction is not necessary since it is possible to define other term structures derived from other securities. For exam-

ple, it is meaningful to define the term structure of sets of coupon or principal Treasury strips. Other examples include off-the-run Treasury issues, agency debentures, LIBOR/interest-rate swaps, or the notes of single-A rated banks and finance companies. The set of securities used to define a term structure is called the reference set. A *market sector* (sometimes referred to as a *market* or a *sector*) consists of all those instruments described by a specific term structure. There is the market sector of coupon or principal Treasury strips, off-the-run *Treasuries*, agency debentures, interest-rate swaps, and single-A rated banks and finance companies, and so forth. Very often, the reference set for a market sector may have restrictions on the structure (noncallable only), liquidity (recent issues only), or price (close to par only) of the securities that make up the set.

The relationship expressed by the term structure is traditionally the par-coupon yield relationship, hence the terminology: *yield curve*. This also is not a necessary restriction. In general, the term structure could be the *discount function*, the *spot-yield curve*, or some other expression of the price or yield relationship between the securities. Given the widespread usage of the (*par*) *yield curve* for the Treasury market, it is not surprising that many market sectors are defined from a reference set derived from the Treasury market. For example, the reference set that defines the agency debenture market is a set of yield spreads to the *on-the-run* Treasuries, so that a 5-year debenture issued by an agency may be priced at par to yield 15 basis points more than the current 5-year Treasury issue. If the Treasury issue is trading at a 6.60% yield to maturity, the par priced agency issue has a 6.75% coupon. By inference, from the spread quote of 15 basis points, the reference yield for the 5-year term is 6.75%. Similar statements can be made for the interest-rate swap and the corporate bond markets.

It needs to be emphasized that the reference set of bonds used to define the term structure

of interest rates and the resulting term structure itself are not one and the same. Indeed, the term structure, as a complete description of the entire yield curve, ultimately can be used to analyze all manner of option-laden, index-amortizing swaps or debentures that are in the same market sector. The “vanilla” reference set consists of individual bonds that are used mainly to define the term structure or to derive its defining relationships—spot-yield curve, spot-rate process, discount function, and the like.

Theories about the term structure of interest rates fall into two categories:

- *Qualitative theories* seek to explain the shape of the yield curve based on economic principles. Three theories attract the widest attention: the expectations, *liquidity preference*, and *preferred habitat* (or hedging pressure) theories.
- *Quantitative theories* seek to mathematically characterize the term structure (often in harmony with one of the qualitative theories).

Usually, a quantitative theory about the term structure of interest rates culminates in a mathematical model, a term structure model that exhibits useful properties. Specifically, a term structure model is the mathematical representation of the relationship among the securities in a market sector. This formalizes the distinction between the reference set used to define a market sector and a term structure model.

TERM STRUCTURE MODELS

The simplest and most familiar term structure model is the (semilogarithmic) graph of the U.S. Treasury yield curve (once found daily in the *Wall Street Journal* and in the business section of many newspapers). This model is useful mainly as a visualization of the yield relationship between the most recently issued shorter-term Treasury instruments and bonds. The graph can be characterized by a mathematical equation and is one example of the set of interpolation models of the term structure.

These “connect-the-dots” models can be useful in providing a quantitative way to price bonds outside the current-coupon Treasury issues, but their utility is rather limited. Bonds that are valued through a linear-interpolation technique may not be “fairly” valued in the sense that an average yield may not be equal to the “par-coupon” yield corresponding to the same date. Later we provide a discussion of how the par-coupon curve is constructed to be fairly valued in comparison to the set of reference (Treasury) issues.

The term structure model as described above simply provides a snapshot of the relationship between the yields for selected Treasury maturities on a given day. It is often required that term structure models exhibit additional “analytic” properties. One such property is the consistency associated with the preclusion of riskless arbitrage when the term structure model is used for pricing. More will be said about this later. For now, it is intended merely to indicate that the “visualization” of the yield relationship to term may be neither completely useful nor adequate.

More generally, term structure models are called on to describe the evolution of a set of interest rates over time. This motivates the following distinction in classifying term structure models:

- *Static models* of the term structure offer a mechanism to establish the “present value of a future dollar” in a deterministic economy. That is, no allowance for uncertainty or interest-rate volatility is explicitly incorporated into the model.
- *Dynamic models* of the term structure, in contrast to static models, explicitly allow for uncertainty in the future course of interest rates.

Ideally, a dynamic model of the term structure should have useful static models embedded within. That is, with no contingency on the receipt of a future cash payment or when there is an assumption of negligible volatility, a

dynamic model should correspond to a consistent static model.

The essence of term structure modeling is the process of converting the market description of a sector's reference set (the data) into a mathematical set of relationships that characterizes all issues in a sector. This is by no means trivial to do correctly. For example, the same model that correctly values a note in the Treasury market should also correctly value an option on that note, the futures contract into which that note may be deliverable, and an option on that futures contract. It should also reveal if the traded basis on that note is rich or cheap relative to the cash, futures, and options markets. It should also be able to describe any stripping or reconstitution opportunities between coupon and principal strips and the cash market. These analyses should not be the result of several models, but of a single term structure model.

A key element of the modeling process is to eliminate distinguishing characteristics associated with each constituent of the reference set. For example, in the on-the-run set of Treasury issues, there are bills as well as notes and bonds. The bills have different conventions for day counting, pricing, and yield expression from those of the coupon-paying issues of the sector. These characteristics need to be removed prior to developing the mathematical relation of the term structure model (as do the distinguishing characteristics for notes and bonds). In this simple example, a model of the Treasury term structure might be the spot curve or the discount function, as opposed to a "connect-the-dots" model to which no yield adjustments have been made.

The mathematical relationship of a term structure model can be used to characterize all issues in a sector. As is the case for the Treasury sector, every instrument can be considered a collection of zero-coupon bonds (the maturities of which correspond to the coupon/principal payment dates, the denominations of which

correspond to the amount of coupon/principal paid). Accordingly, the discount function or equivalently, its corresponding spot-yield curve, furnishes a pricing technique for each zero-coupon bond and, therefore, for each of the instruments. With this insight, the utility of equivalence between the spot-yield curve and discount function, which are derived from the original reference set, is readily apparent.

We begin with the familiar, *discrete-time* modeling approach. That is, units of time quanta are defined (usually in terms of compounding frequency) and financial manipulations are indexed with integer, multiple periods. We continue to build on the discussion by introducing the *continuous-time* analogies to the concepts developed for discrete-time modeling. Continuous-time modeling allows financial manipulations to be freed from discretization artifacts (such as compounding frequency) and provides an algebraic framework that more naturally and rigorously accommodates "rate" as a concept of change. In addition, this approach opens up a huge field of applicable mathematics with the attendant opportunity for abstraction. For example, continuous-time models free the analyst from artificial a priori assumptions about interest-rate lattices; allow concentration on the financial analyses at hand; defer time-step issues to final implementation of an algorithm; and let the analyst choose an approach based on convenience, speed, and accuracy.

DISCRETE-TIME MODELS OF THE TERM STRUCTURE

In the discrete-time framework, we introduce some fundamental concepts in term structure theory. These include the discount function, the spot rate and spot yield, and the forward rate. While these initially may appear to be esoteric in nature, they are in fact closely interrelated quantities that directly represent the term structure, or act to influence the course

of future interest rates in an arbitrage-free environment. In this section these concepts are shown to be incorporated into the different expressions that describe the various qualitative term structure theories, such as the expectation, preferred habitat, and liquidity preference hypotheses. The continuous-time term structure model is evolved next from the same underlying premises as found in discrete time, thereby speeding the exposition.

DISCOUNT FUNCTION

The discount function incorporates market yield-curve information to express the present value of a future dollar as a function of the term to its receipt. As such, the discount function is a valid expression of the term structure of interest rates by virtue of the price/yield relationship. Since the discount function is used to quantify the value of a future dollar, the discount function also provides a direct means to value a coupon-paying bond since the coupon and principal payments are simply scalar multiples of a single dollar. As a result, the discount function can be used as a reference check for other quantitative term structure models.

Quantitative term structure models ultimately deal with the analysis of pure discount bonds. (Discount bonds, or zero-coupon bonds, are the simplest types of bonds to analyze as there is only the repayment of par at maturity. Further, all other bonds can be built from a series of discount bonds and options on discount bonds.) As a consequence of modeling the yield movements of discount bonds, term structure models describe their price movements since the price/yield relationship allows the term structure to be analyzed in terms of either price or yield.

This relationship is addressed further later in this entry, in which the term structure model is expressed in terms of price as a function of rate and time.

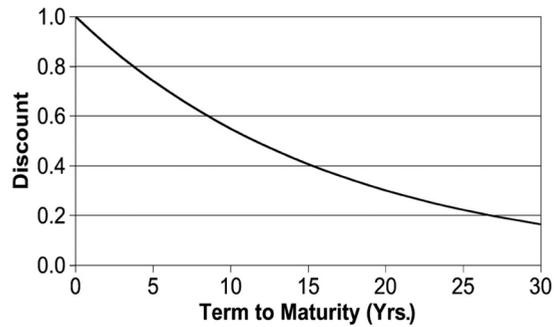

Figure 1 Discount Function

If it is assumed that the discount bond pays one dollar at maturity, then the present value of the bond is some decimal fraction less than one. For a set of discount bonds of increasing maturities, there is the corresponding set of present values starting from approximately 0.999 and decreasing thereafter. This set of present values is called the *discount function* and is shown in Figure 1.

The discount function is the term-to-maturity relationship of the present value of a future unit of cash flow. More formally, for a cash flow, CF , received after a term, T , from today, t , the present value, PV , of that cash flow is discounted, d , from the future value CF as expressed by the relation

$$PV(t, T) = d(t, T) \times CF(t, T) \tag{1}$$

where

$PV(t, T)$ = present value of the cash flow at t

$d(t, T)$ = discount at t for a cash flow received T after t

$CF(t, T)$ cash = flow received at $t + T$

As we are able to generate the discount function, d , for all terms-to-maturity, T , this can be a valid representation of the term structure of interest rates. Indeed, the discount function reflects the Treasury term structure when the discount function exactly reprices the current-coupon Treasury issues.

Deriving the Discount Function for On-the-Run Treasuries

More generally, let $P(t, i) = P_i(t)$ be the set of closing prices on (date) t for the set of current-coupon Treasury bonds (where the index, i , associates a specific issue among several)

$P(t, 3\text{-month})$: price of the 3-month (13-week) bill, at time t

$P(t, 6\text{-month})$: price of the 6-month (26-week) bill, at time t

$P(t, 52\text{-week})$: price of the 1-year (52-week) bill, at time t

$P(t, 2\text{-year})$: price of the 2-year note, at time t

...

$P(t, 30\text{-year})$: price of the 30-year bond, at time t

Each of these instruments has its own time series of cash flows, each with its own individual term-to-maturity (or better, term-to-payment). For the Treasury bills, the cash flows and associated terms-to-maturity are

3-month bill: $CF(t, T(3\text{-month}, 1))$,

6-month bill: $CF(t, T(6\text{-month}, 1))$,

and for the periodic instruments,

2-year note: $CF(t, T(2\text{-year}, 1))$,

$CF(t, T(2\text{-year}, 2))$, ..., $CF(t, T(2\text{-year}, 4))$,

...

30-year bond: $CF(t, T(30\text{-year}, 1))$,

$CF(t, T(30\text{-year}, 2))$, $CF(t, T(30\text{-year}, 60))$

The term to each of the cash flows, $T(i, j) = T_{i,j}$, is specific to the instrument and the context of the notion of "today," t for the purpose of establishing a present value. (In this sense, the dependence on t has been suppressed and it might be more precise to specify T as $T(t; i, j)$, but we believe this to be unnecessary.) The index j is the sequence of the cash flow in the time series for security i . Finally, in general, cash flows only exist in a futures sense. If $T(i, j)$ is less than zero (the cash flow has already been paid), then

those j -cash flows are not included in the series (although this is not an issue for the current-coupon Treasury issues).

The present value of a coupon-paying instrument is simply the sum of the discounted present values of the cash flows that make up the coupon payments and the payment of principal. Accordingly, for the discount function to model the Treasury term structure (i.e., the market sector defined by the on-the-run Treasury reference set), the following equations must be simultaneously satisfied. In this way, the discount function will reprice the current-coupon Treasury issues.

$$P(t, 3\text{-month}) = d(t, T(3\text{-month}, 1)) \times CF(t, T(3\text{-month}, 1))$$

$$= d(t, T_{1,1}) \times CF(t, T_{1,1})$$

$$P(t, 6\text{-month}) = d(t, T(6\text{-month}, 1)) \times CF(t, T(6\text{-month}, 1))$$

$$= d(t, T_{2,1}) \times CF(t, T_{2,1})$$

$$P(t, 2\text{-year}) = P(t, 3) = \sum_{j=1}^4 d(t, T_{3,j}) \times CF(t, T_{3,j})$$

...

$$P(t, 30\text{-year}) = P(t, 8) = \sum_{j=1}^{60} d(t, T_{8,j}) \times CF(t, T_{8,j})$$

The last cash flow of each series consists of the principal payment and, for the notes and bond, one coupon payment. The solution to these simultaneous equations furnishes many distinct points of term in which the discount function is defined; the long bond alone may have as many as 60 term points. Depending on the circumstances surrounding each auction, there may be as many as over 90 distinct points of term defining the discount function.

As with the earlier "connect-the-dots" model for the yield curve, in which the yield points were connected to generate intermediate values for the term structure, similar ideas can be used to accommodate the cash flows that do not fall on one of the terms, $T(i, j)$, enumerated above. In fact, interpolation techniques using spline functions may be applied to create

a continuous discount-function curve, as in Oldrich and Fong (1982).

The discount function forms the basis for the development of a term structure model, as will be developed further in later sections. As the discount function is an expression of the term structure based on price, there is no ambiguity of compounding periodicity, as with yield-based term structure models. The discount function simply expresses the nondimensional, fractional, present value of a unit cash flow to be received after some term. The term may be specified in a unit of time (e.g., years, months, or days) or in periods, in which the period length is a unit of time.

SPOT YIELD CURVE

With the assumption of a compounding convention (usually semiannual), the discount function can be used to derive the equivalent Treasury zero-coupon structure—sometimes referred to as the *spot-yield curve*. In this case, the spot-yield curve is an equivalent term structure representation based on yield that provides a view of the term structure that is more familiar. The equivalence between these two forms of the term structure is used later in this entry.

The *spot yield*, R , is related to the discount function, d , through a price/yield relation. By definition, the present value at t , $PV(t, n)$, of a cash flow received n periods in the future, $CF(t, n)$, has the spot yield, $R(t, n)$, through the relation

$$PV(t, n) = \frac{CF(t, n)}{[1 + R(t, n)]^n} \tag{2}$$

We use the discrete notion of integer periods, with each period of length P , to keep the math simple at this point. The more general case of a noninteger world is treated when a continuous time model is introduced.

Comparing equations (2) and (1) provides the relation between the spot yield and the discount function

$$d(t, n) = \frac{1}{[1 + R(t, n)]^n} \tag{3}$$

where

$d(t, n)$ = discount of a cash flow received n periods after t

$R(t, n)$ = n -period spot yield on t

The spot-yield curve is just the set of spot yields for all terms-to-maturity. In contrast, the spot rate is simply the one-period rate prevailing on t for repayment one period later. In the above notation, the spot rate is denoted $R(t, 1)$.

We can generalize the earlier comment about coupon-paying bonds in terms of the set of spot yields. The present value of a coupon-paying instrument is simply the sum of the discounted (present value) of the cash flows that make up the coupon payments and the payment of principal. The analogy to equation (2) for a coupon-paying bond using spot yields is

$$PV(t, n) = \frac{CF(t, 1)}{[1 + R(t, 1)]} + \frac{CF(t, 2)}{[1 + R(t, 2)]^2} + \dots + \frac{CF(t, n)}{[1 + R(t, n)]^n} \tag{2a}$$

Similarly, the analogy to equation (1) for a coupon-paying bond using the discount function is given by

$$PV(t, n) = d(t, 1) \times CF(t, 1) + d(t, 2) \times CF(t, 2) + \dots + d(t, n) \times CF(t, n) \tag{1a}$$

IMPLIED FORWARD RATE

A consequence of the discount function, spot yield, and spot rate is the immediate relation to the (implied) *forward rates*. The implied forward rate is the spot rate embodied in today's yield curve for some period in the future. The forward rate generally is regarded as an indication of future spot rates in an arbitrage-free economy. In the absence of arbitrage and uncertainty, the future spot rate, by definition, is equal to the forward rate. In the arbitrage-free term structure model discussed later, it can be shown that the future spot rate continuously converges toward the forward rate as the spot rate evolves over time.

Specifically, the one-period forward rate, F , can be determined from the spot yields as follows. Consider the one-period and two-period spot yields; the forward rate, F , may be found from

$$(1 + R(t, 2))^2 = (1 + R(t, 1)) \times (1 + F(t, 1, 1)) \quad (4)$$

where

$R(t, 2)$ = two-period spot yield on t

$R(t, 1)$ = one-period spot rate on t

$F(t, 1, 1)$ = one-period forward rate one period from t

This relation follows from the no-arbitrage assumption intrinsic in the concept of forward rates. The calculation of the forward rate presumes that an investment today for two periods provides the same return as a one-period investment today immediately rolled into another one-period investment one period from now. That is

$$PV(t) = \frac{CF(t, 2)}{[1 + R(t, 2)]^2} \quad (5)$$

$$PV(t) = \frac{CF(t, 2)}{[1 + R(t, 2)] \times [1 + F(t, 1, 1)]} \quad (6)$$

By equating equations (5) and (6), equation (4) results.

Deriving Forward Rates from Spot Yields

Implied from the term structure, through the spot-yield curve, is a set of forward rates. These forward rates may be iteratively defined from the above and written as follows

$$(1 + R(t, n))^n = (1 + R(t, n - 1))^{n-1} \times (1 + F(t, 1, n - 1))$$

where in addition to the earlier notation, $F(t, 1, n - 1)$ = one-period forward rate $n - 1$ periods from t , and noting, through substitution, that

$$(1 + R(t, n))^n = (1 + R(t, 1)) \times (1 + F(t, 1, 1)) \times (1 + F(t, 1, 2)) \times \dots \times (1 + F(t, 1, n - 1)) \quad (7)$$

this furnishes the first $n - 1$ one-period forward rates.

The relation among spot yield, spot rate, and forward rates, equation (7), can be combined with equation (2) to furnish a method for calculating the present value, at t , of a single n -period future cash flow based on a series of one-period forward rates

$$PV(t, n) = \frac{CF(t, n)}{[1 + R(t, 1)] \times \dots \times [1 + F(t, 1, n - 1)]} \quad (8)$$

Since the present value of a coupon-paying security is simply the sum of the discounted present value of the cash flows that make up the coupon payments and the payment of principal (see equations (1a) and (2a)), the analogy to equation (8) for determining the present value of a coupon-paying bond is

$$PV(t, n) = \frac{CF(t, 1)}{[1 + R(t, 1)]} + \frac{CF(t, 2)}{[1 + R(t, 1)] \times [1 + F(t, 1, 1)]} + \dots + \frac{CF(t, n)}{[1 + R(t, 1)] \times \dots \times [1 + F(t, 1, n - 1)]}$$

This equation may be used to define multi-period forward rates.

Deriving Forward Rates from the Discount Function

The discount function provides a direct method for generating forward rates. The one-period forward return $n - 1$ periods from t is obtained through the following

$$1 + F(t, 1, n - 1) = \frac{d(t, n - 1)}{d(t, n)} \quad (9)$$

Equation (9) may be derived from earlier equations, or from the following argument that creates a synthetic forward position. For each unit of cash delivered n periods from today, t , we pay $d(t, n)$. We take a long position in this zero. We also short $d(t, n)/d(t, n - 1)$ units of cash to be delivered $n - 1$ periods from t . For this we receive $d(t, n - 1)$ times $d(t, n)/d(t, n - 1)$, or simply $d(t, n)$, units. There is no net change in our cash position today. After $n - 1$ periods we pay out $d(t, n)/d(t, n - 1)$ and after n periods

receive one unit of cash. Thus the forward price per unit, FP , to be paid $n - 1$ periods from now is

$$FP(t, 1, n - 1) = \frac{d(t, n - 1)}{d(t, n)}$$

where

$FP(t, 1, n - 1)$ = forward price of a one-period unit of cash $n - 1$ periods from now

The forward price then gives the forward one-period rate, $n - 1$ periods from t as

$$FP(t, 1, n - 1) = \frac{1}{1 + F(t, 1, n - 1)}$$

Equating these results in equation (9).

TERM STRUCTURE IN A CERTAIN ECONOMY

As discussed earlier, term structure models describe the evolution of interest rates over time. Often, future interest rates are expressed in terms of the future spot rate. If the future spot rate (or equivalently, the future rate of return on a bond) is known, the future term structure of interest rates may be found from the previously established interrelationships between the spot rate and the discount function or spot yield. In fact, it is this relationship between the spot rate and the discount function that is used to motivate the formulation of the term structure models described later as a function of the spot rate. As a precursor to a generalized term structure theory, we first discuss the ramifications for a term structure in a certain economy. (In this context, "certain" refers to an economy with a lack of randomness, in other words, a lack of uncertainty.)

If the future course of interest rates is known with certainty, then arbitrage arguments demand that future spot rates be identical to forward rates. In the notation presented in equation (7), this is equivalent to noting that

$$R(t + nP, 1) = F(t, 1, n) \tag{10}$$

for $n = 1, 2, 3, \dots$ and where P is the term of the period. If this condition were violated, say, for example,

$$F(t, 1, n) > R(t + nP, 1)$$

then the same arbitrage argument may be made as before: If we buy the synthetic forward (this is a long position in a unit zero to be delivered $n + 1$ periods from today, t); and short $d(t, n + 1)/d(t, n)$ units of cash to be delivered n periods from today, t , no cash changes hands today. However, after n periods, we pay the forward price, FP ,

$$FP(t, 1, n - 1) = \frac{1}{1 + F(t, 1, n - 1)}$$

to receive one unit of cash after $n + 1$ periods. Also, after n periods, at $t + nP$, we sell the one-period unit zero for a price of

$$\frac{1}{1 + R(t + nP, 1)}$$

We know we can do this since there is no uncertainty in the economy. If, as assumed, $F(t, 1, n) > R(t + nP, 1)$, then after n periods the long and short positions yield a positive net cash flow, or a riskless arbitrage, of

$$\frac{1}{1 + R(t + nP, 1)} - \frac{1}{1 + F(t, 1, n)} > 0$$

after n periods with no uncertainty and with no net investment. Arbitrageurs will exploit the imbalance of the n -period forward rate with the spot rate n periods from now by continuing to buy the synthetic forward until demand outstrips supply. In this scenario, the synthetic forward price goes up, and the forward rate, $F(t, 1, n)$, goes down to $R(t + nP, 1)$ —with predictable effect on $d(t, n + 1)$ and/or $d(t, n)$. On the other hand, if $F(t, 1, n) < R(t + nP, 1)$, we may reverse our positions, and the same argument shows that $F(t, 1, n)$ will increase to $R(t + nP, 1)$.

Using the no-arbitrage condition in a certain economy, equation (10), in the present value expression from the implied forward-rate expression, equation (8) (which always holds irrespective of assumptions about the economy),

we have,

$$\begin{aligned} PV(t, n) &= \frac{CF(t, n+1)}{[1 + R(t, 1)] \times [1 + R(t+P, 1)] \times \cdots \times [1 + R(t+nP, 1)]} \\ &= \frac{CF(t, n+1)}{[1 + R(t, n+1)]^{n+1}} \end{aligned} \quad (11)$$

This means that the certain return of holding an $n + 1$ period zero until maturity is the same as the total return on a series of one-period bonds over the same period. Later we will discuss the various forms of equation (11) from various qualitative term structure theories.

Given equation (11), we have, at time P (one period) later,

$$\begin{aligned} PV(t+P, n) &= \frac{CF(t, n+1)}{[1 + R(t+P, 1)] \times \cdots \times [1 + R(t+nP, 1)]} \end{aligned}$$

so we find that the single-period return on a long-term zero is

$$\frac{PV(t+P)}{PV(t)} = 1 + R(t, 1) \quad (12)$$

Since the term-to-maturity was not specified, equation (12) must be true for zeros of any maturity. That is, the return realized on every discount bond over any period is equal to one plus the prevailing spot rate over that period. This will be expanded upon later.

Alternatively, we can use our relation for the discount function in equation (1), noting

$$PV(t+T, n) = d(t+P, n) \times CF(t, n+1)$$

and

$$PV(t, n) = d(t, n+1) \times CF(t, n+1)$$

and restate equation (12) in its discount-function based form:

$$\frac{d(t+P, n)}{d(t, n+1)} = 1 + R(t, 1)$$

While these developments for the certain economy may appear trivial and obvious, they serve as a guide for modeling the term structure under uncertainty as well.

TERM STRUCTURE IN THE REAL WORLD—NOTHING IS CERTAIN

In the real-world economy, the future course of interest rates contains uncertainty. In attempting to deal with uncertainty, however, it would not be inconceivable that a belief in the efficiency of the market would prompt one to use the term structure and the relation between forward rates and spot rates as indicators of expectation about the future. Indeed, market efficiency states that prices reflect all available information bearing on the valuation of the instrument. *Equilibrium* supply and demand for fixed-income instruments reflect a market-cleared consensus of the economic future. As uncertainty represents a departure from this consensus, the expected equilibrium offers a natural starting point for analysis.

Expectations Hypothesis

The expectations theory of the term structure of interest rates offers a good starting point for dealing with an uncertain future. Actually, there is a whole family of expectations theories. Broadly, the expectations theory states that the expected one-period rate of return on an investment is the same, regardless of the maturity of the investment. That is, if the investment horizon is one year, it would make no difference to invest in a one-year instrument, a two-year instrument sold after one year, or two sequential six-month instruments.

The most common form of this statement uses equation (10) as the basis for the theory. This is referred to as the unbiased expectations hypothesis, which states that the expected future spot rate is equal to the forward rate, or

$$E[R(t+nP, 1)] = F(t+kP, 1, n-k)$$

for $k = 0, 1, \dots, n-1$, and where $E[\cdot]$ is the expectation operator.

Using this relation, we find from equation (8) that the present value in an economy

characterized by unbiased expectations is

$$PV(t, n) = \frac{CF(t, n+1)}{[1+R(t, 1)] \times \{1+E [R(t+P, 1)]\} \times \dots \times \{1+E [R(t+nP, 1)]\}} \quad (13)$$

Therefore, the unbiased expectations hypothesis concludes that the guaranteed return from buying an $(n + 1)$ period bond and holding it to maturity is equivalent to the product of the expected returns from holding one-period bonds using a strategy of rolling over a series of one-period bonds until maturity.

Alternatively, the return-to-maturity expectations hypothesis is based on equation (11). Here we find that present value in such an economy is

$$PV(t, n) = \frac{CF(t, n+1)}{E \{ [1+R(t, 1)] \times [1+R(t+P, 1)] \times \dots \times [1+R(t+nP, 1)] \}} \quad (14)$$

The return-to-maturity expectations hypothesis assumes that an investor would expect to earn the same return by rolling over a series of one-period bonds as buying an $(n + 1)$ -period bond and holding it to maturity.

The last version of the expectations hypothesis that we will mention (there are others) is the local-expectations hypothesis (or risk-neutral hypothesis). This hypothesis is based on equation (12), or equivalently, its associated discount function-based equation. Under this hypothesis, the expected rate of return over a single period is equal to the prevailing spot rate of interest. Applying these expressions recursively gives

$$\begin{aligned} PV(t) &= \frac{E [PV(t + P)]}{[1 + R(t, 1)]} \\ &= E \left\{ \frac{PV(t + 2P)}{[1 + R(t + P, 1)] \times [1 + R(t, 1)]} \right\} \\ &= CF(t, n + 1) \times E \left\{ \frac{1}{[1 + R(t, 1)] \times [1 + R(t + P, 1)] \times \dots \times [1 + R(t + nP, 1)]} \right\} \end{aligned} \quad (15)$$

Equations (13), (14), and (15) are clearly different in that the coefficient of the cash flow,

$CF(t, n + 1)$, received $n + 1$ periods in the future is a different expression in each case. Furthermore, by the principle from mathematical analysis known as Jensen's inequality, only one of the expressions can be true if the future course of interest rates is uncertain.

In fact, in discrete time, we find that bond prices given by the unbiased and return-to-maturity hypotheses are equal but less than that given by the expectations hypothesis. Although the three hypotheses are different, in discrete time, any of these hypotheses is an acceptable description of equilibrium.

In the next section, term structure modeling in continuous time is developed. Equations (13), (14), and (15) have continuous-time analogs, which (as in discrete time) are different from one another. This is again due to Jensen's inequality. Unlike in discrete time, however, only the local expectations hypothesis is acceptable as a statement of equilibrium because the expected returns under each of these hypotheses are not consistent with those implied in a general equilibrium, as noted by Cox et al. (1981).

Preferred Habitat Hypothesis

Crucial alternatives to the expectations theory of the term structure of interest rates are theories that add an element of risk when conferring the expected rate of return for bonds of different maturities; that is, the indifference assumption that was stated earlier no longer holds. If the investment horizon is one year, it does make a difference whether to invest in a one-year instrument, a two-year instrument sold after one year, or two sequential six-month instruments. The preferred habitat theory argues that we first must know the investment horizon to determine relative risk among bonds. In the simple example, the horizon is one year. The one-year instrument is safest for this horizon. Under the preferred habitat theory, the investor would require a higher rate of return on both the two-year and six-month instrument.

Liquidity Preference Hypothesis

The liquidity preference theory can be considered a special case of the preferred habitat theory. Here, it is held that investors demand a risk premium as compensation for holding longer-term bonds. In addition, since the variability of price increases with maturity, the risk premium demanded by investors increases. As a special instance of the preferred habitat theory, the liquidity preference theory says that as all investors have a habitat of a single period, the shortest-term bond is judged safest.

With each of these theories, one can assess their efficacy only in the context of the general economy. Specifically, we assume that the economy is one in which investors have an inclination to consume, as well as to invest (in fact, even in a diverse set of risky investments). With a specification of utility of consumption and wealth, as well as a formal expression for risk aversion, the risk-based term structure theories can be viewed in the context of markets. Given that risk-based term structure theories can be viewed in the context of a defined market, the following conclusions can be made.

Term premiums are monotonic in maturity (or term). Interest-rate risk is inherently intertemporal. That is, it is a multiperiod phenomenon, in which an unexpected interest-rate change at any period affects all future returns and risk compounds over time. The traditional notion of preferred habitat seems difficult to reconcile with real markets. As it turns out, the traditional notion omits the importance of risk aversion. As we incorporate a varying need to hedge against interest-rate changes, the theory converges to a more acceptable view of markets. The generalization of these economic analyses has led to what has been called an *eclectic theory* of the term structure that recognizes and accommodates the many factors that play a role in shaping the term structure. Expectations of future events, risk preferences, and the characteristics of a variety of investment alternatives are all important, as are the individual preferences (habitats) of market participants about the timing of

their consumption. It is this eclectic theory that one needs to embrace in the development of the dynamic term structure.

CONTINUOUS-TIME MODELS OF THE TERM STRUCTURE

Now we discuss how the earlier concepts of discount function, spot rate, spot yield, and forward rate have their analogies in the continuous-time domain. It will be seen that while the mathematics are slightly more complex, the roles that each of these quantities play in the term structure of interest rates remain unchanged.

In summary, the priced-based representation of the term structure, or the discount function, facilitates both the mathematical formulation of the problem and its subsequent solution. Once the term structure equation is solved explicitly in terms of price, the price/yield equation (in continuous time) is used to convert the term structure to its equivalent representation in terms of yield.

Given the intertemporal nature of the term structure and the apparent efficiency of the market to incorporate information, it is assumed that the market acts instantaneously, and that a period in time is but an instant. This is the underlying premise for continuous-time models in economics and finance.

Traditional fixed-income analysis assumes that compounding occurs at discrete points or over finite intervals, typically on a semiannual basis. However, as the compounding period grows ever shorter, discrete compounding is replaced by continuous compounding. We expand our original equation (2) for the present value (at t), $PV(t, T)$, of a cash flow received T years from today, $CF(t, T)$, which is invested at the spot yield, $R(t, T)$, to be

$$PV(t, T) = CF(t, T)e^{-TR(t, T)} \quad (16)$$

Equation (16) is the fundamental price/yield relationship for the case of continuous

compounding of a discount bond and is the direct analog of the price/yield relationship shown in equation (2) for discrete compounding.

DISCOUNT FUNCTION

For a pure discount bond that pays one dollar at maturity, $CF(t, T) = 1$. Let P be the price of the pure discount bond. Thus equation (16) becomes

$$P(t, T) = e^{-TR(t,T)} \tag{17}$$

Combining the above with equation (16), which equates the price of a discount bond to the discount function, we obtain

$$P(t, T) = e^{-TR(t,T)} = d(t, T) \tag{18}$$

Equation (18) provides an expression for the relationship between the discount function d and the spot yield R , and is the continuous-time analogy to equation (3).

Spot Rate

In the previous section, the spot rate was defined as the one-period rate of return. Under continuous compounding, the spot rate r is defined as the continuously compounded instantaneous rate of return. Stated another way, the spot rate is the return on a discount bond that matures in the next instant. The spot rate is really an expression of the concept that a discount bond with a specified term-to-maturity and yield is equivalent to a series of instantaneously maturing discount bonds that are continuously reinvested at a rate r until the final term T . This is discussed in the following section.

Spot Yield

If the spot rate is a known function of time, then a loan amount W that is invested at the spot rate r will grow by an increment dW that is given by

$$dW(t) = W(t)r(t)dt \tag{19}$$

where

$dW(t)$ = incremental increase in the value of the loan from time t to time $t + dt$

$W(t)$ = value of loan at time t

$r(t)$ = spot rate at time t

To find the value of the loan W at maturity, integrate equation (19)

$$\int_t^{t+T} \frac{DW(\tau)}{W(\tau)} = \int_t^{t+T} r(\tau)d\tau$$

$$W(t) = W(t + T) \exp\left(-\int_t^{t+T} r(\tau)d\tau\right) \tag{20}$$

If W is a discount bond, $W(t)$ is equal to the present value $P(t, T)$ and the value of $W(t + T)$ is one. Equation (20) is rewritten as

$$P(t, T) = \exp\left(-\int_t^{t+T} r(\tau)d\tau\right) \tag{21}$$

From equation (17), the price P is expressed in terms of its spot yield R . By equating (17) and (21), we obtain the following expression for the *spot yield* in terms of the spot rate

$$R(t, T) = \frac{1}{T} \int_t^{t+T} r(\tau)d\tau \tag{22}$$

Equation (22) is a general expression that always holds.

Another view of the relationship between the spot yield and the spot rate is that instead of continuously reinvesting at the spot rate r for a fixed maturity T to obtain the spot yield R , if the term-to-maturity grows ever shorter, the spot yield R approaches the spot rate r "in the limit." r may be stated as

$$r(t) = R(t, T = 0) = \lim_{T \rightarrow 0} R(t, T) \tag{23}$$

Graphically, the spot rate at $t = 0$ may be visualized as the yield corresponding to the point at which the spot-yield curve intercepts the yield axis.

FORWARD RATE

The forward rate, $F(t_0, t)$ is the marginal rate of return for extending an investment to an additional increment of term at $t > t_0$. The forward rate is defined by

$$R(t, T) = \frac{1}{T} \int_t^{t+T} F(t, \tau) d\tau \quad (24)$$

Comparing the above notations for the forward rate with that in equation (4), note that the parameter “1” from the previous parameter set (denoting one time period) is no longer present. In the continuous-time domain, one time period collapses to just an instant.

Rearranging and applying Leibniz’s rule, the above becomes

$$\begin{aligned} \frac{d}{dT} [TR(t, T)] &= \frac{d}{dT} \int_t^{t+T} F(t, \tau) d\tau \\ &= F(t, t + T) \\ &= F(t, s) \end{aligned} \quad (25)$$

where s is the maturity date. The above equations relate the forward rate to the spot yield R . As with the case of discrete compounding, the forward rate may be expressed similarly in terms of the discount function $d(t, T)$ or the spot rate $r(t)$.

From equations (17), (18), and (25),

$$F(t, t + T) = \frac{-d}{dT} \ln [d(t, T)] \quad (26)$$

where $\ln[\]$ is the natural logarithm.

Separately, from equations (22) and (24),

$$\begin{aligned} r(t) &= \lim_{T \rightarrow 0} R(t, T) \\ r(t) &= \lim_{T \rightarrow 0} R(t, T) \frac{1}{T} \int_t^{t+T} F(t, \tau) d\tau \\ &= \lim_{T \rightarrow 0} \frac{1}{T} F(t, \hat{t}) T \quad (t < \hat{t} < t + T) \\ &= F(t, t) \end{aligned} \quad (27)$$

Under a certain economy, equations (22) and (27) show that the spot rate needs to be equal to the forward rate to preclude arbitrage. In the case in which the spot-yield curve $R(t, T)$ (and consequently the term structure) is defined, it follows that the spot rate needs to be equal to

the instantaneous forward rate over the term of the discount bond for equation (27) to hold true (see equation (7) for the analogy in the case of discrete compounding).

Since R is the yield of a discount bond and the term structure of interest rates is the set of spot yields as a function of maturity, equation (22) defines the term structure when the evolution of the spot rate is a known function of time. However, in general, the spot rate is not known; only the current spot rate is known from the current spot-yield curve. Nevertheless, term structure theory expands the basic relationship that is shown in equation (22), namely that the yield of a discount bond is a function of the spot rate. This is discussed in more detail in the next section when the spot rate assumes the form of a stochastic differential equation.

TERM STRUCTURE IN CONTINUOUS TIME

As stated in the previous section, the term structure of interest rates describes the relationship between the yields of default-free, zero-coupon securities as a function of maturity. Consequently, the term structure may be envisioned as a continuous set of yields for zero-coupon securities over a range of maturities.

Equation (18) describes the price/yield relationship for a single zero-coupon bond of a given maturity. As the term-to-maturity T spans the range of possible maturities within the term structure, the associated spot yields are generated for each maturity point, that is, R is a function of the term T . Furthermore, for any one value of T , the spot yield will vary as a function of the time t . In general, the spot yield R is a function of the term-to-maturity T , the time t and the spot rate r (as shown by equation (22)). R may be expressed as

$$R = R(r, t, T) \quad (28)$$

Equation (28) describes the functional form of the term structure in terms of the spot yield R . In order to describe the term structure completely,

an equation is needed that mathematically specifies the form of the relationship between the spot yield R and the term T over time t .

Such an equation for the term structure may be found by considering that the term structure may be expressed equivalently in terms of the prices of discount bonds (i.e., through the discount function). Thus equation (17) may be rewritten as

$$R(r, t, T) = -\frac{1}{T} \ln[P(r, t, T)] \quad (29)$$

where $\ln[\]$ is the natural logarithm.

If an expression for $P(r, t, T)$ can be found that defines the value of a zero-coupon bond at different points in time and for varying terms T , then the term structure of interest rates has been defined fully. Alternatively, equation (29) provides an equivalent description of the evolution of the term structure over time in terms of the spot yield.

KEY POINTS

- There are three main static models for the term structure of interest rates: the spot yield curve, the discount function, and the curve of implied forward rates; straightforward trans-

formations allow moving from one model to the other.

- These representations exist in both discrete-time and continuous-time versions and may be readily constructed from market data.
- Static models of the term structure suit valuation and comparisons of fixed-income instruments for which there is no dependency (contingency) on future events.
- Even though implied forward rates provide an arbitrage-free forecast for the future course of interest rates, static models do not admit uncertainty about the future.
- There are three main explanations for the future course of interest rates in equilibrium: the expectations hypothesis, the preferred habitat hypothesis, and the liquidity preference hypothesis.

Abstract: The term structure of interest rates represents the cost of (return from) borrowing (lending/investing) for different terms at any one moment in time. The term structure is most often specified for a specific market such as the U.S. Treasury market, the bond market for double A rate financial institutions, the interest rate market for LIBOR and swaps, and so on. The term structure is usually specified via a rate or yield for a given term or the discount to a cash payment at some time in the future. These are often summarized mathematically through a wide variety of models. In addition, term structure models are fundamental to expressing value, risk, and establishing relative value across the spectrum of instruments found in the various interest-rate or bond markets. Dynamic models of the term structure are characterizations that are specifically established to consider future market scenarios where there is uncertainty. As such they are rooted in probability, stochastic process, and martingale theory. Standard models include those derived from assumptions that include a short-rate or a forward rate process as an explanatory factor for the evolution of markets. Instantiations of these models include a general zero-coupon bond pricing equation and the LIBOR market model. An important consideration includes expressing the market price of risk that allows for the complexity of the term structure of interest rates to exist without arbitrage, as found from the traded markets. This consideration provides a platform to analyze bond and interest rate derivatives in the risk-neutral setting or with a real-world/objective probability measure.

Modern financial markets are predicated on the notions of contingency and uncertainty. Many recent financial innovations are directed at coping with the uncertainty of markets and the contingency of obligations. As part

of this evolutionary process, dynamic models of securities and their behavior in the markets are at the forefront of financial economic research and application. In the fixed-income markets, this condition dominates and

drives the need for dynamic term structure models.

The dynamic term structure model of a market sector, as defined by a reference set of securities, is a mathematical set of relationships that can be used to characterize any security in that market sector in which market uncertainty dominates the expected timing and receipt of cash flows. There are several qualitative essentials that need to be accommodated by a useful modeling approach. The ability to value fixed-income securities at any point in time (present or future) for conventional or forward settlement is a necessary first step. This is especially true in the valuation of compound or derivative instruments. Indeed, before the value of a bond option may be determined, the ability to calculate the (probabilistic) expected value of the bond on the future exercise date (conditioned on current market condition) is needed. Complementing this, reasonable variations from this expectation also need to be determined and weighed relative to the expected outcome. It is essentially this same idea that allows for the analysis of a futures contract, an interest-rate cap, or an option on a swap. In addition, to determine the performance risk that results from market moves, a rationale for incorporating market changes needs to be embedded into the modeling process.

With these premises in mind, the following assertions regarding dynamic models for the term structure of interest rates are postulated:

- The model must have the capability to extrapolate into the future an *equilibrium* evolution of the *term structure of interest rates*, given its form on a specified day, and must preclude riskless arbitrage.
- The model must allow a probabilistic description of how the term structure may deviate from its expected extrapolation while maintaining the model's equilibrium assumption.
- The model must embody a rationale to incorporate perturbations from the equilibrium that correspond to the economic fundamentals that drive the financial markets.

A technical discussion of *term structure* models is really equivalent to a discussion of the (zero-coupon or) spot-yield curve. The theory of the term structure of interest rates focuses on a term structure model that models the movement of the spot (zero-coupon) yield over time. Such term structure models are developed where any coupon-paying bond may be viewed in terms of its constituent zero-coupon bonds and analyzed in the context of this term structure model.

In this entry we focus on arriving at dynamic term structure models that respond to these imperatives. We first describe a dynamic term structure model in the case of objective (or real-world) probability measures. The assumptions, derivation, and parameterizations of the general model are described. We then indicated how this dynamic term structure model represents zero-coupon bonds, coupon-paying bonds, and determines par-coupon and horizon yield curves. It can also be used to model option-laden bonds and derivatives. The key feature of this model is dependence on a short-rate model as the (single) explanatory factor.

Next, a dynamic term structure model in a risk-neutral measure is presented. It is here that connections between the risk-neutral and the real-world setting are made; the importance of the forward rate model as the key explanatory factor is identified; and the implementation of computational imperatives in the context of applying the model to interest rate derivatives are identified.

KEY ELEMENTS IN A DYNAMIC TERM STRUCTURE MODEL

The following key ideas guide the development of dynamic term structure models:

- *Equilibrium*
- *Arbitrage-free*
- *Continuous time/continuous state*
- *Spot rate/forward rates* as underlying variable
- *Completeness of markets*

These five principles not only provide an elegant mathematical formulation of the term structure of interest rates, but also one that is applicable to a number of different market sectors and situations. Later we look at alternatives to the spot rate as the underlying variable and introduce a concept that highlights the market-clearing consequence of equilibrium—namely, the consensus of a fair market as embodied in the idea of a martingale in probability theory and forward rates as the underlying variable.

EQUILIBRIUM

General equilibrium models of the economy describe the basic workings of the macro economy as a function of a given “state variable.” This implies that the production processes and assets that constitute the economy are determined by the value of the state variable. Cox, Ingersoll, and Ross (CIR; 1985) showed that this general equilibrium model of the economy may be used to derive a model for the term structure of interest rates in terms of this state variable. Such an approach is considered to be a general equilibrium model of interest rates in that the interest-rate model is a consequence of a general economic model.

In contrast to general equilibrium models, “partial equilibrium” models assume a particular form of the interest-rate process as a given. This type of approach does not require the particular interest-rate process to be a result of some greater underlying theory. Examples of partial equilibrium models are those of Vasicek (1977), Ho and Lee (1986), and Black, Derman, and Toy (1990), among others. In addition, partial equilibrium models are calibrated exogenously to the current term structure of interest rates. Without this exogenous information, partial equilibrium models cannot quantify the term structure.

On the other hand, general equilibrium models theoretically can specify a term structure independently of any bond-market information. It has been observed, though, that such a term structure (as provided by earlier general equi-

librium models) may not be consistent with the entire market term structure. For this reason and due to the difficulty that some term structure practitioners have had in quantifying the parameters in the CIR model, many implementers of term structure models have pursued the development of partial equilibrium models.

We approached these issues in the development of this term structure model in a variety of ways. While the model described herein is not purely a general equilibrium model, we began with the basic CIR model as a starting point and then further generalized that model’s stochastic interest-rate process. Furthermore, we developed an approach for the specification of CIR-type model parameters such that the derived term structure was consistent with the observed market term structure. Thus, drawing upon a cornerstone in term structure theory, we developed an extension to the CIR model that can be readily applied to the financial marketplace.

ARBITRAGE-FREE

One underlying principle that the term structure model under discussion shares with many of the above-mentioned references is that the term structure is *arbitrage-free*. This concept, an extension of the arbitrage-free principles found in the Black-Scholes options theory for commodity and equity markets, states that the term structure observes a given relationship among its constituent parts and that purely arbitrary yield-curve shapes do not occur. Given today’s yield curve, subsequent yield curves are assumed to evolve in a “rational” manner that precludes riskless arbitrage. This indicates that the prices of bonds defining the yield curve move in such a way that it is not possible to create a portfolio of securities that always will outperform another portfolio without entailing any risk or net investment; in other words, there is no “free lunch.” The arbitrage-free principle plays an important role in the mathematical pricing of fixed-income securities.

CONTINUOUS TIME/CONTINUOUS STATE

Another distinguishing feature of this term structure model is the strict adherence to the *continuous-time/continuous-state* approach to the modeling of stochastic processes. This assumes that interest rates and bond prices move in a continuous fashion over time, rather than in discrete jumps. Thus a spot-yield curve may be found for any point in time during the life of a bond, rather than only at specific points (such as a coupon payment date). This concept is consistent with the notion of a continuous yield curve and allows for the use of continuous stochastic calculus.

Continuous Probability Distributions

Furthermore, the generality of the transitional probability density function, as a complete specification of the statistical properties of the rate process, is maintained throughout the term of the bond. This is in contrast to the common approach of describing individual sample paths or scenarios, as found in Monte Carlo approaches to security analysis. The ability to extend the analyses to compound, derivative instruments is unimpaired through the use of this transitional probability density function. Moreover, the continuous-time/continuous-state approach avoids the computational issues associated with the number of sample paths analyzed. Since the complete specification of the statistical properties is maintained, it is as if an infinite number of sample paths are run.

Numerical Solution Technique

The computer numerical solution technique that accompanies the continuous-time formulation is one that is well known in the engineering and physical sciences as the Crank-Nicholson finite-difference method for the solution of partial differential equations (PDEs).

This solution technique has been used extensively in the study of aerodynamics and fluid flow, and has the flexibility to focus its computational efforts in areas that require greater numerical precision, such as the time period surrounding an option exercise period. This is in contrast to binomial interest-rate lattices, which are constrained to jump, for example, in six-month intervals, such as in some commercially available applications.

COMPLETENESS OF MARKETS

One of the key ideas in developing financial models—especially term structure models—is formulating valuation in the context of a replicating portfolio. That is, for a given structure, a portfolio is formed that replicates or hedges the instrument with the same risk-return properties. Then the replicating portfolio dictates the value of the given structure. Otherwise, a self-financing riskless arbitrage can be engaged. Presumably, price convergence would result given sufficient market awareness. Essentially, a market is *complete* if this can be always done with a certain characterization of uniqueness.

DYNAMIC TERM STRUCTURE MODEL

The formulation and implementation of the term structure model needs to be completely general so as to be applicable across a broad range of fixed-income markets in a straightforward and consistent manner. For example, once the value of the fixed-income instrument is found, the value of its derivative (such as its futures contract) also may be found. Furthermore, it is possible to value the quality and delivery options within the bond futures contract. These effects also can be incorporated when valuing an option on the bond futures contract.

General Assumptions

The analytical model that describes spot-rate movement is a one-factor, mean-reverting, diffusion process model. The model assumes:

1. The evolution of interest rates is a continuous process and may be described by a single variable, that is, by the instantaneous spot rate, which is the return on an investment over an infinitesimally short period of time. This allows for the use of continuous-time mathematics, which requires greater technical sophistication, but which increases the flexibility of the mathematical modeling process.
2. The model assumes that interest rates move in a random fashion, which is known as Brownian motion or a Wiener process. The Wiener process has been used in the physical sciences to describe the motion of molecular particles as they diffuse (or spread) over time and space.
3. The term structure of interest rates is assumed to be represented by a Markov process, which states that the future movement in interest rates depends only on the current term structure and that all past information is embodied in the current term structure.
4. The term structure is arbitrage free in that a portfolio of securities derived from the term structure is constrained to have an instantaneous rate of return that is equal to the risk-free rate. Future movements in interest rates are similarly constrained so that the possibility of riskless profit is precluded. This implies that there are a sufficient number of sophisticated investors who will take advantage of any temporary mispricing in the marketplace, thus quickly diluting any arbitrage opportunities that exist.

Technically, an arbitrage-free term structure indicates that a portfolio of securities derived from the term structure may be constructed such that the portfolio instantaneously returns the risk-free rate. Since the above holds true for

any arbitrary set of maturities in this portfolio of securities, it is said to be true for all maturities. This indicates that all securities that comprise the term structure are related in a common fashion. This commonality is expressed through the concept of the market price of risk, which is the incremental return over the risk-free rate that is required for incurring a given amount of additional risk. In this context, risk is measured by the variance of a bond's rate of return. A result of the arbitrage-free nature of the term structure is that all securities share the same market price of risk. As we demonstrate at the end of the entry, the risk premium is one component of the market price of risk.

1. The price of a default-free, zero-coupon (discount) bond at any point in time continuously depends on the spot rate, time, and maturity of the bond. This models the interaction between the bond's price and the probabilistic movement in the spot rate. This is an extension of the point discussed earlier that stated the yield of a discount bond is a function of the spot rate.
2. The market is efficient in that all investors have the same timely access to relevant market information. Furthermore, investors are rational and there are no transaction costs.

SPOT-RATE MODEL

As a result of assumptions 1 through 3 above, the equation that describes the diffusion process for the movement in the spot rate is given by equation (1)

$$dr = k(\theta - r)dt + \sigma\sqrt{r}dz \quad (1)$$

where

r = spot rate, the instantaneous rate of return

dr = infinitesimal change in the spot rate

k = mean reversion constant

θ = "target" spot rate, which will be expressed as a function of time

dt = infinitesimal change in time

σ = volatility of r
 dz = infinitesimal change in the random variable z (a characterization of the Weiner process)

There are many alternatives to the form (1) (see, for example, Hull, 2009) and while this model has some attractive features, we in no way argue that it is “best.” It is just useful and has been shown to work well in practice. Its features include the following.

Mean Reversion

Equation (1) states that the rate r changes with respect to time and the degree of randomness. The first term on the right-hand side of equation (1) states that the “drift” in the spot rate over time is proportional to the difference between the rate r and θ . As r deviates from θ , the change in r is such that r has a tendency to revert back to θ , a feature that is known as *mean reversion*. The presence of mean reversion imposes a centralizing tendency such that rates are not expected to go to extremely high or low levels. In addition, mean reversion precludes the existence of negative interest rates in our interest-rate model, given that the initial interest rates are positive.

One can easily derive a closed-form expression for θ as a function of time. Note that θ is not assumed to be constant, which is usually the case for the traditional CIR approach.

Effect of Randomness

The second term on the right-hand side of equation (1) states that the contribution to the change in r due to randomness is driven by movements in the random variable z . The variable z is normally distributed with a mean of zero and a variance that is proportional to time. This indicates that the amount of random “noise,” as represented by the variable z , may be any positive or negative value, but that its expected value is zero. In addition, as time passes, the variance increases so that the “amplitude” of

the noise also increases. The variables σ and r , which are coefficients of dz in equation (1), show that the change in r also depends on the level of volatility and interest rates. The variable z has its own defined level of uncertainty so that as volatility and rate change, the overall degree of uncertainty is influenced by the level of these variables.

Endogenous Parameterization (Tuning the Model)

Equation (1) describes the rate in terms of the parameters k , σ , and θ . The volatility parameter σ is specified externally so that it reflects either the historical level of volatility or the volatility that is currently present in the market. Secondly, θ reflects the current term structure such that the future movements in r are influenced by today’s term structure. Finally, the mean reversion constant k determines the speed of adjustment of r back to θ . In order for the interest-rate model to be of any utility, the parameter k is chosen to be consistent with the observed market prices of bonds comprising the current yield curve, while θ is derived directly from the current yield curve. This process of determining k and θ “parameterizes” the model to the observed yield curve.

There are several variations of equation (1) that exist within the academic literature that appear to be similar to equation (1); see, for example, Chan et al. (1992). However, the details surrounding the functional form of each term in equation (1) and the associated parameterization process can result in very different models. The specification of parameters for this term structure model is driven by the requirement to be able to precisely reprice the set of securities that constitute the reference yield curve. A properly calibrated term structure model needs to be able to define a bond whose cash flow characteristics match those of an on-the-run issue exactly and then have the price of that constructed bond match exactly the market price of the Treasury issue. By repeating this process

for each of the on-the-run issues, the mean reversion constant and the *risk premium* that are appropriate over the range of reference issues may be quantified.

As a technical side note, the term structure model needs to satisfy internal consistency checks, and the parameter specification process plays a part in the internal system for checks and balances. For the set of chosen parameters, the price furnished by the term structure model—as the solution to a PDE—needs to be equal to that provided by applying the discount function to the cash flows of the specific on-the-run issue, as explained earlier. Thus the discount function is a direct means of verifying the results of the term structure model. In fact, the PDE may be decomposed into two coupled ordinary differential equations (ODE) in the absence of any embedded options. Thus prices obtained from the PDE, ODE, and discount-function approaches all need to be identical.

Calculation of the Spot Rate

The solution to equation (1) is obtained through computer numerical solution techniques and accounts for the current value of the spot rate (as an initial condition) and its level of volatility. As time moves forward, the solution expresses the probable distribution of the spot rate as the spot rate propagates through time. Thus, at any point in time, it is possible to calculate the probability distribution of the spot rate. It was discussed previously that the price of a bond depends on the spot rate so that the spot-rate probability distribution is also the probability distribution for the bond price. This is useful in calculating the probability that an embedded call or put option will be exercised, which is the probability that the price of a particular bond is greater than or less than, respectively, the specified strike price at exercise.

The calculation of the probabilities is made possible by assuming a specific mathematical form for the random variable z , or a Wiener process. Generally, a probability distribution func-

tion is described by its mean and variance as functions of time. If these quantities are known, then the probability of different spot rates is known. The Wiener process assumption states that the statistical variance for the random variable z varies with the length of time under consideration. As time increases, the variance of z also increases. The known change in the variance of z is subsequently translated (in a known fashion) to the change in the variance of the rate r , which may be used to obtain the desired probability in terms of r . In general, we use the solution of the Kolmogorov (forward or backward) equation to establish an expression for the probability density of the short rate.

BOND-PRICE VALUATION MODEL

As a consequence of assumptions 4 and 5 (the price of a default-free discount bond depends continuously on the spot rate), it can be shown that the price of a discount bond of term T is expressed as

$$\frac{\partial P}{\partial t} = rP - [k(\theta - r) + \lambda\sigma r] \frac{\partial P}{\partial r} - \frac{1}{2}\sigma^2 r \frac{\partial^2 P}{\partial r^2} \quad (2)$$

where

- P = price of zero-coupon bond for time t and rate r
- $\partial P/\partial t$ = partial derivative of price with respect to time
- $\partial P/\partial r$ = partial derivative of price with respect to rate
- $\partial^2 P/\partial r^2$ = second partial derivative of price with respect to rate
- λ = "risk premium"

The "risk premium" is the variable that represents the additional return over the risk-free rate that the market requires for holding a longer-term instrument. This is determined from the current term structure. In addition to the bond price equation, to represent the behavior of the instrument, boundary

conditions on the solution to (2) need to be prescribed. These conform to given circumstances, but in the simplest case, they include cash flows and constraints on P as r converges toward zero or becomes arbitrarily large.

Developing the Bond-Price Equation

A development of the *bond-price valuation model* (for the *zero-coupon bond*) follows in a straightforward manner. Arguments of variables are suppressed except when needed to clarify dependencies.

Equation (1) describes the process for the propagation of the spot rate and is given by

$$dr = k(\theta - r)dt + \sigma\sqrt{r}dz$$

If we assume that P is a function of the two variables r and t expressed as the following $P = P(r, t)$, then Ito's lemma (see Shreve, 2004) provides that

$$dP = \left[k(\theta - r) \frac{\partial P}{\partial r} + \frac{\partial P}{\partial t} + \frac{1}{2} \sigma^2 r \frac{\partial^2 P}{\partial r^2} \right] dt + \sigma\sqrt{r} \frac{\partial P}{\partial r} dz$$

To apply the principal of an arbitrage-free term structure, consider the representation of evolutions of the price to be

$$dP = \mu P dt - \rho P dz$$

where

$$\mu = \frac{1}{P} \left[a \frac{\partial P}{\partial r} + \frac{\partial P}{\partial t} + \frac{1}{2} b^2 \frac{\partial^2 P}{\partial r^2} \right]$$

$$\rho = -\frac{1}{P} b \frac{\partial P}{\partial r}$$

Any security W_i with maturity s_i is subject to the same relationship such that

$$dW_i = \mu_i W_i dt - \rho_i W_i dz$$

Consider a portfolio W consisting of owning an amount of W_1 and shorting an amount of W_2 such that

$$W = W_2 - W_1$$

where

$$W_2 = \left[\frac{\rho_1}{\rho_1 - \rho_2} \right] W$$

and

$$W_1 = \left[\frac{\rho_2}{\rho_1 - \rho_2} \right] W$$

Thus

$$dW = dW_2 - dW_1$$

Substituting for dW_1 and dW_2 yields

$$dW = \left[\frac{\mu_1 \rho_2}{\rho_1 - \rho_2} \right] W dt - \left[\frac{\rho_2 \rho_1}{\rho_1 - \rho_2} \right] W dz - \left[\frac{\mu_1 \rho_2}{\rho_1 - \rho_2} \right] W dz + \left[\frac{\rho_1 \rho_2}{\rho_1 - \rho_2} \right] W dz = \left[\frac{\mu_2 \rho_1 - \mu_1 \rho_2}{\rho_1 - \rho_2} \right] W dt$$

Since the stochastic element dz disappears, the rate of return on the portfolio W is equal to the riskless rate r . Therefore,

$$dW = rW dt$$

where we see it must be that

$$r = \frac{\mu_2 \rho_1 - \mu_1 \rho_2}{\rho_1 - \rho_2}$$

This gives the following relationship

$$r \rho_1 - r \rho_2 = \mu_2 \rho_1 - \mu_1 \rho_2$$

or, equivalently,

$$\frac{\mu_2 - r}{\rho_2} = \frac{\mu_1 - r}{\rho_1}$$

Since the maturities s_1 and s_2 were chosen arbitrarily, the above is true for any maturity s . Therefore, the term

$$\frac{\mu - r}{\rho}$$

is not a function of maturity and may be written as

$$\frac{\mu - r}{\rho} = q(t, r)$$

where $q(t, r)$ is the market price of risk.

Applying separation of variables, we choose $q(t, r)$ to be the following

$$q(t, r) = \lambda(t) \sqrt{r}$$

where $\lambda(t)$ is the risk premium, which can be shown to be

$$\lambda(t) = \frac{1}{2} \frac{\sigma}{k} \left[1 - e^{-kt} \right]$$

(As the term extends, the premium is higher.)

We see, therefore, that

$$\frac{\mu - r}{\rho} = q(t, r) \Rightarrow \mu = r + \lambda(t)\sqrt{r}\rho$$

or that the expected return of a bond is equal to the riskless rate plus another term related to the risk premium.

With $\rho = -\frac{1}{P}b\frac{\partial P}{\partial r}$, the above becomes

$$\mu = r + \lambda\sqrt{r} \left(-\sigma\sqrt{r} \frac{\partial P}{\partial r} \frac{1}{P} \right)$$

Substituting the above into $dP = \mu P dt - \rho P dz$ gives (where $\frac{\partial P}{\partial r} < 0$)

$$dP = \left(r - \lambda\sigma r \frac{\partial P}{\partial r} \frac{1}{P} \right) P dt - \rho P dz$$

Equating the coefficients of dt between the above and

$$dP = \left[k(\theta - r) \frac{\partial P}{\partial r} + \frac{\partial P}{\partial t} + \frac{1}{2} \sigma^2 r \frac{\partial^2 P}{\partial r^2} \right] dt + \sigma\sqrt{r} \frac{\partial P}{\partial r} dz$$

gives

$$\frac{\partial P}{\partial t} = rP - [k(\theta - r) + \lambda\sigma r] \frac{\partial P}{\partial r} - \frac{1}{2} \sigma^2 r \frac{\partial^2 P}{\partial r^2}$$

where, at maturity, we have the boundary condition

$$P(r, t) = 1$$

This completes the derivation of equation (2).

Next, if we assume a separation of variables for $P(r, t)$ of the form

$$P(r, t) = \exp [C(t) - B(t)r]$$

it can be derived that the target spot rate, $\theta(t)$, is of the form

$$\theta(t_0 + T) = -\frac{d}{dT} \ln d(t_0, T) - \frac{1}{k} \frac{d^2}{dT^2} \ln d(t_0, T)$$

or

$$\theta(t_0 + T) = F(t_0, t_0 + T) + \frac{1}{k} \frac{d}{dT} F(t_0, t_0 + T)$$

which will provide a solution to equation (2) that will exactly reprice the reference set where the discount function $d(t_0, T)$ and the forward rates $F(t_0, t_0 + T)$ are derived from the reference set using spline functions. Furthermore, this property is true for all volatilities when the above-specified risk premium is used.

THE TERM STRUCTURE

Equation (2) is a PDE whose solution is obtained through a numerical finite-difference technique. The solution gives the price P of the bond for different times and spot rates, and can be visualized as a three-dimensional surface for which the height of the surface is the price of the bond and the location of the point (i.e., longitude and latitude) is given by the time and spot rate. The solution takes into account that the bond's price is par at maturity, regardless of the level of interest rates. As the solution steps back from the maturity date, the price of the bond may be calculated for varying levels of the spot rate and the familiar price/rate graph may be drawn for this time-step. (Not all bond prices are equally likely to occur since interest-rate movements and the probabilities associated with these movements are described by equation (1).)

As the solution process continues backward from maturity to the present day, the theoretical price corresponding to today's spot rate can be calculated. Once the price behavior of a bond is known, the value of an option on that bond may also be calculated. In general, the expected value of the bond may be determined at any time from the present to maturity under the expectation operation over the solution to (2) and the probability density function for r .

Since the solution to equation (2) furnishes the price as a function of time and rate, equation (14) of the previous section may be solved to provide the zero-coupon yield for a bond with the term-to-maturity T . As the term T is varied, the entire term structure may be obtained.

(The obtained term structure, in general, can take a variety of shapes. If the current spot rate is below the current value of the long-term rate, θ , the obtained term structure will be upward sloping. If the current spot rate is substantially above the long-term rate, the obtained term structure will be inverted to downward sloping. For spot-rate values in between, the term structure will be humped, displaying both upward sloping and downward sloping segments. Thus an attractive feature of the term structure model is the ability to obtain term structure specifications that are consistent with those that have been observed historically.)

APPLICATIONS OF THE TERM STRUCTURE MODEL

We conclude this entry with a description of the application of the term structure model developed in the previous section in the valuation of fixed-income securities. For the simple case of noncallable bonds, many term structure models can be used to determine value. In fact, the spline-fit discount function is a very straightforward method of calculating the value of such a bond. However, when option-embedded bonds or compound instruments are considered, using the PDE approach is opportune to reflect the specific nature of the option features. As this entry demonstrates, the PDE-based term structure model is but the first step that leads to a greater assortment of analytical financial tools.

Zero-Coupon Bonds

Most yield curves, such as the U.S. Treasury curve, are expressed in terms of the yields of coupon-bearing bonds, not zero-coupon bonds. Thus a procedure is required to translate the current-coupon yield curve to an initial zero curve (i.e., the current term structure) expressed in terms of a spot-yield curve. One of several methods may be employed; see Vasicek and

Fong (1982). In summary, a reference set of securities is chosen to represent the yield curve, and each of the cash flows from this set of securities is treated as a zero-coupon bond that is part of the term structure. Since each of the reference securities has a known market price, the price/yield relationship, along with a curve-fitting process, is applied sequentially to each of the cash flows to derive the current term structure. This process establishes the set of initial conditions necessary to predict the evolution of the term structure.

If the actual zero-coupon yields are compared to the theoretical zero-coupon yields, then the richness or cheapness of the zero-coupon market may be gauged. Since the discount function may be constructed from any reasonable set of reference bonds, if the reference bonds consisted of off-the-run Treasury issues that are commonly stripped and/or reconstituted, then the corresponding theoretical zero curve should be indicative of the shape and level of the market strip curve.

Additionally, as the Treasury curve flattens or steepens, the theoretical zero curve changes accordingly to reflect the new shape of the Treasury curve. Consequently, as the Treasury curve steepens or flattens, the degree of anticipated yield-spread widening or tightening in the zero market may be estimated.

Coupon-Paying Bonds

While our discussion thus far applies mainly to the price of a zero-coupon bond, it is more common to encounter coupon-paying bonds. To value coupon-paying bonds, we simply sum the present values of each of the coupon payments to determine the price. As discussed earlier, each coupon is treated as an individual zero-coupon bond.

Determination of the Theoretical Fair Value

Once the term structure is defined, it may be used to value any collection of cash flows and

serves as the standard of fair value. The theoretical price of a security that is calculated in this manner may be compared to its actual market price. Any difference in price that results indicates whether the security is rich or cheap relative to its fair value. If the market price is equal to the fair value, then the security is said to be fairly priced.

Generally, Treasury securities are chosen to represent the basis for fair value and most securities (such as corporate and government-agency debt obligations) are cheap to Treasuries. However, if there are a sufficient number of securities from a particular sector or issuer, these issues may be used as the reference set of securities and a new yield curve may be defined to be the standard of fair value. Thus corporate, agency, or municipal debt issues may be compared to their own family of securities or to their own sector to determine their relative value within the specified sector.

Determination of Par-Coupon and Horizon Yield Curves

A *par-coupon* yield curve is a theoretical yield curve comprised of par-priced bonds along the maturity spectrum. Each of these par-priced bonds is constructed from the same discount function, which in turn is derived from a specified set of reference bonds. Since the discount function is defined continuously at different maturity points and cash-flow dates (via a spline-fitting procedure, for example), the par-coupon bonds corresponding to these same points may be determined.

The procedure for constructing a par-coupon bond involves an iterative process in which an initial coupon is assumed. For a given maturity date and associated coupon-payment dates, the cash flows and cash-flow dates are known for the assumed coupon level. The present value of each of the cash flows is found through the discount function, and the sum of the present values is compared to a price of par. The coupon then is varied until a par-priced bond is found. The process may be repeated for as many ma-

turity points as desired to construct an entire par-coupon yield curve.

A par-coupon yield curve is helpful in pricing bonds with off-the-run maturities. Often the question arises as to what exactly is the comparable Treasury yield when pricing off-the-run bonds. Depending on the fixed-income market sector, the comparable Treasury yield may be that of a specific Treasury note, or it may be an interpolated yield. The par-coupon curve provides a more technically rigorous means of calculating the interpolated yield, as opposed to a simple straight-line interpolation scheme.

Another application of the concept of the par-coupon yield curve is the *horizon yield curve*, the par-coupon yield curve for a future horizon date. Since the discount function may be determined as a function of time, the corresponding horizon yield curves at various points in time also may be found. The horizon yield curve is one way to help visualize how the present yield curve may evolve in the future in an arbitrage-free environment. (Of course, as new information is incorporated into the marketplace as time passes, the actual yield curve may deviate from the horizon yield curve. However, a horizon yield curve may still be calculated that reflects particular views about the future movements in both short-term and long-term rates.)

Yield-Curve Shocks and Shifts

The shape of the yield curve is governed by exogenous (*real-world*) factors. As the Federal Reserve alters its monetary policy, or as the inflation outlook changes, the yield curve responds accordingly. These perturbations to the curve can be characterized as “shocks” to short-term rates and as “shifts” to long-term rates. A shock can occur when there is a sudden and unexpected event that causes short-term rates to jump, even though the overall economic fundamentals have not changed.

The clearest example of a shock is the crash of 1987, during which investors fled to the safety of the Treasury market. During October 19, short-term rates dropped by approximately 90

to 100 basis points as investors sought a temporary safe haven. At the same time, long-term rates fell by about 20 to 30 basis points. Since the crash was a market phenomenon, rather than an altering of economic fundamentals, it is characterized as a shock to the system. (This is described mathematically within the term structure model as a change to the initial condition of the differential equation, where the differential equation remains the same. The solution to the differential equation shows how the entire yield curve responds to a shock in short-term rates.)

A shift in the yield curve results from a change in the economic landscape where federal budgetary concerns or inflation outlooks can affect the view on long-term interest rates. (In contrast to a shock, the term structure model represents a shift as a respecification of the parameters to the differential equation, while the initial condition has remained unchanged. The most general situation can consist of a combination of shocks and shifts.)

The basic premise underlying the shocked and/or shifted horizon yield curve is that the curve evolves in an arbitrage-free manner as prescribed by the term structure model despite alterations to the curve. Thus, even though a shock or a shift has occurred, the entire yield curve responds in such a way as to preclude arbitrage. As a result of different combinations of shocks and shifts of varying magnitudes, a series of horizon yield curves can be found for different yield-curve steepening and flattening scenarios.

TERM STRUCTURE OF FORWARD RATES

The financial markets can be viewed as a “game” with bids and offers between participants. To characterize fairness among the participants, the concept of a *martingale* (from probability theory) is introduced. Briefly, a martingale $M(t)$ is a stochastic process with finite first moment for any t and where

$$E [M(s)|F_t] = M(t) \text{ for } s > t$$

with F_t denoting that the conditioning is on a given filtration or data set. Additionally, a portfolio may be thought of as a quantity vector representing a particular set of positions (Øksendal, 2007). If the market is fair, then the discounted future value of any portfolio should be the same as today’s portfolio value when an appropriate discounting methodology is employed. However, in the objective (or real) world, equipped with the real-world measure, discount functions vary according to individual risk preferences, each associated with its own sector/market consensus. It is tedious to quantify these preferences for every case. So, instead of working under the real-world measure, we seek to explore an artificial probability measure under which every situation is risk-neutral. This probability measure is called the *risk-neutral* measure.

Modern pricing theory for financial derivatives is based on replicating a given derivative’s payoff by putting together a self-financing portfolio consisting of the underlying assets and *risk-free* bonds. By buying a derivative and selling its replicated portfolio (or vice versa), the self-financing portfolio is found to be risk-free. Constructing such a risk-free portfolio is beyond the scope of this discussion, but understanding and utilizing the existence and uniqueness of this replicating strategy is the key for what follows (see Björk, 2009). Next, we first examine the derivation of a *risk-neutral probability measure* from a forward-rate model. Then we look at a general *no-arbitrage* condition for the bond market. Finally, we address some practical issues and solutions in a conceptual fashion.

HEATH, JARROW, AND MORTON MODEL OF THE TERM STRUCTURE

Heath, Jarrow, and Morton (1992) proposed a general condition for no-arbitrage using the instantaneous forward-rate curve dynamics. The

instantaneous forward-rate is defined as

$$F(t, T) := -\frac{\partial \ln B(t, T)}{\partial T}$$

where $B(t, T)$ is the zero-coupon bond price at time t and maturity T . This stochastic process is usually written in a differential form

$$dB(t, T) = \alpha(t, T)dt + \sigma(t, T)dW(t)$$

where α and σ satisfy the usual conditions for an Ito process and $W(t)$ is a standard Brownian motion (under the real-world measure). Here, $F(0, T)$ is the initial *forward-rate term structure*. In many situations, instantaneous forward rates are fundamental building blocks for modeling fixed-income contingent claims. For example, a bond price process can be derived from Ito's lemma such that

$$\begin{aligned} \frac{dB(t, T)}{B(t, T)} = & \left[F(t, t) - \int_t^T \alpha(t, u)du \right. \\ & \left. + \frac{1}{2} \left(\int_t^T \sigma(t, u)du \right)^2 \right] dt \\ & - \int_t^T \sigma(t, u)dudW(t) \end{aligned}$$

Details can be found in Shreve (2004). Also, the money market account can be written as

$$\begin{aligned} \frac{dM(t)}{M(t)} &= F(t, t)dt \text{ (or equivalently,} \\ M(t) &= e^{\int_0^t F(u, u)du} \end{aligned}$$

A discount factor, $D(t) = M^{-1}(t)$, is defined similarly. A variation of this setting is one where we use the notation T to represent time-to-maturity (also called term). This alternative model is closer to the market reality because the curve won't shorten and will validate rolling-over trading strategies. For simplicity we set T to be maturity in the rest of this entry.

Let's first assume the existence of a risk-neutral probability measure, which is equivalent to imposing the local expectations

hypothesis, that is,

$$\widehat{E} \left[\frac{dB(t, T)}{B(t, T)} \middle| F_t \right] = F(t, t)dt$$

where the expectations $\widehat{E}[\cdot]$ is taken under this risk-neutral measure. Therefore the discounted bond-price processes $D(t)B(t, T)$ is a martingale for all T , that is,

$$\widehat{E} [D(s)B(s, T)|F_t] = D(t)B(t, T) \text{ for } t \leq s \leq T$$

This hypothesis also implies that the short rate evolves along today's instantaneous forward rate curve. Refer to Björk (2009) or Shreve (2004) for more details. Based on the martingale property we can then derive the HJM no-arbitrage condition shown in Heath et al. (1992) that

$$\alpha(t, T) = \sigma(t, T) \int_t^T \sigma(t, u)du$$

That is, the drift term of the instantaneous forward-rate curve process is tightly defined by the volatility term. This remarkable result tells us that only volatilities matter when modeling interest rates under a risk-neutral measure. Since the martingale property is imposed on all zero-coupon bonds to ensure fairness, arbitrage trades are precluded. If a pricing model is designed only for a derivatives pricing purpose, further investigation on risk premium is not necessary. This is an important point. For once the HJM no-arbitrage condition is applied to a particular model, the existence of a risk-neutral measure is assumed and the risk premium is zero. Nonetheless, not every modeler appreciates the consequence of ignoring the risk premium—especially when an asset and its derivative are priced congruently. For example, mortgage-backed derivatives usually involve prepayment statistics, which cannot be quantified under a risk-neutral measure, and the risk premium is usually given exogenously. The answer of which model should be used is based on the modeler's discretion involving calibration, implementation, and market assumptions, which we will talk about a bit more below.

MARKET PRICE OF RISK

Let the *market price of risk* be denoted by $\Theta(t)$. By the HJM no-arbitrage condition

$$\alpha(t, T) - \sigma(t, T)\Theta(t) = \sigma(t, T) \int_t^T \sigma(t, u)du$$

which shows that the risk premium can be written as

$$\Theta(t) = \frac{\alpha(t, T)}{\sigma(t, T)} - \int_t^T \sigma(t, u)du$$

If Θ exists, then the market is arbitrage-free. Moreover if Θ is unique, then the market is complete. For a multifactor model, completeness can be shown by nonsingularity of the volatility matrix. A remark can be made here that risk premiums are determined endogenously by the HJM no-arbitrage condition following from the local expectations hypothesis. This market price of risk identified in the HJM model is, however, a constant function of all maturities. The lack of flexibility limits the interest rate curve evolution under the real-world measure. In other words, if the curve dynamic is initially set up under a risk-neutral measure, then $\Theta(t)$ is usually impossible to find so that the “model-derived” real-world interest rates could satisfy the “real” real-world statistics.

BOND PRICING

When the market is assumed to be arbitrage-free and complete, zero-coupon bonds can then be derived under a unique risk-neutral measure that

$$\frac{dB(t, T)}{B(t, T)} = F(t, t)dt - \int_t^T \sigma(t, u)du d\tilde{W}(t)$$

The rate of return for any bond is the same as the short rate; nonetheless, the bond-price process is not Markov for a general forward-rate model. This result is critical when it comes to derivatives pricing since Monte Carlo simulation is often the only approach, and it can be slow and imprecise. Furthermore, no closed-form solution for bond dynamics can be

given, thus there is no closed-form solution for bond derivatives. Besides the computational issues due to the complexity in bond dynamics, the HJM framework cannot be used for log-normally distributed forward rates since, under the continuous compounding environment, the process “explodes” with positive probability. Therefore, practitioners seek eclectic methods to resolve the issues. A powerful tool invented for interest-rate derivatives pricing is the technique of “changing the numeraire,” discussed next.

CHANGE OF NUMERAIRE

The *numeraire* is a traded asset used for measuring value. Given a numeraire, all other prices are measured relative to this asset. In general, risk-neutral measures can have various forms in terms of different numeraires. For instance, if a money market account is used as a numeraire, it is the tradition risk-neutral measure as we see in the Black-Scholes option pricing setting. In a traditional risk-neutral world, the general evaluation form is written as

$$V(t) = \hat{E} [D(T)V(T)|F_t]$$

where $V(T)$ is the payoff of a contingent claim maturing at time T , and $V(0)$ is its price at time 0. Normally interest rates and underlying assets are assumed to be uncorrelated. This assumption makes the evaluation of the expectations above easier, but it is obviously invalid when a derivative V is based on interest rates. Further investigation in separating the derivative value process and the discount factor has been established by Geman et al. (1995).

In a traditional risk-neutral world, every discounted traded-asset price process is a martingale. When we take, for example, a zero-coupon bond with maturity T as our numeraire, the drift term of any other discounted traded-asset price process is adjusted according to this zero-coupon bond volatility. The new measure based on the zero-coupon bond numeraire is the T -forward risk-neutral measure. Consequently

we have

$$V(t) = B(t, T)E^T [V(s)|F_t]$$

where $E^T [\cdot]$ is the expectation under the T -forward risk-neutral measure. When the money market account is used as the numeraire, this adjustment to the drift term is unnecessary since the money market account process has zero volatility. In this new pricing equation the discount factor is taken out of the bracket and replaced with the zero-coupon bond discount. Therefore, the expectation is performed solely on the derivative V .

MARKET MODELS

For practitioners, the continuous compounding framework is unnecessary since most interest rates, such as LIBOR, for example, have only 1-week, 1-month, 3-month, 6-month, and 1-year investing intervals. Therefore, adopting the general no-arbitrage condition under the HJM framework, Brace et al. (1997) created a model for simple forward rates, which are compounded under a discrete-time framework. Based on the *change of numeraire* technique, forward rate processes are martingales under specific forward risk-neutral measures. This phenomenon can be justified via analyzing a bond portfolio used to create the payoff of a forward rate agreement: Let $\hat{F}(t, T, T + \tau)$ denote the process of a simple forward rate for the period $[t, T]$ with tenor τ . Then

$$\hat{F}(t, T, T + \tau) = \frac{B(t, T) - B(t, T + \tau)}{\tau B(t, T + \tau)}$$

Here $B(t, T + \tau)$ serves as the numeraire and transforms the traditional risk-neutral probability into a forward risk-neutral probability. By Ito's lemma, the forward rate dynamic can therefore be written as

$$\frac{d\hat{F}(t, T, T + \tau)}{\hat{F}(t, T, T + \tau)} = \gamma(t, T, T + \tau)d\tilde{W}^{T+\tau}(t)$$

where

$$\begin{aligned} \gamma(t, T, T + \tau) = & \frac{1 + \tau \hat{F}(t, T, T + \tau)}{\tau \hat{F}(t, T, T + \tau)} \\ & \times \left[\int_T^{T+\tau} \sigma(t, u) du \right] \end{aligned}$$

The main advantage of the *LIBOR market model* is set on the practical side. First, if γ are assumed to be nonstochastic, then forward rates are log-normal, which coincides with Black's pricing formula. Moreover, the consequence that interest rates are nonnegative and zero-coupon bond prices are nonzero under Monte Carlo simulations makes the model widely accepted. Therefore, for the past two decades, the LIBOR market model has been highly developed for various applications including the LIBOR swap market. Derivations and implementations of these market models can be found in Brigo and Mercurio (2006) and Rebonato (2002, 2004).

INTEREST RATE DERIVATIVES

An interest-rate cap consists of a portfolio of caplets that provide insurance against rising borrowing costs. Let $C(T)$ denote a caplet with maturity T on a simple τ -LIBOR forward rate \hat{F} over time interval $[t, T]$. The payoff of this LIBOR caplet is

$$C(T, T) = L (\hat{F}(T, T, T + \tau) - K)^+$$

where L is the principal amount and K is the strike rate. Under the market model setting with deterministic forward-rate volatilities, the caplet price can be written in Black's formula by

$$\begin{aligned} C(0, T) = & B(0, T)L [\hat{F}(0, T, T + \tau)N(d_1) - KN(d_2)] \\ d_1 = & \frac{\ln\left(\frac{\hat{F}(0, T, T + \tau)}{K}\right) + \frac{1}{2} \int_0^T \gamma^2(u, T, T + \tau) du}{\sqrt{\int_0^T \gamma^2(u, T, T + \tau) du}} \\ d_2 = & d_1 - \sqrt{\int_0^T \gamma^2(u, T, T + \tau) du} \end{aligned}$$

in which the volatility structure is flat with respect to the caplet strike prices. Despite this limitation, the model becomes the building block for replicating exotic interest-rate derivatives since the implied volatilities can be derived from several plain-vanilla traded derivatives. The information determined from this smaller scale market is then extended to characterize the whole-market dynamic. The operation usually involves interpolating, and many techniques are introduced in Rebonato (2002).

For pricing exotic interest-rate derivatives, interpolation on implied volatilities is often necessary, though undesirable because the HJM no-arbitrage condition cannot hold in most cases. LIBOR serial options, for example, are not as actively traded, so the prices are calculated based on the LIBOR cap/floor market. A serial option has two different maturities for the underlying forward rate agreement different from the option itself. Despite the availability of a closed-form solution, the needed volatility input for Black's formula turns out to be a partial integration from time t to the option maturity, and this information is not available from the cap/floor market. Therefore, further heuristic treatment is usually undertaken to connect the dots, in which case the curve would behave in explicit patterns and allow arbitrage.

DESIGNING YOUR NEXT MODEL

No single model is perfect in general for all assets in any market environment. The trade-offs between convenience and accuracy are evaluated by individual trading desks, quantitative analysts, and ultimately validated by the market. Nonetheless, when presenting a new model, three aspects are usually evaluated.

From a financial aspect, a model must be able to price the underlying asset(s) and its derivatives simultaneously. The market for an asset

and its derivatives are congruent, and there is no logic in pricing them separately, thereby risking "model" arbitrage. For example, we construct an interest-rate model for LIBOR-swaps curve in the real world and organically embed it in the model to price LIBOR derivatives such as LIBOR caps, floors, or even serial options in a risk-neutral world. Another example is for an underlying bullet bond and its callable counterpart. A callable bond is a bullet bond with an issuer-long, embedded American-style call option; however, the bullet bond price is determined under the real-world measure and the embedded option can be priced in the risk-neutral world. Therefore, a good model should be able to value a callable bond by valuing the bullet bond and the embedded American-style call option simultaneously.

From a mathematical standpoint, a model must be able to exhibit equivalency under different measures by explicitly characterizing the market price of risk. This mathematical component builds the bridge connecting the real world and a risk-neutral world. A complete financial market infers the existence of a unique market price of risk; but we should emphasize that whether a market is complete or not does not depend on the existence of a set of complete traded assets, but on the existence of an entity that can make the market if an arbitrage opportunity is revealed. Therefore, modern financial markets create not only hedging tools but an intangible equilibrium, which validates the underlying mathematical assumptions.

Finally, as we employ computation, this aspect demands that models/derivatives that require Monte Carlo analysis must be simulated by the same algorithm efficiently under different measures. This issue is more important in interest-rate modeling since there may be a trade-off between satisfying the mathematical requirements of a model and employing a computational implementation. Finding a model that satisfies both criteria is not trivial even

though the markets are assumed to be complete. We specifically use the word “efficiently” to implicitly indicate that a model can be simulated by a recombination tree for American-style options.

Dynamic term structure models represent a highly developed condition where finance, mathematics, and computation come together. As opposed to the case with static term structure models where the term structure appears explicitly, for dynamic models the term structure of interest rates is usually implicitly embedded in models that engage in representing risk/value relative to current conditions for lending and borrowing over the spectrum of terms available in the market. Preclusion of arbitrage is fundamental for these models. We have shown two approaches to dynamic term structure models, one depending on a representation through the spot rate, the other depending on a representation through implied forward rates. In each case the relationship between the objective and risk-neutral world (measure) has been exploited to ensure coherence between underlying asset prices and any resulting derivative. Here, the value of the asset and the derivative each depend on a representation of the same determining condition of interest rates.

KEY POINTS

- Dynamic term structure models of interest rates readily admit uncertainty in valuation/risk analyses requiring a characterization of future market scenarios.
- In building dynamic term structure models it is important that equilibrium, in an arbitrage-free sense, is represented and that variations from the equilibrium may be represented in an appropriate, probabilistic sense through a choice of stochastic processes and probability measures.
- Two approaches in explaining the future course of interest rates embody the short-rate model or an evolution of forward rates.
- Common methods for analyzing fixed-income/interest-rate instruments include formulation through a risk-neutral measure or by maintaining a real-world (objective) probability measure. Each has its own merit.
- The market price of risk is the key link between the risk-neutral and objective probability measures.

Essential Classes of Interest Rate Models and Their Use

PETER FITTON

Manager, Scientific Development CreditXpert Inc.

JAMES F. McNATT, CFA

Executive Vice President, ValueWealth Services

Abstract: Models of the *term structure of interest rates* have become increasingly important in financial modeling. However, the understanding of these models by practitioners has not always kept pace with the breadth of the application of these models. In particular, misinterpretation of the proper uses of a particular model can lead to significant errors. The confusion regarding these models has arisen because of the overuse and misuse of the term “arbitrage-free.”

In this entry, we attempt to clear up some of the most commonly misconstrued aspects of interest rate models: the choice between an arbitrage-free or equilibrium model, and the choice between risk neutral or realistic parameterizations of a model. These two dimensions define four classes of model forms, each of which has its own proper use.

Much of the confusion has arisen from overuse and misuse of the term “arbitrage-free.” Virtually all finance practitioners believe that market participants quickly take advantage of any opportunities for risk-free arbitrage among financial assets, so that these opportunities do not exist for long; thus, the term “arbitrage-free” sounds as if it would be a good characteristic for any model to have. Simply based on these positive connotations, it almost seems hard to believe that anyone would not want their model to be arbitrage-free. Briefly,

in the world of finance this expression has the associations of motherhood and apple pie.

Unfortunately, this has led some users (and even builders) of interest rate models to link uncritically the expression “arbitrage-free” with the adjective “good.” One objective of this entry is to show that arbitrage-free models are not appropriate for all purposes. Further, we show that just because a model uses the arbitrage-free approach does not mean that it is necessarily good, even for the purposes for which arbitrage-free models are appropriately used.

Another common confusion ensues from implicitly equating the terms “arbitrage-free” and “risk neutral.” This arises partly from the fact that, in the academic and practitioner literature, there have been very few papers that have applied the arbitrage-free technique to a model that was not in risk-neutral form. We explain

the reason for this below. The natural result is that the terms have sometimes been used interchangeably. In addition, since quantitative risk management is a relatively new concept to the finance community, most well-known papers have focused only on the application of interest rate models to simple valuation and hedging problems. These have not required either the realistic or equilibrium approaches to modeling. This lack of published work has led to a mistaken belief that an arbitrage-free, risk-neutral model is the only valid kind of term structure model. In this entry, we intend to dispel that notion.

CATEGORIZATION OF APPROACHES TO TERM STRUCTURE MODELING

Arbitrage-Free Modeling

Arbitrage-free models take certain market prices as given and adjust model parameters in order to fit the prices exactly. Despite being called “term structure” models, they do not in reality attempt to emulate the dynamics of the term structure. Instead, they assume some computationally convenient, but essentially arbitrary, random process underlying the yield curve, and then add time-dependent constants to the drift (mean) and volatility (standard deviation) of the process until all market prices are matched. To achieve this exact fit, they require at least one parameter for every market price used as an input to the model.

For valuation, it is possible to produce reasonable current prices for many assets without having a realistic term structure model, by using arbitrage-free models for interpolation among existing prices. To this end, the trading models used by most dealers in the over-the-counter derivatives market employ enormous numbers of time-dependent parameters. These achieve an exact fit to prices of assets in particular classes, without regard to any differences

between the behaviors of the models and the actual behavior of the term structure over time. Placed in terms of a physical analogy, the distinction here is between creating a robot based on a photograph of an animal, and creating a robot based on multiple observations of the animal through time. While the robot produced using only the photograph may *look* like the animal, only the robot built based on behavioral observations will *act* like the animal. An arbitrage-free model is like the former robot, constructed with reference to only a single point in time; that is, a snapshot of the fixed-income marketplace.

Equilibrium Modeling

In contrast to arbitrage-free models, equilibrium term structure models are truly models of the term structure process. Rather than interpolating among prices at one particular point in time, they attempt to capture the behaviors of the term structure over time. An equilibrium model employs a statistical approach, assuming that market prices are observed with some statistical error, so that the term structure must be estimated, rather than taken as given. Equilibrium models do not exactly match market prices at the time of estimation, because they use a small set of state variables (fundamental components of the interest rate process) to describe the term structure. Extant equilibrium models do not contain time-dependent parameters; instead they contain a small number of statistically estimated constant parameters, drawn from the historical time series of the yield curve.

Risk-Neutral Probabilities:

The Derivative Pricing Probability Measure

When we create a model for pricing interest rate derivatives, the “underlying” is not the price of a traded security, as it would be in a model for equity options. Instead, we specify a random

process for the instantaneous, risk-free spot interest rate, the rate payable on an investment in default-free government bonds for a very short period of time. For convenience, we call this interest rate “the short rate.” Financial modelers have chosen to create models around the short rate because it is the only truly riskless interest rate in financial markets. An investment in default-free bonds for any noninstantaneous period of time carries *market risk*, the chance that the short rate will rise during the term of the investment, leading to a decline in the investment’s value.

As with any risky investment, an investor in bonds subject to market risk expects to earn a risk-free return (that is, the return from continuously investing at the short rate, whatever that may be) plus a risk premium, which could increase or decrease as the term of the investment increases. Thus, the spot rate for a particular term is composed of the return expected under the random process for the short rate up to the end of that term, plus a term premium, an additional return to compensate the investor for the interest rate risk of the investment. The term premium offered in the market depends on the aggregate risk preference of market participants, taking into account their natural preferences for securities that conform to their investment (term) needs.

Let r_t be the short rate at time t . Let $D(t, T)$ be the price, at time t , of a discount bond paying one dollar at time T . Let $s(t, T)$ be the spot rate at time t for the term $(T-t)$. Finally, let $\phi(T-t)$ be the term premium (expressed as an annual excess rate of return) required by investors for a term of $(T-t)$. All rates are continuously compounded. We can then write,

$$D(t, T) = \frac{1}{e^{s(t,T) \times (T-t)}} = \frac{1}{e^{\phi(T-t) \times (T-t)}} E \left[\frac{1}{e^{\int_t^T r_s ds}} \right] \tag{1}$$

The second term in the two-term expression above is a discount factor that reflects the expected return from investing continuously at

the short rate for the term $(T-t)$. The first term is the additional discount factor that accounts for the return premium that investors require to compensate them for the market risk of investing for a term of $(T-t)$. The use of an integral in the expression for the expected short rate discount factor is necessary because the short rate is continuously changing over the bond’s term.

From this description and formula, it may seem necessary to know the term premium for every possible term, in addition to knowing the random process for the short rate, in order to value a default-free discount bond. This is not the case, however. As in the pricing of a forward contract or option on a stock, we can use the mathematical sleight-of-hand known as *risk-neutral valuation* to find the relative value of a security that is derivative of the short rate.

The principle of risk-neutral valuation as it applies to bonds and other interest rate derivatives is that, regardless of how risk averse investors are, we can identify a set of spot rates that value discount bonds correctly relative to the rest of the market. We do not have to identify separately the term premium embedded in each spot rate in order to use it to discount future cash flows. This fact can be used to make the valuation of all interest rate derivatives easier by risk adjusting the term structure model; that is, by changing the probability distribution of the short rate so that the spot rate of every term is, under the new model, equal to the expected return from investing at the short rate over the same term. This is accomplished by redefining the model so that, instead of being a random process for the short rate, it is a random process for the short rate plus a function of the term premium. If we specify the process for r_t^* in such a way that

$$r_s^* = r_s + \phi(s-t) + \phi'(s-t) \times (s-t) \tag{2}$$

at every future point in time s (accomplished by adjusting the rate of increase of r_t upward) then

we can write,

$$\begin{aligned}
 D(t, T) &= \frac{1}{e^{\int_t^T r_s ds}} \\
 &= E \left[\frac{1}{e^{\int_t^T (r_s + \phi(T-t)) ds}} \right] = E \left[\frac{1}{e^{\int_t^T r_s^* ds}} \right] \quad (3)
 \end{aligned}$$

By transforming the short rate process in this manner, we have created a process for a random variable which, when used to discount a certain future cash flow, gives an expected present value equal to the present value obtained by discounting that cash flow at the appropriate spot rate. It is important to note that this random variable is no longer the short rate, but something artificial that we might refer to as the *risk-adjusted short rate*.¹

The resulting *risk-neutral model* might be construed as a model for the true behavior of the short rate in an imaginary world of risk-neutral market participants, where there is no extra expected return to compensate investors for the extra price risk in bonds of longer maturity. This impression, while accurate, is not very informative. The important aspect of the risk-neutral model is that the term premiums, whatever their values, that exist in the marketplace are embedded in the interest rate process itself, so that the expected discounted value of a cash flow at the risk-adjusted short rate is equal to the discounted value of the cash flow at the spot rate.²

The value of the *risk-neutral probability measure* is that, under this parameterization, an interest-sensitive instrument's price can be estimated by averaging the present values of its cash flows, discounted at the short-term interest rates along each path of the short rate under which those cash flows occur. In contrast, valuing assets under the model before it was risk adjusted would require a more complicated discounting procedure that applied additional discount factors to the short rate paths to compensate for market risk; however, the price obtained under both approaches would be the same. For this rea-

son, we use randomly generated scenarios from risk-neutral interest rate models for pricing.

To sum up, there is nothing magical about risk neutrality. There are any number of changes of variables we could make to a short rate process that would retain the structure of the model, but have a different (but equivalent) probability distribution for the new variable. We could change the measure to represent imaginary worlds in which market participants were risk seeking (negative term premiums), or more risk averse than in the real world; regardless, as long as we structured the discounting procedure properly we would always determine the same model price for an interest rate derivative. The specific change of variables that produces a risk-neutral model simply makes the algebra easier than the others, because one can ignore risk preferences.

Realistic Probabilities:

The Estimated Market Probability Measure

We have described why risk-neutral interest rate scenarios are preferred for pricing bonds and interest rate derivatives. However, it is important to note that risk-neutral scenarios are not appropriate for all purposes. For example, for scenario-based evaluation of portfolio strategies, realistic simulation is needed. And a computerized system for stress testing asset/liability strategies under adverse movements in interest rates is to actuaries what a wind tunnel is to aerospace engineers. The relevance of the information provided by the testing depends completely on the realism of the simulated environment. Stated differently, the test environment must be like the real environment; if not, the test results are not useful.

The realistic term structure process desired for this kind of stress testing must be distinguished from the risk-neutral term structure process used for pricing. The risk-neutral process generates scenarios in which all term premiums are zero. This process lacks realism; in the real world, term premiums are clearly not

zero, as evidenced by the fact that the implied spot curve from Treasuries has been predominantly upward sloping. This predominantly upward slope reflects an expected return premium for bonds of longer maturity, although at times other configurations of buyer preferences can be inferred; for example, an inverted curve suggests that buyers demand an increasing premium for decreasing the term of their positions.

Thus, the user of an interest rate model must be careful. When generating scenarios for reserve adequacy testing, where the purpose is to examine the effect on a company's balance sheet of changes in the real (risk-averse) world, the user must not use the scenarios from a risk-neutral interest rate model.

WHEN DO I USE EACH OF THE MODELING APPROACHES?

The two dimensions, risk-neutral versus realistic and arbitrage-free versus equilibrium, define four classes of modeling approaches. Each has its appropriate use.

Risk-Neutral and Arbitrage-Free Model

The risk-neutral and arbitrage-free model is the most familiar form of an interest rate model for most analysts. The model has been risk adjusted to use for pricing interest rate derivatives, and its parameters have been interpolated from a set of current market prices rather than being statistically estimated from historical data. It is appropriately used for current pricing when the set of market prices is complete and reliable.

It is worth noting that, just because two models are each both risk neutral and arbitrage-free, we cannot conclude that they will give the same price for a particular interest rate derivative. Two arbitrage-free models will produce the same prices only for the instruments in a subset

common to both sets of input data. The form of the model, and particularly the number of random factors underlying the term structure process, can make a large difference to valuations of the other instruments.

When the market data are sparse, the behavior of the model becomes important. For example, the value of a Bermudan or American swaption depends on the correlations among rates of different maturities. The swaption market is not liquid, nor are its prices widely disseminated, so there is no way to estimate a "term structure of correlations" that would allow a simple arbitrage-free model to interpolate reasonable swaption prices. In this case, a multi-factor model that captures the nature of correlations among rates of different maturities, including the way that those correlations are influenced by the shape of the term structure, will perform better for pricing swaptions than will a one-factor model. Models with good statistical fit to historical correlation series are needed for Bermudan or American options on floating-rate notes, caps, and floors for the same reason. Model behavior is also important for long-dated caps and floors, where there is a lack of reliable data for estimating the "term structure of volatilities" beyond the 5-year tenor.

Risk-Neutral and Equilibrium

There are a number of sources of "error" in quotations of the market prices of bonds, so that the discount rates that exactly match a set of price quotations may contain bond-specific effects, corrupting the pricing of other instruments. These sources, defined as any effects on a bond's market price apart from the discount rates applying to all market instruments, include differences in liquidity, differential tax effects, bid-ask spreads (the bid-ask spread defines a range of possible market prices, implying a range of possible discount rates), quotation stickiness, timeliness of data, the human element of the data collection and reporting process, and market imperfections.

Since arbitrage-free models accept all input prices as given, without reference to their reasonability or comparability to other prices in the input data, they impound in the pricing model any bond-specific effects. In contrast, equilibrium models capture the global behavior of the term structure over time, so security-specific effects are treated in the appropriate way, as noise. For this reason, risk-neutral equilibrium models can have an advantage over arbitrage-free models in that equilibrium models are not overly sensitive to outliers. Also, for current pricing (as distinguished from horizon pricing, described below), equilibrium models can be estimated from historical data when current market prices are sparse. Thus, a risk-neutral and equilibrium model can be used for pricing when the current market prices are unreliable or unavailable.

For most standard instruments, circumstances rarely prevail such that the current market prices needed for estimating an arbitrage-free model are not available. However, such circumstances always prevail for horizon pricing, where the analyst calculates a price for an instrument in some assumed future state of the market. Since arbitrage-free models require a full set of market prices as input, arbitrage-free models are useless for horizon pricing, the future prices being unknown. Thus, the horizon prices obtained under the different values of the state variables in an equilibrium model provide an analytical capability that arbitrage-free models lack.

USING MODELS OF BORROWER BEHAVIOR WITH A RISK-NEUTRAL INTEREST RATE MODEL

Often, an interest rate model is not enough to determine the value of a fixed-income security or interest rate derivative. To value mortgage-backed securities or collateralized mortgage obligations (CMOs), one also needs a prepayment model. To value bonds or interest rate derivatives with significant credit risk, one

needs a model of default and recovery. To value interest-sensitive annuities and insurance liabilities, one needs models of lapse and other policyholder behaviors. In all of these behavioral models, the levels of certain interest rates are important explanatory variates, meaning that, for example, the prepayment speeds in a CMO valuation system are driven primarily by the interest rate scenarios.

Common practice has been to estimate parameters for prepayment, default, and lapse models using regression on historical data about interest rates and other variables. Then, in the valuation process, the analyst uses the interest rates from a set of risk-neutral scenarios to derive estimates for the rates of prepayment, default, or lapse along those scenarios. This borrower behavior information is combined with the interest rates to produce cash flows and, ultimately, prices. Unfortunately, this practice leads to highly misleading results.

The primary problem here is that the regressions have been estimated using historical data, reflecting the *real* probability distributions of borrower behavior, and then used with scenarios from a risk-neutral model, with an *artificial* probability distribution. The risk-neutral model is not a process for the short rate; rather, it is a process for the risk-adjusted short rate. Since the real world is risk averse, the risk-adjusted short rate usually has an expected value much higher than the market's forecast of the short rate; the extra premium for interest rate risk permits one to value optionable default-free bonds by reference to the forward rate curve.

The same procedure can be applied to corporate bonds. Corporate bonds are exposed to default risk in addition to interest rate risk. One may construct a behavioral model of failure to pay based on historical data about default rates and recovery, perhaps using bond ratings as explanatory variates in addition to interest rates. One can then attempt to compute the present value of a corporate bond by finding the expected value of the discounted cash flows from the two models in combination: a risk-neutral model of the Treasury curve, and a

realistic model of default behavior as a function of interest rates and other variables. Because the cash flows of the bond, adjusted for default, will be less than the cash flows for a default-free bond, the model will price the corporate bond at a positive spread over the Treasury curve.

This spread will almost certainly be substantially too low in comparison to the corporate's market price. The reason for this is that, just as investors demand a return premium for interest rate risk, they demand an additional return for default risk. The application of an econometrically estimated model of default to pricing has ignored the default risk premium encapsulated in the prices of corporate bonds. Market practice has evolved a simple solution to this; one adjusts the default model to fit (statistically, in the equilibrium case; exactly, in the arbitrage-free case) the current prices of active corporates in the appropriate rating class. By using the market prices of active corporates to embed the default risk premium in the model, the analyst is really applying the principle of risk-neutral valuation to the default rate. The combined model of risk-adjusted interest rates and risk-adjusted default rates now discounts using the corporate bond spot rate curve instead of the Treasury spot curve.

The same technique of risk neutralizing a model by embedding information about risk premiums derived from current market prices can be applied to prepayment models as well. The results of a prepayment model can be risk adjusted by examining the prices of active mortgage-backed securities. Unfortunately, one can only guess at the appropriate expected return premium for insurance policy lapse risk or mortality risk. Nevertheless, these quantities should be used to "risk neutralize" these models of behavior to the extent practical. The integrity of risk-neutral valuation depends on risk adjusting all variables modeled; otherwise, model prices will be consistently overstated.

A final note can be made in this regard about option-adjusted spread (OAS). OAS can be understood in this context as a crude method to

risk adjust the pricing system to reflect all risk factors not explicitly modeled.

Realistic and Arbitrage-Free

A *realistic, arbitrage-free model* starts by exactly matching the term structure of interest rates implied by a set of market prices on an initial date, then evolves that curve into the future according to the realistic probability measure. This form of a model is useful for producing scenarios for evaluation of hedges or portfolio strategies, where it is important that the initial curve in each scenario exactly matches current market prices. The difficulty with such an approach lies in the estimation; realistic, arbitrage-free models are affected by confounding, where it is impossible to discriminate between model misspecification error and the term premiums. Since the model parameters have been set to match market prices exactly, without regard to historical behavior, too few degrees of freedom remain to estimate both the term premiums and an error term. Unless the model perfectly describes the true term structure process (that is, the time-dependent parameters make the residual pricing error zero at all past and future dates, not just on the date of estimation), the term premiums cannot be determined. The result is that realistic, arbitrage-free models are not of practical use.

Realistic and Equilibrium

Since the arbitrage-free form of a realistic model is not available, the equilibrium form must be used for stress testing, Value-at-Risk (VAR) calculations, reserve and asset adequacy testing, and other uses of realistic scenarios.

Some analysts express concern that, because the predicted initial curve under the equilibrium model does not perfectly match observed market prices, then the results of scenario testing will be invalid. However, the use of an equilibrium form does not require that the predictions be used instead of the current market prices as the first point in a scenario. The

Table 1 When to Use Each of the Model Types

Model Classification	Risk Neutral	Realistic
Arbitrage-free	<ul style="list-style-type: none"> • Current pricing, where input data (market prices) are reliable 	<ul style="list-style-type: none"> • Unusable, since term premium cannot be reliably estimated
Equilibrium	<ul style="list-style-type: none"> • Current pricing, where inputs (market prices) are unreliable or unavailable • Horizon pricing 	<ul style="list-style-type: none"> • Stress testing • Reserve and asset adequacy testing

Table 2 Four Forms of the Black-Karasinski Model

Model Classification	Risk Neutral	Realistic
Arbitrage-free	$du = \kappa(t) (\theta(t) - u) dt + \sigma(t) dz$ <ul style="list-style-type: none"> • u_0 and $\theta(t)$ matched to bond prices • $\kappa(t)$ and $\sigma(t)$ matched to cap or option prices 	$du = \kappa(t) (\theta(t) - \lambda(u,t) - u) dt + \sigma(t) dz$ <ul style="list-style-type: none"> • u_0 and $\theta(t)$ matched to bond prices • $\kappa(t)$ and $\sigma(t)$ matched to cap or option prices • $\lambda(u,t)$ cannot be reliably estimated
Equilibrium	$du = \kappa(\theta - u) dt + \sigma dz$ <ul style="list-style-type: none"> • u_0 statistically fit to bond prices • κ, θ, σ historically estimated 	$du = \kappa(\theta - \lambda(u) - u) dt + \sigma dz$ <ul style="list-style-type: none"> • u_0 statistically fit to bond prices • $\kappa, \theta, \sigma, \lambda(u)$ historically estimated

scenarios can contain the observed curve at the initial date and the conditional predictions at future dates. This does not introduce inconsistency, because the *equilibrium model* is a statistical model of term structure behavior; by taking this approach we explicitly recognize that its predictions will deviate from observed values by some error. In contrast, the use of an *arbitrage-free, realistic model* implicitly assumes that the model used for the term structure process is absolutely correct.

Summary of the Four Essential Classes

Table 1 summarizes the uses of the four Essential Classes of interest rate models. Table 2 shows the mathematical form of a commonly used interest rate model, disseminated by Black and Karasinski (1991), under each of the modeling approaches and probability measures. In each equation, u is the natural logarithm of the short rate.

In the above models, σ is the instantaneous volatility of the short rate process, κ is the rate of mean reversion, θ is the mean level to which the natural logarithm of the short rate is reverting, and λ represents the term premium demanded

by the market for holding bonds of longer maturity. The value of the state variable u at the time of estimation is represented by u_0 .

The realistic model forms can be distinguished from the risk-neutral forms by the presence of the term premium function λ . The difference between the arbitrage-free forms and the equilibrium forms can be discerned in that the parameters of the arbitrage-free forms are functions of time.

KEY POINTS

- Models of the term structure of interest rates are important in financial modeling.
- The most commonly misconstrued aspects of interest rate models are important to understand to make the correct choice between an arbitrage-free or equilibrium model, and the correct choice between risk-neutral or realistic parameterizations of a model.
- A common confusion is the result of implicitly equating the terms “arbitrage-free” and “risk neutral.”
- Arbitrage-free models take certain market prices as given and adjust model parameters in order to fit the prices exactly.

- Equilibrium term structure models are truly models of the term structure process because rather than interpolating among prices at one particular point in time, they attempt to capture the behaviors of the term structure over time.
- The principle of risk-neutral valuation as it applies to bonds and other interest rate derivatives is that, regardless of how risk averse investors are, a set of spot rates that value discount bonds correctly relative to the rest of the market can be identified.
- The two dimensions, risk-neutral versus realistic and arbitrage-free versus equilibrium, define four classes of modeling approaches.
- The risk-neutral and arbitrage-free model is appropriately used for current pricing when the set of market prices is complete and reliable.
- Because equilibrium models capture the global behavior of the term structure over time, so security-specific effects are treated as noise, a risk-neutral and equilibrium model can be used for pricing when the current market prices are unreliable or unavailable.
- For several reasons, realistic, arbitrage-free models are not of practical use.

NOTES

1. This is not the way that risk neutrality is usually presented. Typically, writers have focused on the stochastic calculus, using Girsanov's theorem to justify a change of

probability measure to an equivalent (i.e., an event has zero probability under one measure if and only if it has zero probability under the other measure) martingale measure. This complexity and terminology can obscure the simple intuition that we are making a change of variables in order to restate the problem in a more easily solvable form. For this approach to explaining risk neutral valuation, see Courtadon (1982) or Harrison and Pliska (1981).

2. Note that this is not the same as the expectations hypothesis of the term structure, which holds that the term structure's shape is determined solely by the market's expectations about future rates. The expectations hypothesis is a theory of the real term structure process, whereas the risk-neutral approach is an analytical convenience that takes no position about the truth or falsity of any term structure theory.

Abstract: Interest rates are commonly modeled using stochastic differential equations. One-factor models use a stochastic differential equation to represent the short rate and two-factor models use a stochastic differential equation for both the short rate and the long rate. The stochastic differential equations used to model interest rates must capture some of the market properties of interest rates such as mean reversion and/or a volatility that depends on the level of interest rates. There are two distinct approaches used to implement the stochastic differential equations into a term structure model: equilibrium and no arbitrage.

In modeling the behavior of interest rates, *stochastic differential equations* (SDEs) are commonly used. The SDEs used to model interest rates must capture some of the market properties of interest rates such as mean reversion and/or a volatility that depends on the level of interest rates. For a *one-factor model*, the SDE is used to model the behavior of the short-term rate, referred to simply as the “short rate.” The addition of another factor (i.e., a *two-factor model*) involves extending the SDE to represent the behavior of the short rate and a long-term rate (i.e., long rate).

There are two distinct approaches used to implement the SDEs into a *term structure model*:

equilibrium and no arbitrage. Each can be used to value bonds and interest rate contingent claims. Both approaches start with the same SDEs but apply the SDE under a different framework to price securities.

Equilibrium models such as those developed by Vasicek (1977), Cox, Ingersoll, and Ross (1985), Longstaff (1989, 1992), Longstaff and Schwartz (1992), and Brennan and Schwartz (1979, 1982) all start with an SDE model and develop pricing mechanisms for bonds under an equilibrium framework. The actual implementation may vary depending on the model. Vasicek and Cox, Ingersoll, and Ross (CIR) develop analytic pricing expressions while Backus, Foresi, and

Telmer (2001) present econometric and recursive approaches to implement the equilibrium models. Brennan and Schwartz use a finite difference scheme that approximates a partial differential equation.

No arbitrage models such as Black and Karasinski, (1991), Black, Derman, and Toy (1990), Ho and Lee (1986), Heath, Jarrow, and Morton (1992), and Hull and White (1990, 1993) begin with the same or similar SDE models as the equilibrium approach but use market prices to generate an interest rate lattice. The lattice represents the short rate in such a way as to ensure there is a no arbitrage relationship between the market and the model. The numerical approach used to generate the lattice will depend on the SDE model(s) being used to represent interest rates.

No arbitrage models are the preferred framework to value interest rate derivatives. This is because they minimally ensure that the market prices for bonds are exact. Equilibrium models will not price bonds exactly, and this can have tremendous effects on the corresponding contingent claims. No arbitrage lattices also allow for a systematic valuation approach to almost all interest rate securities.

Three general SDE functional forms are considered in this entry. The first is the *Hull-White (HW) model*. The HW model is a more general version of the *Ho and Lee (HL)*¹ approach except that it allows for mean reversion. Implementing the HW in a binomial framework removes a degree of freedom, and in this case the HW model collapses to the HL model if a constant time step is retained. The second model we consider is the *Black-Karasinski (BK) model*. The BK model is a more general form of the *Kalotay, Williams, and Fabozzi (KWF) model*.² The BK model (like the HW model) in the binomial setting does not have enough degrees of freedom to be properly modeled and so the time step must be allowed to vary. The third is the *Black, Derman, and Toy model*.

We implement the HW and BK trinomial models using the Hull and White approach.

Within the trinomial setting the time step remains constant and *mean reversion* can be explicitly incorporated. We discuss the SDEs, the properties of the SDEs, the numerical solutions to the SDEs, and the binomial and trinomial interest rate lattices for these models.

The focus of our presentation is on the end user and developer of interest rate models. We will highlight some significant differences across models. Most of these are due to the different distributions that underlie the models. This is done to emphasize the need to calibrate all models to the market prior to their use. By calibrating the models to the market we reduce the effects of the distributional differences and ensure a higher level of consistency in the metrics produced by the models.

The outline of this entry is as follows. In the next section we present the SDEs and some of their mathematical properties. We also use the mathematics to highlight properties of the short rate. We then develop the methodology used to implement our approach in both the binomial and trinomial frameworks. A comparison of some numerical results across the different models including some interest rate risk and valuation metrics is then presented.

THE GENERAL MODELS FOR THE SHORT RATE

The models considered in this entry take the form of the following one-factor SDE:

$$df(r(t)) = [\theta(t) + \rho(t)g(r(t))]dt + \sigma(r(t), t)dz \quad (1)$$

where f and g are suitably chosen functions, θ is determined by the market, and ρ can be chosen by the user of the model or dictated by the market. We will show that θ is the drift of the short rate and ρ is the tendency to an equilibrium short rate. The term σ is the local volatility of the short rate. The term $dz = \varepsilon\sqrt{dt}$ arises from a normally distributed Wiener process, since $\varepsilon \sim N(0,1)$, where $N(0,1)$ is the normal

distribution with mean 0 and standard deviation of 1. This means that the term $\sigma(r(t), t)dz$ has an average or expected value of 0.

Equation (1) has two components. The first component is the expected or average change in rates over a small period of time, dt . This is the component where certain characteristics of interest rates, such as mean reversion, are incorporated. The second component is the unknown or the risk term since it contains the random term. This term dictates the distribution characteristics of interest rates. Depending on the model, interest rates are either normally or lognormally distributed.

The Ho-Lee Model

In the HL model or process $f(r) = r$, $g(r) = 0$, and $\rho = 0$ in equation (1). The HL process is, therefore, given by

$$dr = \theta dt + \sigma dz \tag{2}$$

Since z is a normally distributed Wiener process, we say the HL process is a normal process for the short rate. The solution to equation (2), assuming $r(0) = r_0$ is given by

$$r(t) = r_0 + \int_0^t \theta ds + \int_0^t \sigma dz \tag{3a}$$

where the integral involving σ is a stochastic integral. If θ is constant this can be expressed as

$$r(t) = r_0 + \theta t + \int_0^t \sigma dz \tag{3b}$$

Equation (3b) shows that the HL process models an interest rate that can change proportionally with time t through the constant of proportionality, θ , and a random disturbance determined by σ . That is, the larger θ is in magnitude, the larger the average change in the short rate over time. This is why θ is called the “drift in the short rate.” Also, the smaller θ is, the larger the influence of the random disturbance. The short rate can be negative in

the HL process. This is a shortcoming of the model. Hull (2000) shows that θ is related to the slope of the term structure.

To obtain a numerical approximation for equation (2) we approximate equation (2) by using equations (3a) and (3b). Letting $t_k = k\tau$ and $r_k \approx r(k\tau)$ gives

$$r_{k+1} - r_k = \theta_k \tau + \sigma_k \Delta z_k$$

or

$$r_{k+1} = r_k + \theta_k \tau + \sigma_k \Delta z_k \tag{4}$$

where Δz_k is a numerical (discrete) approximation to dz . Since $dz = \varepsilon \sqrt{dt}$, we can further approximate equation (4) by

$$r_{k+1} = r_k + \theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{5}$$

where ε_k is a random number given by a normal distribution $N(0,1)$. Equation (5) is the form of the expression that is used for r_{k+1} to build the HL binomial tree.

We first consider the solution to equation (5) without the stochastic term when θ is constant. Equation (5) under these requirements is

$$r_{k+1} = r_k + \tau \theta \tag{6a}$$

and the solution is given by

$$r_k = c + k\delta \tag{6b}$$

where c and δ are constants. In particular, $c = r_0$ and $\delta = \theta\tau$. It is seen from this last equation that the mean short rate in the HL process increases or decreases at a constant rate θ over time depending on the sign of θ . As a matter of fact, equation (6b) shows that the short rate grows without bound if $\theta > 0$ and decreases without bound (i.e. becomes very negative) if $\theta < 0$.

The Hull-White Model

In the HW model or process $f(r) = r$, $g(r) = r$, and $\rho = -\phi$. Therefore, the stochastic process for the HW model for the short rate is

$$dr = (\theta - \phi r)dt + \sigma dz \tag{7}$$

The short rate process in the HW model is seen to be normal as in the HL process. We consider the case where the parameters θ and ϕ are constant over time. Note that if $\phi = 0$ the HL process reduces to the HW process. (The HW process will, therefore, be similar to the HL process if ϕ is close to 0.) We will see that the introduction of ϕ in the HW model is an attempt to incorporate mean reversion and to correct for the uncontrolled growth (or decline) in the HL model discussed later.

Eliminating the stochastic term in equation (7) gives the ordinary differential equation

$$dr = (\theta - \phi r)dt \quad (8)$$

whose solution is given by

$$r(t) = \frac{\theta}{\phi} + ce^{-\phi t} \quad (9)$$

where

$$c = r_0 - \frac{\theta}{\phi} \quad (10)$$

If $\phi > 0$ we see from equation (9) that

$$\lim_{t \rightarrow \infty} r(t) = \frac{\theta}{\phi} = \mu$$

Therefore, for positive mean reversion ($\phi > 0$) the HW process will converge to the short rate, μ . Due to this, the term μ , is called the “target” or “long run mean rate.” For negative mean reversion ($\phi < 0$), the short rate grows exponentially over time.

Factoring ϕ in equation (7) leads to

$$dr = \phi(\mu - r)dt + \sigma dz$$

and eliminating the stochastic term leads to

$$dr = \phi(\mu - r)dt$$

We see that if $r > \mu$ then dr is negative and r will decrease and if $r < \mu$ then dr is positive and r will increase. That is, r will approach the target rate μ . The larger ϕ is, the faster this approach to the target rate μ . This is why ϕ is called the “mean reversion” or “mean reversion rate.” It regulates how fast the target rate is reached. However, it does not eliminate the negative rates that can occur in the HL process.

Since the target rate μ is equal to θ/ϕ , we can solve for the drift, θ , or the mean reversion, ϕ . That is,

$$\theta = \mu\phi \quad (11)$$

or

$$\phi = \frac{\theta}{\mu} \quad (12)$$

It is seen from equations (11) and (12) that there is a strong relationship between the drift and mean reversion that can be used to reach any desired target rate. How large the mean reversion should be is an important financial question. Equations (11) and (12) can be used to set target rates. Equations (9) and (10) allow one to determine how long it takes to reach the target rate.

Approximating equation (7) gives us

$$r_{k+1} = r_k + (\theta_k - \phi_k r_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau} \quad (13)$$

If θ and ϕ are constant and we eliminate the stochastic term, then the solution to equation (13) has the form

$$r_k = \alpha\beta^k + \gamma$$

To determine α , β , and γ we substitute this form for r_k into equation (13) under these conditions and obtain that $\beta = (1 - \phi\tau)$, $\gamma = \theta/\phi = \mu$, and $\alpha = r_0 - \mu$. Therefore,

$$r_k = \alpha(1 - \phi\tau)^k + \frac{\theta}{\phi} \quad (14)$$

Note that if $0 < \phi\tau < 2$ then $-1 < 1 - \phi\tau < 1$ and

$$\lim_{k \rightarrow \infty} r_k = \frac{\theta}{\phi} = \mu$$

which is the same result we obtained from equation (9) for the HW SDE. The condition $0 < \phi\tau < 2$ is easily maintained in modeling the short rate.

The Kalotay-Williams-Fabozzi Model

For the KWF process $f(r) = \ln(r)$, $g(r) = 0$, and $\rho = 0$ in equation (1). This leads to the

differential process

$$d \ln(r) = \theta dt + \sigma dz \tag{15a}$$

This model is directly analogous to the HL model. If $u = \ln r$, then we obtain the HL process (equation (2)) for u

$$du = \theta dt + \sigma dz \tag{15b}$$

Because u follows a normal process, $\ln(r)$ follows a normal process and so r follows a lognormal process. Since u follows the same process as the HL and HW models, u can become negative, but $u = \ln(r)$ and $r = e^u$ ensuring r is always positive. Therefore, the KWF model eliminates the problems of negative short rates that occurred in the HL and HW models.

Eliminating the stochastic term in equation (15) we obtain

$$d \ln(r) = \theta(t)dt$$

and

$$du = \theta(t)dt$$

From equation (3a) we have

$$\ln r(t) = u = u(0) + \int_0^t \theta(s) ds$$

since $u(0) = \ln r(0) = \ln r_0$,

$$\ln r(t) = \ln r(0) + \int_0^t \theta(s) ds$$

Taking the exponential of both sides gives us

$$r(t) = r_0 e^{\int_0^t \theta(s) ds} \tag{16}$$

showing that $r(t) > 0$ since $r(0) > 0$. Therefore, if $\theta(t) > 0$ the short rate in the KWF process can grow without bound and if $\theta(t) < 0$ the short rate in the KWF process can decay to 0.

From equation (5) for the HL process the discrete approximation to equation (15b) is

$$u_{k+1} = u_k + \theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{17a}$$

and the exponential of this equation gives the discrete approximation to equation (15a):

$$r_{k+1} = r_k e^{\theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau}} \tag{17b}$$

From equation (17b) and equation (16) we see that the numerical approximation to equation (15a) has similar properties to the solution to the HL SDE. That is, if $\theta(t) > 0$ the short rate can grow without bound and if $\theta(t) < 0$ the short rate can decay to 0.

The Black-Karasinski Model

In the BK model we set $f(r) = \ln r$, $p = -\phi$, and $g(r) = \ln r$ in equation (1) to obtain the SDE

$$d \ln r = (\theta - \phi \ln r)dt + \sigma dz \tag{18a}$$

We now work with equation (18a) using equation (7) for the HW process in a manner similar to how we used results from the HL process to develop the KWF process. If we let $u = \ln r$ in equation (18a) we obtain

$$du = (\theta - \phi u)dt + \sigma dz \tag{18b}$$

which is the HW process for u . Again, note that u has all the same properties as r in the HW model. Since $r = e^u$ in the BK process, $r > 0$. This is the advantage the BK model has over the HW model. Therefore, we see that the BK process is an extension of the KWF process as the HW process is an extension of the HL process. The main difference is the BK is a lognormal extension of the lognormal KWF process. As a matter of fact, if $\phi = 0$ the BK process reduces to the KWF process. Black and Karasinski introduced ϕ to control the growth of the short rate in the KWF process.

From equation (9) we have

$$u(t) = \frac{\theta}{\phi} + ce^{-\phi t}$$

and after taking exponentials

$$r(t) = e^{u(t)} = e^{\frac{\theta}{\phi} + ce^{-\phi t}} \tag{19}$$

For $\phi < 0$ we see that r grows without bound and that for $\phi > 0$

$$\lim_{t \rightarrow \infty} r(t) = e^{\frac{\theta}{\phi}} = \mu$$

The target rate for the BK process is the exponential of the target rate for the HW process.

As in the HW process, from equation (19) (or equations (9) and (10)) we see that

$$c = \ln r_0 - \frac{\theta}{\phi} \quad (20)$$

in the BK process. The closer the initial rate is to the target rate, the faster the BK process converges to the target rate. From equations (19) and (20) we see that if the initial short rate is the target rate, then $r(t) = \mu$ for all t in the BK process, which is analogous to the HW process.

Given the target rate μ , we can solve for the drift or the mean reversion similarly to equations (11) and (12) in the HW model. We have

$$\theta = \phi \ln \mu \quad (21)$$

and

$$\phi = \frac{\theta}{\ln \mu} \quad (22)$$

We discretize $u = \ln r$ in equation (18b) just as we did for the HW SDEs and then let $r = e^u$. This is analogous to how we used the HL discrete process to get the KWF discrete process. The equations corresponding to equation (13) are

$$u_{k+1} = u_k + (\theta_k - \phi_k u_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau} \quad (23a)$$

or after taking the exponential of both sides of equation (23a)

$$r_{k+1} = r_k e^{(\theta_k - \phi_k \ln r_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau}} \quad (23b)$$

For constant θ and ϕ (similarly to equation (14)), the solution to equation (23b) after eliminating the stochastic term is

$$r_k = e^{\alpha(1-\phi r)^k + \frac{\theta}{\phi}} \quad (24)$$

Note from equation (24) that

$$\lim_{k \rightarrow \infty} r_k = e^{\frac{\theta}{\phi}} = \mu$$

for $0 < \phi\tau < 2$. This is similar to the result we obtained from equation (14) for the HW SDEs.

The Black-Derman-Toy Model

The Black-Derman-Toy (BDT) model is a lognormal model with mean reversion, but the mean reversion is endogenous to the model.

The mean reversion in the BDT model is determined by market conditions.

The equation describing the interest rate dynamics in the BDT model has $f(r) = \ln r$ and $g(r) = \ln r$ in equation (1) as in the BK model. Therefore, the short rate in the BDT model follows the lognormal process

$$d \ln r + [\theta(t) + \rho(t) \ln r]dt + \sigma(t)dz$$

However, in the BDT model $\rho(t) = \frac{d}{dt} \ln \sigma(t) = \frac{\sigma'(t)}{\sigma(t)}$ giving us

$$d \ln r = \left(\theta(t) + \frac{\sigma'(t)}{\sigma(t)} \ln r \right) dt + \sigma(t)dz \quad (25a)$$

Making the substitution $u = \ln r$ leads to

$$du = \left(\theta(t) + \frac{\sigma'(t)}{\sigma(t)} u \right) dt + \sigma(t)dz \quad (25b)$$

Notice the similarity in equations (25) and the equations (18) of the BK model. We expect

$$\frac{\sigma'(t)}{\sigma(t)}$$

to behave similarly to $-\phi(t)$ in the BK model. This expression should give mean reversion in the short rate when it is negative. That is, we expect that if $\sigma'(t) < 0$ (implying $\sigma(t)$ is decreasing) then the BDT model will give mean reversion. On the other hand, when $\sigma'(t) > 0$ (implying $\sigma(t)$ is increasing) the short rates in the BDT model will grow with no mean reversion. If $\sigma(t)$ is constant in the BDT model, then $\sigma'(t) = 0$ so $\rho = 0$ and equation (25a) becomes the KWF model (equation (15)). Therefore, we will only study the case of varying local volatility for the BDT model.

Eliminating the stochastic term in equation (25) leads to

$$\begin{aligned} d \ln r &= du = \left(\theta(t) + \frac{\sigma'(t)}{\sigma(t)} u \right) dt \\ &= \left(\theta(t) + \frac{\sigma'(t)}{\sigma(t)} \ln r \right) dt \end{aligned} \quad (26)$$

Solving this equation for u , as we did in the KF and BK models, gives us

$$u(t) = \left[\frac{u(0)}{\sigma(0)} + \int_0^t \frac{\theta(s)}{\sigma(s)} ds \right] \sigma(t)$$

or

$$r(t) = e^{\left(\frac{\log(r_0)}{\sigma_0} + \int_0^t \frac{\theta(s)}{\sigma(s)} ds\right)\sigma(t)} = e^{\frac{\sigma(t)\log(r_0)}{\sigma_0}} e^{\sigma(t) \int_0^t \frac{\theta(s)}{\sigma(s)} ds}$$

or

$$r(t) = r_0 e^{\frac{\sigma(t) - \sigma_0 \log(r_0)}{\sigma_0}} e^{\sigma(t) \int_0^t \frac{\theta(s)}{\sigma(s)} ds} \tag{27}$$

Note that the BDT mean short rate depends on the local volatility. If the local volatility has a decreasing structure, then the first exponential term in equation (27) has a negative exponent and will cause a decrease in the short rate and vice versa if the local volatility has an increasing structure. It is important to note that mean reversion in the BDT model comes from the local volatility structure (i.e., it is endogenous).

We now consider numerical solutions to the BDT process. To discretize equation (25a) for the BDT model we start off again by approximating du in equation (25b) by u to get

$$u_{k+1} = u_k + (\theta_k + \rho_k u_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{28}$$

The exponential of equation (28) gives us

$$r_{k+1} = r_k e^{[(\theta_k + \rho_k \ln r_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau}]} \tag{29}$$

where

$$\rho_k = \frac{\sigma'_k}{\sigma_k}$$

We approximate this term by

$$\frac{\sigma_{k+1} - \sigma_k}{\tau} \frac{1}{\sigma_k}$$

That is, we approximate σ'_k by a discrete approximation to the derivative. We now have

$$u_{k+1} = u_k + \left(\theta_k + \frac{\sigma_{k+1} - \sigma_k}{\tau} \frac{1}{\sigma_k} u_k \right) \tau + \sigma_k \varepsilon_k \sqrt{\tau}$$

or

$$u_{k+1} = \frac{\sigma_{k+1}}{\sigma_k} u_k + \theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{30}$$

If the random term is 0 equation (30) becomes

$$u_{k+1} = \frac{\sigma_{k+1}}{\sigma_k} u_k + \theta_k \tau \tag{31}$$

In particular, if

$$\frac{\sigma_{k+1}}{\sigma_k} = \alpha$$

where α is a constant then

$$u_k = \alpha^k u_0 + \sum_{j=0}^{k-1} \alpha^j \theta_{k-j-1} \tau$$

The exponential of this gives

$$r_k = r_0 e^{(\alpha^k - 1) \ln r_0} e^{\sum_{j=0}^{k-1} \alpha^j \theta_{k-j-1} \tau}$$

This equation is interesting because $\ln r_0 < 0$. If $\alpha > 1$ then the first exponential term decreases. When $\theta < 0$ the second exponential term also decreases and the BDT short rate should approach a target rate. Conversely, when $\theta > 0$ the second exponential term increases. In this case we can approach a target rate or the second term can dominate. If $\alpha < 1$ then a similar situation arises. Therefore, in order to get meaningful numerical results for the BDT short rates we strongly recommend that α be close to 1 and that the term structure of spot rates not have too large a slope.

The analysis of the equations without the stochastic term presented in this section is important. Recall that the characteristics of the random term are such that average influence of this term will be much smaller than the mean term in the SDEs. Consequently, the properties presented within this section will also hold under more general circumstances. The discrete approximations we developed for the models will be used to build the binomial and trinomial models in the next section. Note that we are highlighting the difference across the models and do not calibrate the models to market information.

For numerical reasons, the BK and HW models are best implemented in the trinomial framework. The HL, KWF, and BDT models are more easily implemented in the binomial framework.³ We will discuss the specifics of this in the next section. For the trinomial framework we use the approach of Hull and White (1994).

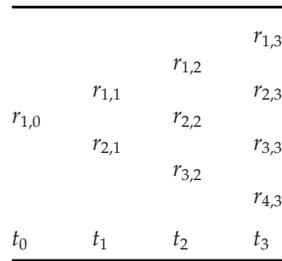

Figure 1 Binomial Lattice

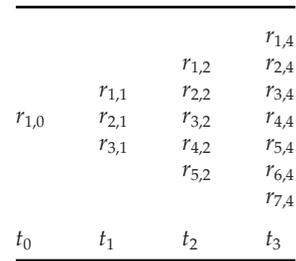

Figure 2 Trinomial Lattice

BINOMIAL AND TRINOMIAL SOLUTIONS TO THE STOCHASTIC DIFFERENTIAL EQUATIONS

In this section we present the *binomial* and *trinomial lattice models* that are obtained for the discretized versions of SDEs given in the previous section. The binomial method models the short rate in a geometrically analogous manner as equities.⁴ The up move has a probability q and so the down move has a probability of $1 - q$. We use $q = 0.5$ within the framework of risk neutrality. This binomial process of two possible moves for the short rate in the next time period is then continued at each time to produce a binomial lattice of interest rates.

The trinomial model is similar in spirit to the binomial except there are three possible states emanating from each node. From each point in time we call the upward-most move the “up move,” the downward-most move the “down move,” and the center move the “middle move.” The probabilities for an up move, middle move, and down move are given by q_1 , q_2 , and q_3 with $q_1 + q_2 + q_3 = 1$.

Interest rate lattices should possess the property of recombination for them to be computationally tractable. That is, from any given node in the binomial model we will require an up move followed by a down move to get to the same point as a down move followed by an up move. This ensures that the number of nodes in the binomial lattice increase by only one at each time step. In the trinomial case recombination

is a little more complicated. From any node in the trinomial lattice an up move followed by a down move will get to the same node as two successive middle moves and as a down move followed by an up move. This ensures that the number of nodes in the trinomial lattice increase by only two at each time step.

Figure 1 represents a binomial short rate lattice and Figure 2 represents a trinomial short rate lattice. The notation $r_{j,k}$ is used to denote the short rate value at level j at time t_k . In the binomial lattice, an up move from $r_{j,k}$ is given by $r_{j,k+1}$ and a down move is given by $r_{j+1,k+1}$. At time t_k there are $k + 1$ possible values for the short rate in the binomial lattice. That is, j ranges from 1 to $k + 1$. In the trinomial model, an up move, middle move, and down move from the short rate $r_{j,k}$ are given by $r_{j,k+1}$, $r_{j+1,k+1}$, and $r_{j+2,k+1}$, respectively. In the trinomial model there are $2k + 1$ possible values for the short rate at time t_k . That is, j ranges from 1 to $2k + 1$. The short rates forming the top of the lattice will be called the up state for the short rates and the short rates forming the bottom of the lattice will be called the down state for the short rates. For the binomial and trinomial model, the up state is the set of short rates $r_{1,k}$ for $0 \leq k \leq n$ and the down state for the binomial case is the set of short rates $r_{k,k}$ for $0 \leq k \leq n$; within the trinomial tree the down state is the set of short rates $r_{2k+1,k}$ for $0 \leq k \leq n$.

Hull-White Binomial Lattice

Since the HW model is a more general version of the HL model we present the binomial version

only for the HW. In the HW binomial lattice the expressions for $r_{j,k}$ that correspond to equation (13) are

$$r_{j,k+1} = r_{j,k} + \theta_k \tau_k - \phi_k r_{j,k} \tau_k + \sigma_k \sqrt{\tau_k} \quad (32)$$

for an up move and

$$r_{j+1,k+1} = r_{j,k} + \theta_k \tau_k - \phi_k r_{j,k} \tau_k - \sigma_k \sqrt{\tau_k} \quad (33)$$

for a down move. (We are using τ_k for Δt_k .)

These equations suggest that in order to have recombination the following must be true:

$$\tau_{k+1} = \tau_k \frac{4 \left(\frac{\sigma_k}{\sigma_{k+1}} \right)^2}{\left[1 + \sqrt{1 + 4 \left(\frac{\sigma_k}{\sigma_{k+1}} \right)^2 \tau_k \phi_{k+1}} \right]^2} \quad (34)$$

Equation (34) illustrates that if you want a constant time step when the local volatility is constant, the mean reversion must be 0. The recombination requirement has put the stringent condition on the HW binomial lattice that the mean reversion is determined by the local volatility. To avoid this problem within the binomial framework we must allow the time step to vary with k in equations (32) through (34). As a matter of fact, for a constant time step,

$$\phi_{k+1} = \frac{\sigma_k - \sigma_{k+1}}{\sigma_k \tau} \quad (35)$$

which can also be solved for σ_{k+1} to give

$$\sigma_{k+1} = \sigma_k (1 - \phi_{k+1} \tau) \quad (36)$$

Equation (36) shows that the mean reversion can be used to match any given local volatility for a constant time step. If the local volatility is decreasing the mean reversion will be positive, and if the local volatility is increasing the mean reversion will be negative. We point out that if a variable time step is used, one does not have to have mean reversion match local volatility.

Black-Karasinski Binomial Lattice

Since the BK model is a more general form of the KWF model, we only present the binomial version for the BK model. The expressions corre-

sponding to equations (32) and (33) of the HW model and from equation (23b) are

$$r_{j,k+1} = r_{j,k} e^{(\theta_k - \phi_k \ln(r_{j,k})) \tau_k + \sigma_k \sqrt{\tau_k}} \quad (37)$$

for an up move and

$$r_{j+1,k+1} = r_{j,k} e^{(\theta_k - \phi_k \ln(r_{j,k})) \tau_k - \sigma_k \sqrt{\tau_k}} \quad (38)$$

for a down move.

Using equations (37) and (38) we can develop equations for the BK binomial lattice that are identical to equations (34) and (36) for the HW binomial lattice. This should be expected since the BK SDE is just a lognormal version of the HW SDE. A crucial point here is that we can use the HW and BK models to match local volatility and to compare results. It is important to point out that the HW and BK binomial lattices have a constant time step. If a variable time step is used, then interpolation is required to give the short rates at the fixed time steps. We do not offer this framework. Instead we present the HW and the BK models in the trinomial framework.

Within the binomial framework, the HW and BK models only approximate the distributional properties of their respective SDEs. The accuracy of the approximation is a function of the mean reversion. As the mean reversion increases, the accuracy decreases. Note that since the HL and KWF models have a zero mean reversion the distributional characteristics of their SDEs are perfectly matched within the binomial framework. This is the reason for using the trinomial method for the HW and BK models.

The Trinomial Lattices

A better way to keep a constant time step and to match the appropriate distributional properties is to use a trinomial lattice instead of a binomial lattice. If we use a trinomial lattice for the HW SDEs, then from equation (13) we use

$$r_{j,k+1} = r_{j,k} + \theta_k \tau - \phi_k r_{j,k} \tau + \alpha_k \sigma_k \sqrt{\tau} \quad (39a)$$

for an up move,

$$r_{j+2,k+1} = r_{j,k} + \theta_k \tau - \phi_k r_{j,k} \tau - \alpha_k \sigma_k \sqrt{\tau} \quad (39b)$$

for a down move, and

$$r_{j+1,k+1} = r_{j,k} + \theta_k \tau - \phi_k r_{j,k} \tau \quad (39c)$$

for a middle move. Similarly, if we use a trinomial lattice for the BK SDEs then from equation (23b) we use

$$r_{j,k+1} = r_{j,k} e^{(\theta_k - \phi_k \ln(r_{j,k}))\tau + \alpha_k \sigma_k \sqrt{\tau}} \quad (40a)$$

for an up move,

$$r_{j+2,k+1} = r_{j,k} e^{(\theta_k - \phi_k \ln(r_{j,k}))\tau - \alpha_k \sigma_k \sqrt{\tau}} \quad (40b)$$

for a down move, and

$$r_{j+1,k+1} = r_{j,k} e^{(\theta_k - \phi_k \ln(r_{j,k}))\tau} \quad (40c)$$

for a middle move.

Note that a constant time step is now used. The expression α_k is used to guarantee recombination. The probabilities of an up, middle, and down move are chosen to give the correct variance.

The No Arbitrage Equations

The procedure to generate the no arbitrage equations for the binomial and trinomial lattices is outlined in the appendix. The no arbitrage polynomial for the short rates in the binomial tree is given by

$$f_i = c_{1,i} \prod_{j=1}^i (1 + r_{j,i} \tau) + \sum_{m=1}^i c_{m+1,i} \prod_{\substack{n=1 \\ n \neq m}}^i (1 + r_{n,i} \tau) \quad (41)$$

where, for $i \geq 3$

$$a_{1,i} = \prod_{n=0}^{i-1} \prod_{m=1}^i (1 + r_{m,n} \tau)$$

$$\begin{aligned} a_{2,i} &= b_{1,i-1}, a_{j,i} = b_{j-2,i-1} + b_{j-1,i-1}, & \text{for } j = 3, \dots, i, \\ a_{i+1,j} &= b_{i-1,i-1}, & \text{and } c_{1,i} = P_{i+1} a_{1,i}, \\ c_{j+1,i} &= q^{i-j} (1-q)^{j-1} a_{j+1,i} & \text{for } j = 1, \dots, i. \end{aligned}$$

We solve equation (41) for θ_i by setting $f_i = 0$. We then use θ_i to compute $r_{j,i}$ for $j = 1, \dots, i$ at the i th period. The bisection method will converge quickly because there is

only one root between -1 and 1 for the HW binomial lattice and one root between 0 and 1 for the BK binomial lattice.⁵

After generating the new rates we let

$$b_{j,i} = \alpha_{j+1,i} \prod_{\substack{m=1 \\ m \neq j}}^i (1 + r_{m,i} \tau)$$

For the variable time step, τ_i we replace the terms $(1 + r_{j,i} \tau)$ by $(1 + r_{j,i} \tau)^{\tau_i/\tau}$ and the terms $(1 + r_{n,i} \tau)$ by

$$(1 + r_{n,i} \tau)^{\tau_i/\tau}$$

in equation (41).

Similarly, the no arbitrage polynomial for the trinomial trees is given by

$$f_i = c_{1,i} \prod_{j=1}^{2i-1} (1 + r_{j,i} \tau) + \sum_{m=1}^{2i-1} c_{m+1,i} \prod_{\substack{n=1 \\ n \neq m}}^{2i-1} (1 + r_{n,i} \tau) \quad (42)$$

where we first let

$$a_{1,i} = \prod_{j=1}^{2i-3} (1 + r_{j,i} \tau)$$

$$a_{2,i} = q_1 b_{1,i-1} a_{2,i-1}, a_{3,i} = q_2 b_{1,i-1} a_{2,i-1} + q_1 b_{2,i-1} a_{3,i-1}$$

$$a_{j,i} = q_3 b_{j-3,i-1} a_{j-2,i-1} + q_2 b_{j-2,i-1} a_{j-1,i-1} + q_1 b_{j-1,i-1} a_{j,i-1},$$

for $j = 4, \dots, 2i - 2$,

$$\begin{aligned} a_{2i-1,i} &= q_3 b_{2i-4,i-1} a_{2i-3,i-1} + q_2 b_{2i-3,i-1} a_{2i-2,i-1} a_{2i,i} \\ &= q_3 b_{2i-3,i-1} a_{2i-2,i-1} \end{aligned}$$

and then let

$$c_{1,i} = P_{i+1} a_{1,i}, c_{j,i} = a_{j,i} \text{ for } j = 2, \dots, 2i + 1$$

We solve equation (42) for θ_i by setting $f_i = 0$ using the bisection method. From this the short rates for either the HW or BK trinomial lattices are determined at step i . We then let

$$b_n = \prod_{\substack{j=1 \\ j \neq n}}^{2i-1} (1 + r_{j,i} \tau)$$

for $n = 1, \dots, 2i - 1$ and then repeat the process. In these derivations $P_i = 1/(1 + R_i \tau)^i$ is the discount factor given by the spot rates (zero curve).

The Hull and White Lattice

We now briefly outline the Hull and White methodology for generating HW and BK trinomial lattices.⁶ The Hull and White methodology uses

$$r_{j,k} = x + (j_k)\Delta\rho \tag{43}$$

for the HW trinomial lattice short rates and

$$r_{j,k} = e^{[x+(j_k)\Delta\rho]} \tag{44}$$

for the BK trinomial lattice short rates.

They choose $\Delta\rho = \sigma\sqrt{3\tau}$ to minimize numerical error and introduce the mean reversion through the probabilities $q_1, q_2,$ and q_3 . Specifically, they use

$$q_1 = \frac{1}{6} + \frac{(j_k)^2\phi^2\tau^2 + (j_k)\phi\tau}{2}$$

$$q_2 = \frac{2}{3} - (j_k)^2\phi^2\tau^2$$

and

$$q_3 = \frac{1}{6} + \frac{(j_k)^2\phi^2\tau^2 - (j_k)\phi\tau}{2}$$

for the up, middle, and down moves at $r_{j,k}$, respectively, since this matches the expected change and variance of the short rate over the next time period. However, as they point out, these probabilities must remain positive. In order to do this they “prune” the upper and lower branches of their lattice at the level j that keeps these probabilities positive. Since q_2 is the only one that can become negative they require the following

$$j < \frac{\sqrt{6}}{3\phi\tau} \approx \frac{0.816}{\phi\tau}$$

At this maximum value of j , Hull and White apply a different branching procedure with different probabilities in order to “prune” the lattice. However, as they point out, using this value of j can lead to computational problems so they actually use the first j satisfying

$$j_k > \frac{3 - \sqrt{6}}{3\phi\tau} \approx \frac{0.184}{\phi\tau}$$

This leads to a reduction in the spread of the rates.

COMPARATIVE STUDY OF THE NUMERICAL SOLUTIONS

In this section a comparison between the methodologies is presented. In particular, we look at the effects of mean reversion and local volatility on the drift and the spread in the short rates. We present numerical results for the term structures, volatility, and mean reversion in Table 1. The table also includes the bond information for use later.

Original Term Structure with No Mean Reversion

We first consider the original term structure with no mean reversion for the HL and HW models. In Figure 3 we present the binomial tree for the HL model and the trinomial for the HW model using the HW trinomial methodology. We use a 10% volatility throughout the trees. We see that the spread in the short rates increases over time in the models as expected.

Figure 3 The HL Binomial and HW Trinomial Trees for the Original Term Structure with No Mean Reversion

We also see that the HL model can give negative short rates.

In Figure 4 we present the binomial tree for the KWF model, the trinomial for the BK model using the HW trinomial methodology, and the BDT binomial model. The KWF and BK models use the 10% volatility throughout the tree and

no mean reversion. Note the volatile nature of the BDT model. This is due to the time varying volatility structure and the way mean reversion is incorporated into the BDT model through this decreasing volatility structure. Note that all the short rates are positive and that the spread in the rates is significantly less than in Figure 3.

Figure 4 The BDT and KWF Binomial and the BK Trinomial Trees for the Original Term Structure with No Mean Reversion

Table 2 presents the trinomial lattices for the HW and BK models using the information in Table 1 and a mean reversion of 5%. The volatility is 10%. Notice the pruning that takes place within the lattice when we have mean reversion. This produces lattices that are significantly

different from those shown in Figures 3 and 4. This is a peculiarity of the Hull and White methodology. The pruning is a result of incorporating mean reversion into the model and ensuring that the distributional characteristics of the SDEs are retained.

Comparison of the Models Using Common Risk and Value Metrics

Here we contrast the effective duration, effective convexity, and the option-adjusted spread (OAS) for 10-year callable and putable bonds each with a one-year delay on the embedded option. The information in Table 1 is used for the analysis. We computed the effective duration for the original term structures shown in Table 1 using a yield change of 25 basis points. The original term structure is then shifted up and down in a parallel manner by ± 250 basis points and by ± 500 basis points, respectively. In other words, we computed the effective duration at five different term structure levels using a yield change of 25 basis points.

Table 3 presents the effective duration and convexity results for the two securities for each model. The results are interesting. It is clear that the normal models do not agree with the lognormal models. Specifically, the normal models do not match the characteristics of the price yield

relationship at extreme interest rate levels.⁷ Furthermore, each model gives slightly different results. This is an important finding and must be appreciated by any user of these models.

Table 4 presents the OAS results. We used a market price that is 3% below the model price for the OAS computation. They are consistent with the results in Table 3. Note that the normal models produce OAS values larger than any of the lognormal models. This is due to the distributional differences and the property of allowing very low and negative interest rates. Clearly, normal models are not desirable when evaluating securities with embedded options.⁸

APPENDIX

In this appendix we outline how to obtain equations (41) and (42). For equation (41) we use Figure 1. For equation (42) we use Figure 2.

Table 4 Option-Adjusted Spread Results

	Ho-Lee	BDT	KWF	HW-HW	BK-HW
Callable Bond	0.8454%	0.4785%	0.5449%	0.8350%	0.5063%
Putable Bond	0.5884%	0.4732%	0.5249%	0.5688%	0.4774%

We first solve for $r_{1,1}$ and $r_{2,1}$ in Figure 1. Equating the price from the spot rate term structure with the price from the binomial lattice gives us

$$P_2 = \frac{1}{(1 + R_2\tau)^2} = \frac{qp_{1,1} + (1 - q)p_{2,1}}{1 + r_{1,0}\tau} \quad (\text{A1})$$

Substituting in the discount factors $p_{j,1} = 1/(1 + r_{j,1}\tau)$ for $j = 1, 2$ and clearing fractions we obtain

$$P_2(1 + r_{1,0}\tau)(1 + r_{1,1}\tau)(1 + r_{2,1}\tau) - q(1 + r_{2,1}\tau) - (1 - q)(1 + r_{1,1}\tau) = 0 \quad (\text{A2})$$

We let $r_{1,0} = R_1$. This equation can now be solved for θ_1 .

For the next period in the binomial lattice we have from Figure 1 that

$$P_3 = \frac{1}{(1 + R_3\tau)^3} = \frac{qp_{1,1} + (1 - q)p_{2,1}}{1 + r_{1,0}\tau} = \frac{q\left(\frac{qp_{1,2} + (1 - q)p_{2,2}}{1 + r_{1,1}\tau}\right) + (1 - q)\left(\frac{qp_{2,2} + (1 - q)p_{3,2}}{1 + r_{2,1}\tau}\right)}{1 + r_{1,0}\tau}$$

which reduces to

$$\begin{aligned} &P_3(1 + r_{1,0}\tau)(1 + r_{1,1}\tau)(1 + r_{2,1}\tau)(1 + r_{1,2}\tau) \\ &\quad \times (1 + r_{2,2}\tau)(1 + r_{3,2}\tau) \\ &- q^2(1 + r_{2,1}\tau)(1 + r_{2,2}\tau)(1 + r_{3,1}\tau) \\ &\quad - q(1 - q)[(1 + r_{1,1}\tau) + (1 + r_{2,1}\tau)] \\ &\quad \times (1 + r_{1,2}\tau)(1 + r_{3,2}\tau) - (1 - q)^2(1 + r_{1,1}\tau) \\ &\quad \times (1 + r_{1,2}\tau)(1 + r_{2,2}\tau) = 0 \end{aligned} \quad (\text{A3})$$

We now solve equation (A3) for θ_2 using the bisection method.

From equation (A2) and equation (A3) we can generate the remainder of the no arbitrage equations that give the short rates in the binomial lattice. Note that equation (A2) can be written as

$$c_{1,1}(1 + r_{1,1}\tau)(1 + r_{2,1}\tau) + c_{2,1}(1 + r_{2,1}\tau) + c_{3,1}(1 + r_{1,1}\tau) = 0 \quad (\text{A4})$$

and that equation (A3) can be written as

$$\begin{aligned} &c_{1,2}(1 + r_{1,2}\tau)(1 + r_{2,2}\tau)(1 + r_{3,2}\tau) \\ &\quad + c_{2,2}(1 + r_{2,2}\tau)(1 + r_{3,2}\tau) + c_{3,2}(1 + r_{1,2}\tau) \\ &\quad \times (1 + r_{3,2}\tau) + c_{4,2}(1 + r_{1,2}\tau)(1 + r_{2,2}\tau) = 0 \end{aligned} \quad (\text{A5})$$

We now introduce some variables that will help to generate the coefficients $c_{i,k}$ for the polynomials that determine the interest rates at time period k . We start by doing it for the polynomials in equations (A4) and (A5). This is done in two steps. The first step is to notice how the coefficients are related to the interest rates at the previous time periods. Note that if we let $a_{1,1} = 1 + r_{1,0}\tau$, $a_{2,1} = -1$, and $a_{3,1} = -1$ then $c_{1,1} = P_2a_{1,1}$, $c_{2,1} = qa_{2,1}$, and $c_{3,1} = (1 - q)a_{3,1}$ in equation (A4). In order to generate equation (A5) we first let $b_{1,1} = a_{2,1}(1 + r_{2,1}\tau)$, $b_{2,1} = a_{3,1}(1 + r_{1,1}\tau)$. We can then generate $a_{1,2} = (1 + r_{1,0}\tau)(1 + r_{1,1}\tau)(1 + r_{2,1}\tau)$, $a_{2,2} = b_{1,1}$, $a_{3,2} = b_{1,1} + b_{2,1}$, and $a_{4,2} = b_{2,1}$. It is now seen that $c_{1,2} = P_3a_{1,2}$, $c_{2,2} = q^2a_{2,2}$, $c_{3,2} = q(1 - q)a_{3,3}$, and $c_{4,2} = (1 - q)^2a_{4,2}$. We now let $b_{1,2} = a_{3,1}(1 + r_{2,2}\tau)$

$(1 + r_{3,2}\tau)$, $b_{2,2} = a_{3,2}(1 + r_{1,2}\tau)(1 + r_{3,2}\tau)$, and $b_{3,2} = a_{4,2}(1 + r_{1,2}\tau)(1 + r_{2,2}\tau)$ and continue the process to obtain equation (41).

For the trinomial lattice no arbitrage polynomial we first solve for $r_{1,1}$, $r_{2,1}$, and $r_{3,1}$ in Figure 2. Equating the price from the spot rate term structure with the price from the trinomial lattice gives us

$$P_2 = \frac{1}{(1 + R_2\tau)^2} = \frac{q_1p_{1,1} + q_2p_{2,1} + q_3p_{3,1}}{1 + r_{1,0}\tau}$$

which is similar to equation (A1). Proceeding as in the binomial lattice we find that

$$\begin{aligned} &P_2(1 + r_{1,0}\tau)(1 + r_{1,1}\tau)(1 + r_{2,1}\tau)(1 + r_{3,1}\tau) \\ &\quad - q_1(1 + r_{2,1}\tau)(1 + r_{3,1}\tau) - q_2(1 + r_{1,1}\tau) \\ &\quad \times (1 + r_{3,1}\tau) - q_3(1 + r_{1,1}\tau)(1 + r_{2,1}\tau) = 0 \end{aligned} \quad (\text{A6})$$

As in the binomial case, $r_{1,0} = R_1$ and equation (A6) is solved for θ_1 using the bisection method.

For the next period in the trinomial lattice (Figure 2) gives us

$$P_3 = \frac{1}{(1 + R_3\tau)^3} = \frac{q_1 p_{1,1} + q_2 p_{2,1} + q_3 p_{3,1}}{1 + r_{1,0}\tau}$$

$$= \frac{q_1 \left(\frac{q_1 p_{1,2} + q_2 p_{2,2} + q_3 p_{3,2}}{1 + r_{1,1}\tau} \right) + q_2 \left(\frac{q_1 p_{2,2} + q_2 p_{3,2} + q_3 p_{3,3}}{1 + r_{2,1}\tau} \right) + q_3 \left(\frac{q_1 p_{3,3} + q_2 p_{3,4} + q_3 p_{3,5}}{1 + r_{3,1}\tau} \right)}{1 + r_{1,0}\tau}$$

which simplifies to the following equation similar to equation (A3)

$$P_3 (1 + r_{1,0}\tau) \prod_{j=1}^3 (1 + r_{j,1}\tau) \prod_{j=1}^5 (1 + r_{j,2}\tau)$$

$$- q_1^2 (1 + r_{2,1}\tau) (1 + r_{3,1}\tau) \prod_{j=2}^5 (1 + r_{j,2}\tau)$$

$$- [q_1 q_2 (1 + r_{2,1}\tau) (1 + r_{3,1}\tau) + q_1 q_2 (1 + r_{1,1}\tau)$$

$$\times (1 + r_{3,1}\tau)] \prod_{\substack{j=1 \\ j \neq 2}}^5 (1 + r_{j,2}\tau)$$

$$- [q_1 q_3 (1 + r_{2,1}\tau) (1 + r_{3,1}\tau) + q_2^2 (1 + r_{1,1}\tau)$$

$$\times (1 + r_{3,1}\tau) + q_3 q_1 (1 + r_{1,1}\tau) (1 + r_{2,1}\tau)]$$

$$\times \prod_{\substack{j=1 \\ j \neq 3}}^5 (1 + r_{j,2}\tau) \tag{A7}$$

$$- [q_2 q_3 (1 + r_{1,1}\tau) (1 + r_{3,1}\tau) + q_3 q_2 (1 + r_{1,1}\tau)$$

$$\times (1 + r_{2,1}\tau)] \prod_{\substack{j=1 \\ j \neq 4}}^5 (1 + r_{j,2}\tau)$$

$$- q_3^2 (1 + r_{1,1}\tau) (1 + r_{2,1}\tau) \prod_{j=1}^4 (1 + r_{j,2}\tau) = 0$$

Equation (A7) is also solved for θ_2 using the bisection method. We now proceed as in the binomial lattice case to generate the no arbitrage equation for θ_i given in equation (42).

KEY POINTS

- Interest rates are commonly modeled using stochastic differential equations.
- One-factor models use a stochastic differential equation to represent the short rate and

two-factor models use a stochastic differential equation for both the short rate and the long rate.

-
- The stochastic differential equations used to model interest rates must capture some of the market properties of interest rates such as mean reversion and/or a volatility that depends on the level of interest rates.
 - The approaches used to implement the SDEs into a term structure model include equilibrium and no arbitrage.
 - There are five different term structure models that evolve from three general stochastic differential equations.
 - Without market calibration the models produce very different results.
 - Both the end user and the developer must be aware of these properties in order to properly implement and interpret any results from the models.
 - Even with calibration the models can produce different results. Calibration reduces the differences across the models but does not eliminate them.

Trading Cost Models

Modeling Market Impact Costs

PETTER N. KOLM, PhD

Director of the Mathematics in Finance Masters Program and Clinical Associate Professor,
Courant Institute of Mathematical Sciences, New York University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Portfolio managers and traders need to be able to effectively model the impact of trading costs on their portfolios and trades.

Trading is an integral component of the equity investment process. A poorly executed trade can eat directly into portfolio returns. This is because equity markets are not frictionless, and transactions have a cost associated with them. Costs are incurred when buying or selling stocks in the form of, for example, brokerage commissions, bid-ask spreads, taxes, and market impact costs.

In recent years, portfolio managers have started to more carefully consider transaction costs. The literature on market microstructure, analysis and measurement of transaction costs, and market impact costs on institutional trades is rapidly expanding.¹ One way of describing transaction costs is to categorize them in terms of *explicit costs* such as brokerage and taxes, and *implicit costs*, which include market impact costs, price movement risk, and opportunity cost. *Market impact cost* is, broadly speaking, the price an investor has to pay for obtaining liquidity in the market, whereas price movement risk is the risk that the price of an asset increases or decreases from the time the investor

decides to transact in the asset until the transaction actually takes place. *Opportunity cost* is the cost suffered when a trade is not executed. Another way of seeing transaction costs is in terms of fixed costs versus variable costs. Whereas commissions and trading fees are fixed, bid-ask spreads, taxes, and all implicit transaction costs are variable.

Portfolio managers and traders need to be able to effectively model the impact of trading costs on their portfolios and trades. In this entry, we introduce several approaches for the modeling of transaction costs, in particular market impact costs.

MARKET IMPACT COSTS

The *market impact cost* of a transaction is the deviation of the transaction price from the market (mid) price² that would have prevailed had the trade not occurred. The price movement is the cost, the market impact cost, for liquidity. Market impact of a trade can be negative if, for example, a trader buys at a price below the

no-trade price (i.e., the price that would have prevailed had the trade not taken place). In general, liquidity providers experience negative costs while liquidity demanders will face positive costs.

We distinguish between two different kinds of market impact costs, temporary and permanent. Total market impact cost is computed as the sum of the two. The temporary market impact cost is of transitory nature and can be seen as the additional liquidity concession necessary for the liquidity provider (e.g., the market maker) to take the order, inventory effects (price effects due to broker/dealer inventory imbalances), or imperfect substitution (for example, price incentives to induce market participants to absorb the additional shares).

The permanent market impact cost, however, reflects the persistent price change that results as the market adjusts to the information content of the trade. Intuitively, a sell transaction reveals to the market that the security may be overvalued, whereas a buy transaction signals that the security may be undervalued. Security prices change when market participants adjust their views and perceptions as they observe news and the information contained in new trades during the trading day.

Traders can decrease the temporary market impact by extending the trading horizon of an order. For example, a trader executing a less urgent order can buy or sell his or her position in smaller portions over a period and make sure that each portion only constitutes a small percentage of the average volume. However, this comes at the price of increased opportunity costs, delay costs, and price movement risk.

Market impact costs are often asymmetric; that is, they are different for buy and sell orders. Several empirical studies suggest that market impact costs are generally higher for buy orders. Nevertheless, while buying costs might be higher than selling costs, this empirical fact is most likely due to observations during rising/falling markets, rather than any true market microstructure effects. For example, a study by

Hu shows that the difference in market impact costs between buys and sells is an artifact of the trade benchmark.³ (We discuss trade benchmarks later in this entry.) When a pre-trade measure is used, buys (sells) have higher implicit trading costs during rising (falling) markets. Conversely, if a post-trade measure is used, sells (buys) have higher implicit trading costs during rising (falling) markets. In fact, both pre-trade and post-trade measures are highly influenced by market movement, whereas during- or average-trade measures are neutral to market movement.

Despite the enormous global size of equity markets, the impact of trading is important even for relatively small funds. In fact, a sizable fraction of the stocks that compose an index might have to be excluded or their trading severely limited. For example, RAS Asset Management, which is the asset manager arm of the large Italian insurance company RAS, has determined that single trades exceeding 10% of the daily trading volume of a stock cause an excessive market impact and have to be excluded, while trades between 5% and 10% need execution strategies distributed over several days.⁴ According to RAS Asset Management estimates, in practice funds managed actively with quantitative techniques and with market capitalization in excess of €100 million can operate only on the fraction of the market above the €5 million, splitting trades over several days for stocks with average daily trading volume in the range from €5 million to €10 million. They can freely operate only on two-thirds of the stocks in the MSCI Europe.

LIQUIDITY AND TRANSACTION COSTS

Liquidity is created by agents transacting in the financial markets when they buy and sell securities. Market makers and brokers–dealers do not create liquidity; they are intermediaries who facilitate trade execution and maintain an orderly market.

Liquidity and transaction costs are interrelated. A highly liquid market is one where large transactions can be immediately executed without incurring high transaction costs. In an indefinitely liquid market, traders would be able to perform very large transactions directly at the quoted bid-ask prices. In reality, particularly for larger orders, the market requires traders to pay more than the ask when buying and to receive less than the bid when selling. As we discussed previously, this percentage degradation of the bid-ask prices experienced when executing trades is the market impact cost.

The market impact cost varies with transaction size: The larger the trade size, the larger the impact cost. Impact costs are not constant in time, but vary throughout the day as traders change the limit orders that they have in the limit order book. A *limit order* is a conditional order; it is executed only if the limit price or a better price can be obtained. For example, a buy limit order of a security XYZ at \$60 indicates that the assets may be purchased only at \$60 or lower. Therefore, a limit order is very different from a *market order*, which is an unconditional order to execute at the current best price available in the market (guarantees execution, not price). With a limit order, a trader can improve the execution price relative to the market order price, but the execution is neither certain nor immediate (guarantees price, not execution).

Notably, there are many different limit order types available such as pegging orders, discretionary limit orders, immediate or cancel order (IOC) orders, and fleeting orders. For example, fleeting orders are those limit orders that are canceled within two seconds of submission. Hasbrouck and Saar find that fleeting limit orders are much closer substitutes for market orders than for traditional limit orders.⁵ This suggests that the role of limit orders has changed from the traditional view of being liquidity suppliers to being substitutes for market orders.

At any given instant, the list of orders sitting in the limit order book embodies the liquidity that exists at a particular point in time. By observing the entire limit order book, impact costs can be calculated for different transaction sizes. The limit order book reveals the prevailing supply and demand in the market.⁶ Therefore, in a pure limit order market, we can obtain a measure of liquidity by aggregating limit buy orders (representing the demand) and limit sell orders (representing the supply).⁷

We start by sorting the bid and ask prices, $p_1^{\text{bid}}, \dots, p_k^{\text{bid}}$ and $p_1^{\text{ask}}, \dots, p_l^{\text{ask}}$, (from the most to the least competitive) and the corresponding order quantities $q_1^{\text{bid}}, \dots, q_k^{\text{bid}}$ and $q_1^{\text{ask}}, \dots, q_l^{\text{ask}}$. We then combine the sorted bid and ask prices into a supply and demand schedule according to Figure 1. For example, the block $(p_2^{\text{bid}}, q_2^{\text{bid}})$ represents the second best sell limit order with price p_2^{bid} and quantity q_2^{bid} .

We note that unless there is a gap between the bid (demand) and the ask (supply) sides, there will be a match between a seller and buyer, and a trade would occur. The larger the gap, the lower the liquidity and the market participants' desire to trade. For a trade of size Q , we can define its liquidity as the reciprocal of the area between the supply and demand curves up to Q (i.e., the "dotted" area in Figure 1).

However, few order books are publicly available and not all markets are pure limit order markets. In 2004, the New York Stock Exchange (NYSE) started selling information on its limit order book through its new system called the *NYSE OpenBook*[®]. The system provides an aggregated real-time view of the exchange's limit-order book for all NYSE-traded securities.⁸

In the absence of a fully transparent limit order book, expected market impact cost is the most practical and realistic measure of market liquidity. It is closer to the true cost of transacting faced by market participants as compared to other measures such as those based upon the bid-ask spread.

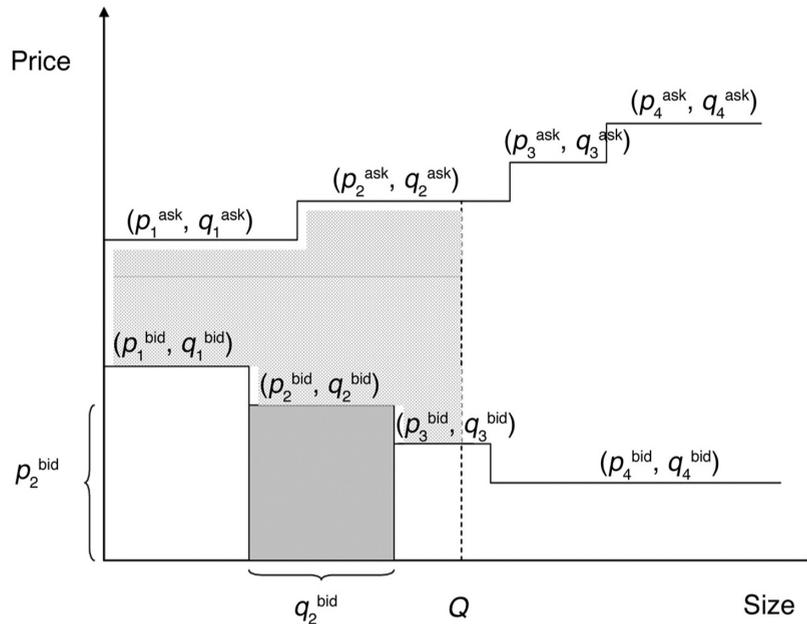

Figure 1 The Supply and Demand Schedule of a Security

MARKET IMPACT MEASUREMENTS AND EMPIRICAL FINDINGS

The problem with measuring implicit transaction costs is that the true measure, which is the difference between the price of the stock in the absence of a money manager's trade and the execution price, is not observable. Furthermore, the execution price is dependent on supply and demand conditions at the margin. Thus, the execution price may be influenced by competitive traders who demand immediate execution or by other investors with similar motives for trading. This means that the execution price realized by an investor is the consequence of the structure of the market mechanism, the demand for liquidity by the marginal investor, and the competitive forces of investors with similar motivations for trading.

There are many ways to measure transaction costs. However, in general this cost is the difference between the execution price and some

appropriate benchmark, a so-called *fair market benchmark*. The fair market benchmark of a security is the price that would have prevailed had the trade not taken place, the no-trade price. Since the no-trade price is not observable, it has to be estimated. Practitioners have identified three different basic approaches to measure the market impact:⁹

1. Pre-trade measures use prices occurring before or at the decision to trade as the benchmark, such as the opening price on the same day or the closing price on the previous day.
2. Post-trade measures use prices occurring after the decision to trade as the benchmark, such as the closing price of the trading day or the opening price on the next day.
3. Same-day or average measures use average prices of a large number of trades during the day of the decision to trade, such as the *volume-weighted average price* (VWAP) calculated over all transactions in the security on the trade day.¹⁰

The volume-weighted average price is calculated as follows. Suppose that it was a trader's objective to purchase 10,000 shares of stock XYZ. After completion of the trade, the trade sheet showed that 4,000 shares were purchased at \$80, another 4,000 at \$81, and finally 2,000 at \$82. In this case, the resulting VWAP is $(4,000 \times 80 + 4,000 \times 81 + 2,000 \times 82)/10,000 = \80.80 .

We denote by χ the indicator function that takes on the value 1 or -1 if an order is a buy or sell order, respectively. Formally, we now express the three types of measures of market impact (MI) as follows

$$MI_{pre} = \left(\frac{p^{ex}}{p^{pre}} - 1 \right) \chi$$

$$MI_{post} = \left(\frac{p^{ex}}{p^{post}} - 1 \right) \chi$$

$$MI_{VWAP} = \left(\frac{\sum_{i=1}^k V_i \cdot p_i^{ex}}{\sum_{i=1}^k V_i} / p^{pre} - 1 \right) \chi$$

where p^{ex} , p^{pre} , and p^{post} denote the execution price, pre-trade price, and post-trade price of the stock, and k denotes the number of transactions in a particular security on the trade date. Using this definition, for a stock with market impact MI the resulting *market impact cost* for a trade of size V , MIC , is given by

$$MIC = MI \cdot V$$

It is also common to adjust market impact for general market movements. For example, the pre-trade market impact with market adjustment would take the form

$$MI_{pre} = \left(\frac{p^{ex}}{p^{pre}} - \frac{p_M^{ex}}{p_M^{pre}} \right) \chi$$

where p_M^{ex} represent the value of the index at the time of the execution, and p_M^{pre} the price of the index at the time before the trade. Market-adjusted market impact for the post-trade and same-day trade benchmarks are calculated in an analogous fashion.

The above three approaches to measure market impact are based upon measuring the fair market benchmark of stock at a point in time. Clearly, different definitions of market impact lead to different results. Which one should be used is a matter of preference and is dependent on the application at hand. For example, Elkins and McSherry, a financial consulting firm that provides customized trading costs and execution analysis, calculates a same-day benchmark price for each stock by taking the mean of the day's open, close, high, and low prices. The market impact is then computed as the percentage difference between the transaction price and this benchmark. However, in most cases VWAP and the Elkins McSherry approach lead to similar measurements.¹¹

As we analyze a portfolio's return over time an important question to ask is whether we can attribute good/bad performance to investment profits/losses or to trading profits/losses. In other words, in order to better understand a portfolio's performance it can be useful to decompose investment decisions from order execution. This is the basic idea behind the *implementation shortfall approach* suggested by Perold (1998).

In the implementation shortfall approach, we assume that there is a separation between investment and trading decisions. The portfolio manager makes decisions with respect to the investment strategy (i.e., what should be bought, sold, and held). Subsequently, these decisions are implemented by the traders.

By comparing the actual portfolio profit/loss (P/L) with the performance of a hypothetical paper portfolio in which all trades are made at hypothetical market prices, we can get an estimate of the implementation shortfall. For example, with a paper portfolio return of 6% and an actual portfolio return of 5%, the implementation shortfall is 1%.

There is considerable practical and academic interest in the measurement and analysis of international trading costs. Domowitz, Glen, and Madhavan (1999) examine international equity

trading costs across a broad sample of 42 countries using quarterly data from 1995 to 1998. They find that the mean total one-way trading cost is 69.81 basis points. However, there is an enormous variation in trading costs across countries. For example, in their study the highest was Korea with 196.85 basis points whereas the lowest was France with 29.85 basis points. Explicit costs are roughly two-thirds of total costs. However, one exception to this is the United States where the implicit costs are about 60% of the total costs.

Transaction costs in emerging markets are significantly higher than those in more developed markets. Domowitz, Glen, and Madhavan argue that this fact limits the gains of international diversification in these countries, explaining in part the documented home bias of domestic investors.

In general, they find that transaction costs declined from the middle of 1997 to the end of 1998, with the exception of Eastern Europe. It is interesting to notice that this reduction in transaction costs happened despite the turmoil in the financial markets during this period. A few explanations that Domowitz et al. suggest are that (1) the increased institutional presence has resulted in a more competitive environment for brokers/dealers and other trading services; (2) technological innovation has led to a growth in the use of low-cost electronic crossing networks (ECNs) by institutional traders; and (3) soft dollar payments are now more common.

FORECASTING AND MODELING MARKET IMPACT

In this section, we describe a general methodology for constructing forecasting models for market impact. These types of models are very useful in predicting the resulting trading costs of specific trading strategies and in devising optimal trading approaches.

Explicit transaction costs are relatively straightforward to estimate and forecast. There-

fore, our focus in this section is to develop a methodology for the *implicit* transaction costs, and more specifically, market impact costs. The methodology is a linear factor-based approach where market impact is the dependent variable. We distinguish between trade-based and asset-based independent variables or *forecasting factors*.

Trade-Based Factors

Some examples of trade-based factors include:

- Trade size
- Relative trade size
- Price of market liquidity
- Type of trade (information or informationless trade)
- Efficiency and trading style of the investor
- Specific characteristics of the market or the exchange
- Time of trade submission and trade timing
- Order type

Probably the most important market impact forecasting variables are based on absolute or relative trade size. Absolute trade size is often measured in terms of the number of shares traded, or the dollar value of the trade. Relative trade size, on the other hand, can be calculated as number of shares traded divided by average daily volume, or number of shares traded divided by the total number of shares outstanding. Note that the former can be seen as an explanatory variable for the temporary market impact and the latter for the permanent market impact. In particular, we expect the temporary market impact to increase as the trade size to the average daily volume increases because a larger trade demands more liquidity.

Each type of investment style requires a different need for immediacy.¹² Technical trades often have to be traded at a faster pace in order to capitalize on some short-term signal and therefore exhibit higher market impact costs. In contrast, more traditional long-term value strategies can be traded more slowly. These types of strategies

can in many cases even be liquidity providing, which might result in negative market impact costs.

Several studies show that there is a wide variation in equity transaction costs across different countries.¹³ Markets and exchanges in each country are different, and so are the resulting market microstructures. Forecasting variables can be used to capture specific market characteristics such as liquidity, efficiency, and institutional features.

The particular timing of a trade can affect the market impact costs. For example, it appears that market impact costs are generally higher at the beginning of the month as compared to the end of it.¹⁴ One of the reasons for this phenomenon is that many institutional investors tend to rebalance their portfolios at the beginning of the month. Because it is likely that many of these trades will be executed in the same stocks, this rebalancing pattern will induce an increase in market impact costs. The particular time of the day a trade takes place does also have an effect. Many informed institutional traders tend to trade at the market open as they want to capitalize on new information that appeared after the market close the day before.

As we discussed earlier in this entry, market impact costs are asymmetric. In other words, buy and sell orders have significantly different market impact costs. Separate models for buy and sell orders can therefore be estimated. However, it is now more common to construct a model that includes dummy variables for different types of orders such as buy/sell orders, market orders, limit orders, and the like.

Asset-Based Factors

Some examples of asset-based factors are:

- Price momentum
- Price volatility
- Market capitalization
- Growth versus value
- Specific industry or sector characteristics

For a stock that is exhibiting positive price momentum, a buy order is liquidity demanding and it is, therefore, likely that it will have higher market impact cost than a sell order.

Generally, trades in high volatility stocks result in higher permanent price effects. It has been suggested by Chan and Lakonishok (1997) and Smith et al. (2001) that this is because trades have a tendency to contain more information when volatility is high. Another possibility is that higher volatility increases the probability of hitting and being able to execute at the liquidity providers' price. Consequently, liquidity suppliers display fewer shares at the best prices to mitigate adverse selection costs.

Large-cap stocks are more actively traded and therefore more liquid in comparison to small-cap stocks. As a result, market impact cost is normally lower for large caps.¹⁵ However, if we measure market impact costs with respect to relative trade size (normalized by average daily volume, for instance), they are generally higher. Similarly, growth and value stocks have different market impact cost. One reason for that is related to the trading style. Growth stocks commonly exhibit momentum and high volatility. This attracts technical traders that are interested in capitalizing on short-term price swings. Value stocks are traded at a slower pace and holding periods tend to be slightly longer.

Different market sectors show different trading behaviors. For instance, Bikker and Spierdijk (2007) show that equity trades in the energy sector exhibit higher market impact costs than other comparable equities in nonenergy sectors.

A Factor-Based Market Impact Model

One of the most common approaches in practice and in the literature in modeling market impact is through a linear factor model of the form:

$$MI_t = \alpha + \sum_{i=1}^I \beta_i x_i + \varepsilon_t$$

where α, β_i are the factor loadings and x_i are the factors. Frequently, the error term ε_t is assumed to be independently and identically distributed. Recall that the resulting market impact cost of a trade of (dollar) size V is then given by $MIC_t = MI_t \cdot V$. However, extensions of this model including conditional volatility specifications are also possible. By analyzing both the mean and the volatility of the market impact, we can better understand and manage the trade-off between the two. For example, Bikker and Spierdijk use a specification where the error terms are jointly and serially uncorrelated with mean zero, satisfying

$$\text{Var}(\varepsilon_t) = \exp\left(\gamma + \sum_{i=1}^J \delta_j z_j\right)$$

where γ, δ_j , and z_j are the volatility, factor loadings, and factors, respectively.

Although the market impact function is linear, this of course does not mean that the dependent variables have to be. In particular, the factors in the previous specification can be nonlinear transformations of the descriptive variables.

Consider, for example, factors related to trade size (e.g., trade size and trade size to daily volume). It is well known that market impact is nonlinear in these trade size measures. One of the earliest studies in this regard was performed by Loeb (1983), who showed that for a large set of stocks the market impact is proportional to the square root of the trade size, resulting in a market impact cost proportional to $V^{3/2}$. Typically, a market impact function linear in trade size will underestimate the price impact of small- to medium-sized trades whereas larger trades will be overestimated.

Chen, Stanzl, and Watanabe (2002) suggest to model the nonlinear effects of trade size (dollar trade size V) in a market impact model by using the Box-Cox transformation; that is,

$$MI(V_t) = \alpha_b + \beta_b \frac{V_t^{\lambda_b} - 1}{\lambda_b} + \varepsilon_t$$

where t and τ represent the time of transaction for the buys and the sells, respectively. In their

specification, they assumed that ε_t and ε_τ are independent and identically distributed with mean zero and variance σ^2 . The parameters $\alpha_b, \beta_b, \lambda_b, \alpha_s, \beta_s$, and λ_s were then estimated from market data by nonlinear least squares for each individual stock. We remark that $\lambda_b, \lambda_s \in [0, 1]$ in order for the market impact for buys to be concave and for sells to be convex.

In their data sample (NYSE and Nasdaq trades between January 1993 and June 1993), Chen, Stanzl, and Watanabe report that for small companies the curvature parameters λ_b, λ_s are close to zero, whereas for larger companies they are not far away from 0.5. Observe that for $\lambda_b = \lambda_s = 1$ market impact is linear in the dollar trade size. Moreover, when $\lambda_b = \lambda_s = 0$ the impact function is logarithmic by the virtue of

$$\lim_{\lambda \rightarrow 0} \frac{V^\lambda - 1}{\lambda} = \ln(V)$$

As just mentioned, market impact is also a function of the characteristics of the particular exchange where the securities are traded as well as of the trading style of the investor. These characteristics can also be included in the general specification outlined previously. For example, Keim and Madhavan (1996, 1997) proposed the following two different market impact specifications

$$1. MI = \alpha + \beta_1 \chi_{OTC} + \beta_2 \frac{1}{p} + \beta_3 |q| + \beta_4 |q|^2 + \beta_5 |q|^3 + \beta_6 \chi_{Up} + \varepsilon$$

where

χ_{OTC} = a dummy variable equal to one if the stock is an OTC traded stock or zero otherwise.

p = the trade price.

q = the number of shares traded over the number of shares outstanding.

χ_{Up} = a dummy variable equal to one if the trade is done in the upstairs¹⁶ market or zero otherwise.

$$2. MI = \alpha + \beta_1 \chi_{\text{Nasdaq}} + \beta_2 q + \beta_3 \ln(MCap) + \beta_4 \frac{1}{p} + \beta_5 \chi_{\text{Tech}} + \beta_6 \chi_{\text{Index}} + \varepsilon$$

where

χ_{Nasdaq} = a dummy variable equal to one if the stock is traded on Nasdaq or zero otherwise.

q = the number of shares traded over the number of shares outstanding.

$MCap$ = the market capitalization of the stock.

p = the trade price.

χ_{Tech} = a dummy variable equal to one if the trade is a short-term technical trade or zero otherwise.

χ_{Index} = a dummy variable equal to one if the trade is done for a portfolio that attempts to closely mimic the behavior of the underlying index or zero otherwise.

These two models provide good examples for how nonlinear transformations of the underlying dependent variables can be used along with dummy variables that describe specific market or trade characteristics.

Several vendors and broker-dealers such as MSCI Barra¹⁷ and ITG¹⁸ have developed commercially available market impact models. These are sophisticated multimarket models that rely upon specialized estimation techniques using intraday data or tick-by-tick transaction-based data. However, the general characteristics of these models are similar to the ones described in this section.

We emphasize that in the modeling of transaction costs it is important to factor in the objective of the trader or investor. For example, one market participant might trade just to take advantage of price movement and hence will only trade during favorable periods. This investor's trading cost is different from that of an investor who has to rebalance a portfolio within a fixed time period and can therefore only partially use an opportunistic or liquidity searching strategy. In particular, this investor

has to take into account the risk of not completing the transaction within a specified time period. Consequently, even if the market is not favorable, this investor may decide to transact a portion of the trade. The market impact models described previously assume that orders will be fully completed and ignore this point.

KEY POINTS

- Trading and execution are integral components of the investment process. A poorly executed trade can eat directly into portfolio returns because of transaction costs.
- Transaction costs are typically categorized in two dimensions: fixed costs versus variable costs, and *explicit costs* versus *implicit costs*.
- In the first dimension, fixed costs include commissions and fees. Bid-ask spreads, taxes, delay cost, price movement risk, market impact costs, timing risk, and opportunity cost are variable trading costs.
- In the second dimension, explicit costs include commissions, fees, bid-ask spreads, and taxes. Delay cost, price movement risk, market impact cost, timing risk, and opportunity cost are implicit transaction costs.
- Implicit costs make up the larger part of the total transaction costs. These costs are not observable and have to be estimated.
- Liquidity is created by agents transacting in the financial markets by buying and selling securities.
- Liquidity and transaction costs are interrelated: In a highly liquid market, large transactions can be executed immediately without incurring high transaction costs.
- A limit order is an order to execute a trade only if the limit price or a better price can be obtained.
- A market order is an order to execute a trade at the current best price available in the market.
- In general, trading costs are measured as the difference between the execution price and

some appropriate fair market benchmark. The fair market benchmark of a security is the price that would have prevailed had the trade not taken place.

- Typical forecasting models for market impact costs are based on a statistical factor approach where the independent variables are trade-based factors or asset-based factors.

NOTES

1. See, for example, Domowitz, Glen, and Madhavan (2001) and Keim and Madhavan (1998).
2. Since the buyer buys at the ask and the seller sells at the bid, this definition of market impact cost ignores the bid-ask spread, which is an explicit cost.
3. Hu (2009).
4. Private communication, RAS Asset Management.
5. Hasbrouck and Saar (2008).
6. Note that even if it is possible to view the entire limit order book it does not give a *complete* picture of the liquidity in the market. This is because hidden and discretionary orders are not included. For a discussion on this topic, see Tuttle (2002).

Monte Carlo Simulation in Finance

DESSISLAVA A. PACHAMANOVA, PhD

Associate Professor of Operations Research, Babson College

Abstract: Monte Carlo simulation has become an essential tool for pricing and risk estimation in financial applications. It allows finance professionals to incorporate uncertainty in financial models, and to consider additional layers of complexity that are difficult to incorporate in analytical models. The main idea of Monte Carlo simulation is to represent the uncertainty in market variables through scenarios, and to evaluate parameters of interest that depend on these market variables in complex ways. The advantage of such an approach is that it can easily capture the dynamics of underlying processes and the otherwise complex effects of interactions among market variables. A substantial amount of research in recent years has been dedicated to making scenario generation more accurate and efficient, and a number of sophisticated computational techniques are now available to the financial modeler.

This entry provides an introduction to Monte Carlo simulation and its applications to finance, from financial derivative *pricing* to portfolio *risk management*. We begin with a discussion of the main ideas behind *simulation* and a listing of several important areas in finance where simulation techniques are widely used. We then discuss technical issues that are important for understanding the advantages and limitations of the Monte Carlo simulation technique, such as how random numbers are actually generated, what techniques are used for increasing the accuracy of estimates from simulation, and what software can be helpful for applications.

MAIN IDEAS AND IMPORTANT CONCEPTS

Simulation can be most generally defined as imitation of real-life systems with the goal of

studying important characteristics of their behavior. Monte Carlo simulation is named after the main residential area of the Monaco principality, which was well known for its casino. The term alludes to randomness and process repetition, analogous to casino games such as roulette.

The idea of applying Monte Carlo simulation to finance arises naturally, given the inherent variability in markets and the need for finance professionals to evaluate strategies with uncertain outcomes. Consider, for example, a portfolio manager who would like to estimate the effect of a market downturn on the portfolio (e.g., if the market goes down by 10%). What would be the resulting portfolio value? If the portfolio beta is 1, the expected decline in the portfolio value will be 10% as well; if the portfolio beta is 0.9, the portfolio will decline 9% if the market declines by 10%. More generally,

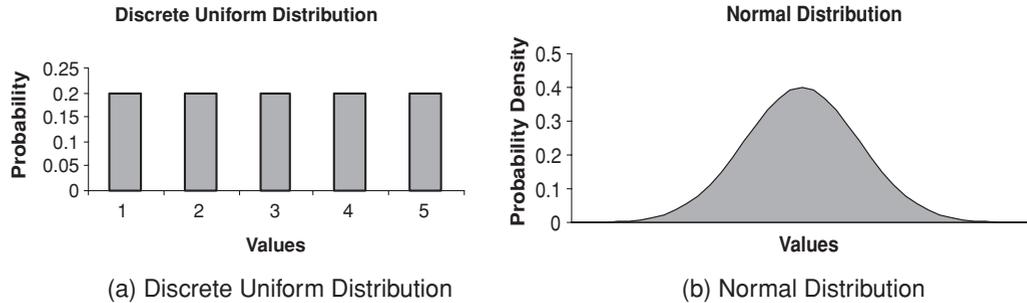

Figure 1 Examples of Probability Distributions

a portfolio manager may want to assess the exposure of a portfolio to a set of risk factors suggested by economic theory or empirical evidence such as interest rate changes, commodity price changes, exchange rate movements, and so on. These risk factors and their interactions with each other are not straightforward to evaluate. One can imagine that a portfolio manager would consider scenarios for possible joint realizations of market variables—for example, in a global recession or under favorable monetary policy changes—and would assess the change to the portfolio value in each of these scenarios. Taking it yet another step further, a portfolio manager may assign probabilities to the different scenarios, thus expressing a view on their likelihood of occurring. Assigning probabilities to outcomes produces probability distributions. Examples of probability distributions include the discrete uniform distribution (see Figure 1a), which assigns equal probabilities to all possible discrete outcomes, and the normal distribution (Figure 1b), which is continuous (defined on a range, as opposed to discrete values), and allocates more probability to outcomes close to the average than to those far from the average.

The example in the previous paragraph illustrates a Monte Carlo simulation system: Possibly random inputs (the risk factors) incorporating subjective or statistically estimated views via probability distributions are entered into an evaluation model (computation of change in portfolio value), and the resulting output (the portfolio change) is not a single

number, but a probability distribution of outcomes that incorporates characteristics of the input probability distributions and their complex interactions. The actual simulation process involves generating a certain number of scenarios, evaluating the portfolio change for each scenario, and obtaining a corresponding set of scenarios for the portfolio change. The latter set of scenarios can then be analyzed to determine most likely outcomes for portfolio change, variability of estimated portfolio change, range of possible outcomes, and the like. One can use the simulation output also to estimate any portfolio risk measure such as value-at-risk (VaR) or expected tail loss (ETL). Since VaR has been adopted by regulators and is commonly used by portfolio managers, we will use VaR in our illustrations. When generating scenarios for the factors influencing the future value of the portfolio, it is easy to collect information on possible portfolio losses relative to the current value of the portfolio in each scenario. Then, the 95% VaR, for example, can be computed as the 95th percentile of the distribution of portfolio losses (see Figure 2).

As another illustration of a simulation model, consider the problem of finding the fair price of a simple European call option on a stock with current stock price S_t . If the strike price is K and the option matures at time T , the option payoff at time T can be expressed as

$$V_T = \max \{S_T - K, 0\}$$

According to a fundamental theory in asset pricing, the fair price of a financial asset

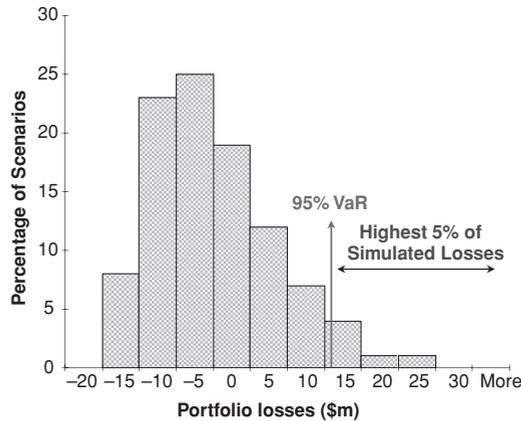

Figure 2 Determining Portfolio VaR from Simulation

under certain conditions can be meaningfully estimated as the expected value (equivalently, as a “probability-weighted average”) of the possible payoffs of the financial asset in different states of the world in the future. The fair value of the option at time t will therefore be the expected value of the discounted payoff:

$$V_t = E \left[e^{-r(T-t)} \max \{ S_T - K, 0 \} \right]$$

where r is the short-term risk-free rate.

The expected value in the expression above is meaningful only if one can specify a probability distribution of possible outcomes for the future price of the asset. For example, consider a European call option on a common stock with an exercise price of \$20. Assume that the short-term risk-free rate is 0%, and suppose that the stock price at time T can only take the values \$18, \$21, and \$23 with (risk-neutral) probabilities $3/6$, $2/6$, and $1/6$, respectively. Then the fair price of the option can be computed as the weighted average of the payoffs in the three possible states of the world:

$$\begin{aligned} V &= \frac{3}{6} \max \{ 18 - 20, 0 \} + \frac{2}{6} \max \{ 21 - 20, 0 \} \\ &\quad + \frac{1}{6} \max \{ 23 - 20, 0 \} \\ &= \frac{3}{6} \cdot 0 + \frac{2}{6} \cdot 1 + \frac{1}{6} \cdot 3 = \frac{5}{6} = 0.83 \end{aligned}$$

That is, the fair value of the option is \$0.83.

Typically, however, the stock price can take many more values, and the option price cannot be valued exactly. It therefore makes sense to generate a large number (e.g., 1,000) of scenarios for the future value of the stock price using the risk-neutral probabilities, and average out the payoffs to the option. The average obtained from the simulation will approximate the true expected value of the option.

The Black-Scholes formula for European options (Black and Scholes, 1973) is widely used in the financial industry. It provides a closed-form expression for computing the price of the option. The underlying assumption used in the derivation of the Black-Scholes formula is that the percentage changes in the asset price are increments of a Brownian motion.¹ The evolution of the stock price can then be described by the equation

$$dS_t = \mu S_t dt + \sigma S_t dW_t \tag{1}$$

where W_t is standard Brownian motion, and μ and σ are called “drift” and “volatility” of the process, respectively.

Equation (1) says that the change in the asset price at any time period is determined by two components: (1) a drift term that is a fraction of the current asset price level, and (2) a “random noise” term that assumes that volatility is proportional to the current price level. For technical reasons (namely, absence of arbitrage), when pricing an option on an asset whose movement is described by equation (1), the drift μ is replaced by the risk-free rate r . The technical details of equation (1) are not important for our purposes. The important result is that under the assumption for the random process followed by the stock price in (1), the value of the stock price S_T at time T can be computed as

$$S_T = S_t e^{(r - \frac{1}{2}\sigma^2)(T-t) + \sigma\sqrt{(T-t)}\tilde{w}} \tag{2}$$

where \tilde{w} is a random variable following a normal distribution with mean 0 and standard deviation 1 (see Figure 1b).

Hence, the option price obtained from the Black-Scholes formula can be approximated by simulation if a large number of values for the normal random variable \tilde{w} are generated, thus creating scenarios for the stock price S_T at time T and allowing for computing the discounted payoffs of the option. Suppose we generate n scenarios for \tilde{w} : w_1, \dots, w_n . Then, the price of the European option will be

$$V_t = e^{-r(T-t)} \cdot \sum_{i=1}^n \frac{1}{n} \max \left\{ S_t e^{(r - \frac{1}{2}\sigma^2)(T-t) + \sigma\sqrt{(T-t)}w_i} - K, 0 \right\}$$

Note that the expression above is still a weighted average of the payoffs of the option in each scenario: the “weight,” or the probability of each scenario, is assumed to be $1/n$, since the scenarios are picked at random, and the frequency of their occurrence already incorporates the probability distribution of \tilde{w} .

It appears unnecessarily complicated to price the option this way, and indeed, in practice simulation is rarely used for such simple problems. There are more complex derivative instruments and more sophisticated models for asset price behavior; in such cases, it may be simpler to generate scenarios and evaluate prices by simulation than to look for closed-form analytical expressions like the Black-Scholes formula. In addition, in the case of portfolios and baskets of multiple assets, generating joint scenarios for multiple securities in simulation can help capture the otherwise complicated effect of interactions among different risk factors influencing the future value of the portfolio or derivative instrument.

How Many Scenarios?

A simulation may not be able to capture all possible realizations of uncertainties in the model. For instance, consider the European option pricing example above. If the percentage change in the stock price is assumed to be the increment of a Brownian motion, the possible number of

values for the stock price S_T at time T is infinite. (This is because the number of values the normal random variable \tilde{w} can take is infinite—the normal distribution has an infinite range.) Thus, one could never obtain the exact value of the option price by simulation. One can, however, get close. The accuracy of the estimation will depend on the number of generated scenarios. If the scenario generation is truly random, then the standard error (the “variability”) in the estimate of the average will be

$$\frac{s}{\sqrt{n}}$$

where s is the standard deviation of the simulated discounted option payoffs, and n is the number of scenarios. This result follows from the central limit theorem (CLT). This theorem states that if a sample of n independent and identically distributed observations is drawn from a distribution with mean μ and standard deviation σ , then the sample mean (which is an estimate of the true distribution mean μ) will follow a normal distribution around the actual distribution mean μ with standard deviation σ/\sqrt{n} as the sample size n tends to infinity, regardless of the shape of the original distribution, as long as n is large. The fact that the distribution standard deviation σ in the CLT can be replaced by the sample standard deviation s follows from additional theoretical results on the convergence of s to σ in distribution as the number of observations grows large.

Hence, to double the accuracy of estimating the mean of the output distribution, one would have to quadruple the number of scenarios. This can get expensive computationally, especially in more complicated multistage situations. Fortunately, there are modern methods for generating random numbers and scenarios that can help reduce the computational burden.

While the average output from a simulation is important, it is often not the only quantity of interest, something that practitioners tend to forget when using simulation to value complex financial instruments. For example, as

mentioned earlier, in assessing the risk of a portfolio, a portfolio manager may be interested in the percentiles of the distribution of outputs (VaR for portfolios) or the worst-case and best-case scenarios. Unfortunately, it is not as straightforward to determine the accuracy of those estimates from a simulation. There are some useful results from probability theory that apply.² However, the general question of how many scenarios one should generate to get a good representation of the output distribution does not have an easy answer. This issue is complicated further by the fact that results from probability theory do not necessarily apply to many of the scenario-generating methods used in practice, which do not simulate “truly random” samples of observations, but instead use smarter methods that reduce the number of scenarios needed to achieve good estimate accuracy. We will discuss some such methods later in this entry.

Estimator Bias

The statistical concept of estimator bias is important in simulation applications because it shows whether an estimator estimates the “right thing” on average (that is, whether it approaches the true parameter one needs to estimate given a sufficient number of replications). For example, the average obtained from a sample of scenarios is an unbiased estimator of the true expected value. Depending on the way scenarios are generated, however, one may introduce a bias in the estimate of the parameter of interest.

Suppose, for example, that one generates scenarios for the future asset price in the option pricing example introduced earlier in this entry, but instead of the formula describing the evolution of the asset price in continuous time (equation (2)), one divides the time between now and the maturity of the option into small intervals of length h and uses a “discrete-time” formula [based on equation (1)] to approximate the stock price at each time period between t and T , com-

piling the changes to obtain the final asset price at the maturity of the option.

Simulating the asset price in this manner will generate a bias in the estimate of the expected present value of the option, because the simulated changes in the asset price along the way are not continuous or instantaneous, but happen over a fixed-length time interval. This kind of bias is referred to as “discretization error bias.” Of course, in the case of geometric Brownian motion with fixed drift and volatility described by equation (1) one can obtain an unbiased estimator of the average option payoff by simulating the future asset price with the continuous-time formula (2). However, in many instances it is not possible to find such a closed-form expression for the future asset price; for example, such a formula does not exist when the volatility σ in the random process for the asset price is time-dependent, or when one uses a mean-reversion process to describe the evolution of the underlying price. In such cases, one can reduce the time interval length h to reduce the bias, but it is important to keep in mind that reducing the time interval length increases the number of steps necessary to create a scenario for the future asset price, and becomes computationally expensive.

Estimator Efficiency

If there are two ways to obtain an estimate of a quantity of interest and the estimators are otherwise equivalent in terms of bias, which estimator should be preferable; that is, which estimator is more “efficient”? Statistical theory states that one should prefer the estimator with the smaller standard deviation, because it is more accurate. For example, consider two unbiased estimators, both of which are obtained as averages from a sample of independent replications. Their standard errors will be given by

$$\frac{s_1}{\sqrt{n_1}} \quad \text{and} \quad \frac{s_2}{\sqrt{n_2}}$$

where s_1 and s_2 are the standard deviations from the samples of scenarios, and n_1 and n_2 are the number of scenarios for each of the estimators.

In the case of simulation, statistical concepts frequently need to be extended to include numerical and computational considerations. For example, suppose that it takes longer to generate the scenarios for the estimator with the smaller standard deviation. Is that estimator still preferable, given that one can use the extra time to generate additional scenarios for the other estimator, thus reducing the latter estimator's standard error? It is natural (and theoretically justified) to modify the measure of variability and efficiency so that it includes a concept of time. If τ_1 and τ_2 are the times it takes to generate one scenario for each of the two estimators, then one should select the estimator with the smaller of the time-adjusted standard deviations $s_1\sqrt{\tau_1}$, $s_2\sqrt{\tau_2}$.

FINANCIAL APPLICATIONS OF SIMULATION

Simulation has become an important staple in a financial modeler's toolbox. This section lists some important examples of simulation applications in finance.

Financial Derivative Pricing

The use of Monte Carlo simulation in derivative pricing dates back to Boyle (1977). Although the technique is not widely used for pricing of European-style securities with a single underlying stochastic variable, it is helpful for pricing European-style securities with multiple underlying stochastic variables, path-dependent options, such as Asian and American options, as well as basket options, where correlations between assets need to be taken into consideration. Additional examples of Monte Carlo simulation applications in financial derivative pricing include options on the spread between

two assets, barrier options, and quantos, whose payoff depends both on a stock price and an exchange rate. We already described a simple example of pricing a European call by simulation. In this section, we discuss further simulation issues in the context of pricing Asian options.

The value of an Asian option is determined by the average price of the underlying asset either continuously over the time to maturity or at a prespecified set of monitoring dates t_1, \dots, t_T . In particular, the payoff of an Asian call option is

$$V_T = \max \{ S_{\text{average}} - K, 0 \}$$

Thus, to price the option, one needs information not only on the value of the asset at time T , but also on the possible paths the asset could take to reach its terminal value. If the percentage change in the underlying asset price S is assumed to be the increment of a Brownian motion and if the average is computed as a geometric (as opposed to an arithmetic) average, there are analytical formulas for pricing continuous-time Asian options. However, there are no exact formulas in the case of discrete monitoring dates or different assumptions on the process followed by the asset price.

To price the option by simulation, one would generate possible paths for the underlying asset price. Let $S_{t_i}(j)$ be the simulated asset price at time t_i , $i = 1, \dots, T$, for path j , $j = 1, \dots, n$. For example, if the percentage change in the underlying asset price S is assumed to be the increment of a Brownian motion, then the asset price at time t_1 can be simulated given the asset price at time 0 as

$$S_{t_1} = S_0 e^{(r - \frac{1}{2}\sigma^2)(t_1 - 0) + \sigma\sqrt{(t_1 - 0)}\tilde{w}_0}$$

where, as defined earlier, \tilde{w}_0 is a random variable following a normal distribution with mean 0 and standard deviation 1 (the subscript "0" stands for the fact that this realization of \tilde{w} is for the time period $(0, t_1]$). Having generated a realization of S_{t_1} , one can simulate a possible

value for S_{t_2} by using the formula

$$S_{t_2} = S_{t_1} e^{(r - \frac{1}{2}\sigma^2)(t_2 - t_1) + \sigma\sqrt{(t_2 - t_1)}\tilde{w}_1}$$

and generating a realization of the normal random variable \tilde{w}_1 . After repeating this T times, one has generated a path for the asset price. Averaging the (properly discounted) option payoff over n paths produces the fair price of the Asian option.

The simulation process makes it easy to calibrate model parameters to observed market factors and to incorporate additional layers of modeling complexity. For example, suppose that at time 0 one observes a term structure of zero-bond prices $B(0, t_1), \dots, B(0, t_T)$ that is not necessarily consistent with a single interest rate r . In other words, one cannot find a short rate r such that

$$B(0, t_i) = e^{-rt_i}$$

for all intermediate time periods t_i . It would be difficult to correct for this in a closed-form formula such as the Black-Scholes formula for European options. However, the correction can be easily implemented in the simulation: one only needs to simulate future asset prices at each intermediate time period as

$$S_{t_{i+1}} = S_{t_i} \frac{B(0, t_i)}{B(0, t_{i+1})} e^{-\frac{1}{2}\sigma^2(t_{i+1} - t_i) + \sigma\sqrt{(t_{i+1} - t_i)}\tilde{w}_i}$$

Similarly, if one observes forward prices $F(0, t_1), \dots, F(0, t_T)$ on the underlying asset, one can obtain a more accurate representation of the possible scenarios in the simulation by using the formula

$$S_{t_{i+1}} = S_{t_i} \frac{F(0, t_{i+1})}{F(0, t_i)} e^{-\frac{1}{2}\sigma^2(t_{i+1} - t_i) + \sigma\sqrt{(t_{i+1} - t_i)}\tilde{w}_i}$$

The complexity of the pricing model can be increased further by incorporating realistic models for the volatility σ . The simulation technique therefore has a tremendous modeling potential.

Estimating Sensitivities

For trading, hedging, and risk management purposes, the estimation of the sensitivity of derivative prices to different inputs is sometimes even more critical than the estimation of the prices themselves. These sensitivity measures are popularly referred to as the “Greeks” because each sensitivity measure is traditionally denoted by a Greek letter. A natural way to think of evaluating the sensitivity of a derivative price to a change in an underlying parameter is to use Monte Carlo simulation to compute the price of the derivative, and then use Monte Carlo simulation again to compute the price of the derivative if the input parameter is changed by a small amount h . This kind of estimation (referred to as a “finite-difference method”), however, presents both theoretical and practical challenges. On the theoretical side, finite difference methods frequently result in a large amount of bias. On the practical side, the amount of computation required for the estimation of the sensitivity is large (double the amount of computation used in the pricing of the derivative), and can become prohibitive if this computation is done in the context of evaluating the sensitivity of a whole portfolio of securities to changes in underlying factors.

In specific circumstances, the computational burden can be reduced by finding an expression for the Greek variable of interest that can be calculated as a by-product when paths are generated in a single simulation. Such expressions exist when computing the Black-Scholes delta or the delta of an Asian option.³ These methods are referred to as “pathwise methods”—namely, the evolution of the underlying model over paths is differentiated, and the parameter with respect to which the change is computed is treated as a parameter of that evolution. For example, consider the delta (denoted by Δ) for an option price calculated with the Black-Scholes formula, where delta is defined as the (mathematical) derivative of the option value with respect to the value of the underlying asset. To

Table 1 Scenarios for Portfolio VaR Estimation

Scenario	Market Variable 1	Market Variable 2	...	Market Variable m	Change in Portfolio Value (\$ million)
1	3.54	21.54	...	0.17	100.32
2	3.27	22.03	...	0.18	101.54
...
n	3.83	22.32	...	0.15	100.87

calculate the value of delta, one would generate n paths for the evolution of the asset price, and keep track of the paths in the simulation that end up in-the-money. Let the sum of the asset prices at the end of all in-the-money paths be Ω . Then, the delta at time t can be computed as

$$\Delta_t = e^{-r(T-t)} \cdot \frac{\Omega}{S_t \cdot n}$$

More recently, efficient estimators for sensitivity from simulation trials have been developed based on Malliavin calculus.⁴

Portfolio Risk Management

Earlier, we mentioned the importance of simulation for portfolio risk measurement and management. We now explain the simulation procedure in more detail.

To estimate the portfolio VaR, for example, one would generate n possible scenarios for the possible changes in m market variables that influence the change in the portfolio value, and compute the change in portfolio value in each scenario (see Table 1). Sometimes historical data are used to create the scenarios, but typically the scenarios are generated in a more sophisticated manner. The changes in the portfolio value are then sorted, and the 95% VaR, for example, can be computed as the 5th percentile of the so-obtained empirical distribution of portfolio value changes. (This is equivalent to computing the 95% VaR as the 95th percentile of the empirical distribution of future portfolio losses, as illustrated in Figure 2.)

While this standard Monte Carlo simulation procedure is comprehensive, it can be very slow, especially when the portfolio contains complex derivative securities whose changes in value

must be reevaluated in every scenario for the market variables. In fact, the portfolio VaR calculation by simulation involves a number of “subsimulations” evaluating the sensitivities of the securities in the portfolios to each of the market variables. For large portfolios, the computational cost of generating each scenario for the change in portfolio value can become prohibitive.

In practice, several approaches are used to speed up the calculation of VaR. One of the earliest approaches, popularized by JP Morgan’s RiskMetrics software in the 1990s, is to assume that all changes in market variables are normally distributed. If the portfolio value is a linear function of these market variables (this happens, e.g., when the portfolio contains equities and factor models are used to represent the changes in asset value relative to changes in market variable values), then the change in portfolio value is also normally distributed, and can be computed in closed form, by expressing the VaR as a multiple of the standard deviation of changes in the market variables. This approach does not necessarily have to involve simulation, and actually works reasonably well for large equity-only portfolios that contain liquid assets, because the empirical distributions of their returns can be indeed very close to normal. However, it can grossly underestimate the true portfolio VaR when the portfolio contains complex derivatives (which are nonlinear functions of the returns on the underlying market variables) or fixed income securities (which depend nonlinearly on interest rates).

The nonlinearity can be partially incorporated in the estimate of the change in portfolio value by using second-order information,

so-called “Delta-Gamma” or quadratic approximation to the change in portfolio value.⁵ In other words, the change in portfolio value is expressed not only through the changes in the values of the market variables, but also through the changes in the market variables squared and scaled by their so-called Hessian matrix. (From a mathematical perspective, this is a multidimensional Taylor expansion involving the Greeks of the different securities in the portfolio.) Since traders of complex derivatives often have to keep track of this information for their own risk management purposes, the portfolio risk management process amounts to disciplined accumulation of information that is already available. This method is only an approximation, but it can reduce substantially the time for computing the portfolio VaR.

Valuing Mortgage-Backed Securities

Monte Carlo methods are often used for valuing mortgage-backed securities (MBSs) such as collateralized mortgage obligations (CMOs) and stripped MBSs (mortgage strips). The cash flows for such products can be calculated using different pricing models. The highly uncertain terms in those cash flow models, such as the behavior of interest rates and the expected prepayments over the life of the MBS, are often simulated to determine the expected cash flows to the MBS holder, which then provide the sample average (“fair”) value for the MBS.

Valuing Credit-Risky Securities

Similar ideas to those for pricing CMOs are used for pricing collateralized debt obligations (CDOs), which employ securitization to package credit-risky debt obligations (bonds and loans) in ways analogous to the way mortgages are packaged in CMOs. In order to price the CDO, one needs to simulate the defaults of different bond issuers in the collection.⁶

Simulation is also used for pricing other credit-risky instruments, such as first-to-default baskets and basket default swaps.⁷ The simulation techniques applied in such cases can be quite advanced, as credit defaults are considered “rare events” and need to be modeled with care. We will discuss the main ideas of simulation modeling techniques for rare events, such as importance sampling, later in this entry.

RANDOM NUMBER GENERATION

At the core of Monte Carlo simulation is the *generation of random numbers*. In fact, however, generating random numbers from a wide variety of distributions reduces to generating random numbers on the unit interval from 0 to 1 uniformly, that is, generating random numbers on the interval $[0,1]$ in such a way that each value between 0 and 1 is equally likely to occur. Many computer languages and software packages have a command for generating a random number between 0 and 1: “=RAND()” in Microsoft Excel, “rand(1)” in MATLAB and FORTRAN, and “rand()” in C++.

From a Uniform Random Variable to a Variable from an Arbitrary Distribution

The most common method for converting a random number between 0 and 1 to a number from an arbitrary probability distribution is to evaluate the so-called “inverse” of the cumulative probability distribution function at the random number between 0 and 1. The idea works because the total mass for a probability distribution is always 1, and the cumulative probability for any value of the distribution (defined as the probability that this particular value or any value below it will occur) is always between 0 and 1. For example, suppose that one would like to generate a random number from the normal distribution in Figure 1b. Suppose

the =RAND() command in Excel returns the number 0.975. The next step is to look for a corresponding random number from a normal distribution so that 97.5% of the probability mass (the area under the probability density curve) is to the left of that number. In Excel in particular, the function '=NORMINV(RAND(), mean, standard deviation)' can be used to find that random number on the x-axis of a normal distribution with the specified mean and standard deviation.

"Inverting" the cumulating probability distribution is trickier for discrete probability distributions, but the idea still applies. For example, suppose that given a random number generator on the interval [0,1], one would like to simulate values for a random variable that takes the value 5 with probability 50%, the value 15 with probability 30%, and the value 35 with probability 20%. Let us split the unit interval [0,1] into three intervals based on the cumulative probabilities 50%, 80% and 100% for obtaining the values 5, 15, and 35: [0,0.5], (0.5,0.8], and (0.8,1]. If the random number that is drawn falls in the interval [0,0.5] (which happens 50% of the time if the number generator is truly random), then one records a value of 5 for that trial. If the random number is in the interval (0.05, 0.8] (which happens with probability 30%), then one records a value of 15 for that trial. Finally, if the random number is in the third interval (which happens with probability 20%), one records a value of 35. Thus, if many trials are run, the values 5, 15, and 35 are generated with the desired probabilities. In Excel, one can simulate these values with the corresponding probabilities by creating a table with the interval ranges in the first two columns, and the corresponding values (5, 15, and 35) in the third column, and using the Excel function

VLOOKUP(lookup_value, table_array, col_index_num)

to look up the range in which a number generated with RAND() falls.⁸

What Defines a "Good" Random Number Generator?

Given the discussion in the previous section, generating "good" uniform random numbers on [0,1] is critical for the performance of simulation algorithms. Interestingly, defining "good" random number generation is not as straightforward as it appears. Early random number generators tried to use "truly random" events for random number generation, such as the amount of background cosmic radiation. In practice, however, this kind of random number generation is time consuming and difficult. Moreover, it was realized that the ability to reproduce the random number sequence and to analyze the random number characteristics is actually a desirable property for random number generators. In particular, the ability to reproduce a sequence of random numbers allows for reducing the variance of estimates and for debugging computer code by rerunning experiments in the same conditions in which they were run in previous iterations of code development.

Most simulation software products employ random number generation algorithms that produce streams of numbers that appear to be random, but are in fact a result of a clearly defined series of calculation steps in which the next "random number" x_n in the sequence is a function of the previous "random number" x_{n-1} , that is, $x_n = f(x_{n-1})$. The sequence starts with a number called the seed, and if the same seed is used in several simulations, each simulation sequence will contain exactly the same numbers, which is helpful for code debugging and drawing fair comparisons between different strategies evaluated under uncertainty. It is quite an amazing statistical fact that some of these recursion formulas (named "pseudo-random number generators") define sequences of numbers that imitate random behavior well and appear to obey (roughly) some major laws of probability, such as the CLT and the Glivenko-Cantelli lemma.

In general, a pseudo-random number generator is considered “good” if it satisfies the following conditions:

1. The numbers in the generated sequence are uniformly distributed between 0 and 1. This can be tested by running a chi-square or a Kolmogorov-Smirnov test.
2. The sequence has a long cycle (that is, it takes many iterations before the sequence begins repeating itself).
3. The numbers in the sequence are not autocorrelated. This can be verified by running a Durbin-Watson test on the sequence of numbers. The Durbin-Watson test is widely used in statistics for identifying autocorrelation in time series of observations.

In the following section, we discuss briefly a couple of important types of pseudo-random number generators. The goal is not to provide comprehensive coverage of random number generators, but rather to give readers a flavor of the main ideas behind the method of producing apparently random numbers with deterministic algorithms.

Pseudo-Random Number Generators

One of the earliest pseudo-random number generators developed is called the midsquare technique. It takes a number (the seed), squares it, and takes the set of middle digits as the next random number. It is easy to predict when such an approach may run into difficulties. As soon as the “middle digits” become a small number such as 1 or 0, the sequence ends with the same numbers generated over and over again; that is, the sequence converges to a constant value (typically 0) or to a very short cycle of values.

A better, commonly used type of pseudo-random number generators is congruential pseudo-random number generators. They are based on sequences of numbers of the form

$$x_n = f(x_{n-1}) \bmod m$$

where $\bmod m$ stands for “modulus m ”. $f(x_{n-1}) \bmod m$ is the remainder after dividing $f(x_{n-1})$ by m . For example, $5 \bmod 3 = 2$, $15 \bmod 5 = 0$, etc. Note that $f(x_{n-1}) \bmod m$ will always be an integer between 0 and $m-1$. Thus, to create a good representation of randomness, one would want to make the range for the modulus as large as possible. For a 32-bit computer, for example, the maximum integer that can be stored is $2^{31} - 1$, which is large enough for practical purposes.

More advanced generators include matrix multiplicative congruential generators, multiple recursive generators, and shuffled generators. Most pseudo-random number generators used in popular software products nowadays have been thoroughly tested and are very good.

VARIANCE REDUCTION TECHNIQUES

Paradoxically, truly random numbers can be too random for all practical purposes. Recall that the error in the average estimate obtained from truly random Monte Carlo simulation is proportional to $1/\sqrt{n}$, where n is the number of scenarios for the random variable (this fact would be approximately true for good pseudo-random number generators as well). Much research has been dedicated in recent years to finding ways to reduce that error and to be computationally savvy when generating scenarios. Several methods for *variance reduction*, widely used in financial applications, are listed below.⁹

Antithetic Variables

Simulating a random number is computationally expensive. One technique that is used to reduce the error in the average estimate in derivative pricing without increasing the number of simulated values is to incorporate the generated random number twice in computing the derivative payoff: once as the original simulated number, and another as its “antithetic” number.

For example, recall from our earlier option pricing example that one possibility to model the value of the stock price S_T at time T is by using equation (2). In that expression, \tilde{w} is a random variable following a normal distribution with mean 0 and standard deviation 1. Suppose that n values for the normal random variable \tilde{w} are generated. With the *antithetic variable* method, the value of the derivative payoff in each of the n scenarios is computed as the average of two payoffs: one obtained by plugging in the simulated value for \tilde{w} , and another obtained by plugging in the negative of the simulated value for \tilde{w} . These n “adjusted” payoffs are otherwise treated in the same way as in the traditional simulation method described earlier in this entry: At the end, the n payoffs are averaged and properly discounted to obtain the “fair” estimate of the derivative price. The difference is that this approach substantially reduces the standard error in the average estimate, while keeping the number of simulation trials at n .

The antithetic variable approach does not apply only to normal random variables. As explained in the previous section, random number generation typically happens in two stages: First, a random number between 0 and 1 is generated, and then this random number is “inverted” to obtain a random number from the desired probability distribution. Thus, one can apply the antithetic technique at the first stage, and treat the randomly generated number U as two realizations: U and its “antithetic” variable $1-U$. For example, if the number generated on the interval $[0,1]$ is 0.7, then the antithetic number is 0.3. Both of these numbers can then be “inverted” to obtain a pair of *antithetic variables* from a prespecified distribution.

Stratified Sampling

Observations in the tails of input distributions that are typically less likely to be generated may never occur in a simulation, because the probability of their occurrence is small. Such observations, however, contain important information about extreme events which are of partic-

ular interest in financial applications. In order to ensure that they appear in the simulation, one would need to generate a huge number of scenarios.

This problem is often addressed by *stratified sampling*. Most generally, the term “stratified sampling” refers to any technique that divides the random values into ranges (called “strata” in statistics), and sampling from each range to ensure that a good representation of the distribution is obtained.

A simple way of stratifying the numbers in the $[0,1]$ interval to ensure that, when “inverted,” the generated random numbers cover well the whole range of a probability distribution of interest, is to divide the $[0,1]$ interval into k smaller intervals of equal length:

$$\left[0, \frac{1}{k}\right], \left(\frac{1}{k}, \frac{2}{k}\right], \dots, \left(\frac{k-1}{k}, 1\right]$$

Random numbers can then be drawn sequentially from each small interval. Therefore, values from the tails of the distribution of interest (which will be generated when uniform random numbers from the intervals $[0, \frac{1}{k}]$ and $(\frac{k-1}{k}, 1]$ are drawn) obtain better representation.

In multiple dimensions (that is, when simulating several random variables), this method extends to dividing a hypercube (as opposed to an interval) into smaller hypercubes, and drawing an observation along each dimension of the smaller hypercubes. An enhanced extension to the basic stratified sampling method is Latin hypercube sampling (an option in many advanced simulation software products), which permutes the coordinates of an initially generated random vector of observations—one observation within each small hypercube—to reduce the number of times an actual random number is generated while ensuring that all strata are sufficiently well represented.

Importance Sampling

Importance sampling is an alternative to stratified sampling for dealing with rare events, or

extreme observations, and for reducing the number of simulation trials necessary to achieve a particular level of accuracy. The method changes the underlying scenario probabilities so as to give more weight to important outcomes in the simulation. Such outcomes are generated with greater frequency than they otherwise would. At the end, the observations' weights are scaled back in the computation of the parameter of interest, so that the estimation is correct.

There is no single recipe for how to construct good importance sampling methods. The specific construction depends on the underlying random process dynamics. For example, when pricing a European call option in the Black-Scholes setting, generating paths that are out-of-the-money is wasteful. This is because only paths that are in-the-money count in the final computation of the option price—the contribution of out-of-the-money paths to the option price is 0. Although in practice one would not use importance sampling for pricing a European call option for which there is a closed-form formula, we will use European call option pricing as a context in which to explain the importance sampling method.

First, note that in-the-money paths will occur only if the asset price at expiration is greater than the strike price; that is, they will result from realizations of the standard normal random variable \tilde{w} such that

$$S_t e^{(r - \frac{1}{2}\sigma^2)(T-t) + \sigma\sqrt{T-t}\tilde{w}} > K$$

From this inequality, one can derive that only normal random numbers higher than

$$\frac{\ln(K/S_t) - (r - \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}}$$

will lead to in-the-money paths. Equivalently, this means that only random numbers between

$$N\left(\frac{\ln(K/S_t) - (r - \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}}\right) \text{ and } 1$$

on the unit interval [0,1], when “inverted” to obtain normal random numbers, will lead to in-

the-money paths ($N(\cdot)$ here denotes the cumulative normal distribution). Thus, one only needs to simulate random numbers in that range of the [0,1] interval. When computing the option price at the end, instead of weighing each payoff equally by multiplying it by $1/n$ as one would do in standard Monte Carlo sampling, one multiplies the sum of the payoffs obtained from the simulation by the probability that a particular random path would be in-the-money assuming truly random sampling, which is the standard Monte Carlo method. The latter probability is

$$\begin{aligned} &1 - N\left(\frac{\ln(K/S_t) - (r - \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}}\right) \\ &= N\left(\frac{\ln(S_t/K) + (r - \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}}\right) \end{aligned}$$

The call option price is then

$$\begin{aligned} V_t &= e^{-r(T-t)} \cdot N\left(\frac{\ln(S_t/K) + (r - \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}}\right) \\ &\cdot \sum_{i=1}^n \max\left\{S_t e^{(r - \frac{1}{2}\sigma^2)(T-t) + \sigma\sqrt{T-t}w_i} - K, 0\right\} \end{aligned}$$

where w_1, \dots, w_n are all random numbers generated from a normal distribution in the range higher than

$$\frac{\ln(K/S_t) - (r - \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}}$$

As mentioned above, this is only a simple example in order to illustrate the main idea of importance sampling. More practical (albeit more technically challenging) applications can be found, for instance, in Chapter 4.6 in Glasserman (2004).

Quasi-Random (Low-Discrepancy) Sequences

A truly random number generator may produce clustered observations (see Figure 3a), which necessitates generating many scenarios in order to obtain a good representation of the output distribution of interest. Recall from our earlier discussion that stratified sampling can

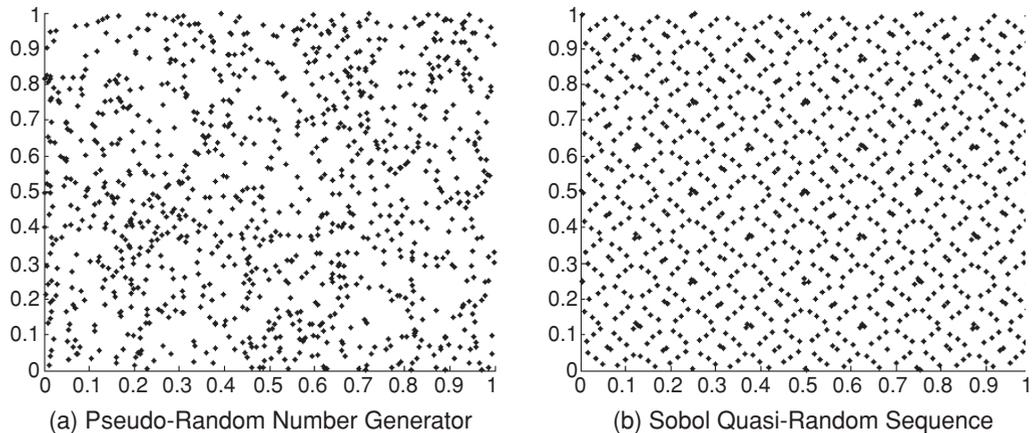

Figure 3 One Thousand Simulated Number Values for Two Uniform Random Variables on the Interval $[0,1]$

be used to deal with this problem—it divides the ranges of possible values into a fixed number of strata, so as to “disperse” observations more evenly over the range. Quasi-random sequences instead ensure a smooth representation of the range by continuously “filling in” gaps on the unit interval $[0,1]$ left by previously generated random numbers (see an example of 1,000 generated values of a quasi-random sequence in Figure 3b). The term “quasi-random” is actually a misnomer, because, unlike pseudo-random number sequences, quasi-random number sequences do not pretend to be random. They are deterministic on purpose, and their roots can be found in real analysis and abstract algebra rather than in simulation or probability theory. The term *low discrepancy sequences* is often used interchangeably with the term “quasi-random” sequences, and is more accurate.

Important examples of quasi-random sequences were suggested by Sobol (1967), Faure (1982), Halton (1960), and Hammersley (1960). These sequences build on a family of so-called Van der Korput sequences.¹⁰ For example, the Van der Korput sequence of base 2 is

$$0, \frac{1}{2}, \frac{1}{4}, \frac{3}{4}, \frac{1}{8}, \frac{5}{8}, \frac{3}{8}, \frac{7}{8}, \dots$$

The actual generation of Van der Korput sequences is somewhat technical, but the outcome

is intuitive. Note that as new points are added to the sequence, they appear on alternate sides of $\frac{1}{2}$ in a balanced way. The main idea is that as the number of generated values increases, the sequence covers uniformly the unit interval.

The values generated with quasi-random sequences are treated as “random” numbers for the purposes of simulation modeling. In particular, instead of generating random numbers between 0 and 1 and “inverting” them to obtain an arbitrary probability distribution, one would “invert” the numbers in the quasi-random sequence. Different sequences have different advantages for specific financial applications, but the Faure and Sobol sequences in particular have been proven to generate very accurate estimates for derivative pricing in tests.¹¹

Figure 4 illustrates the value of a European call option computed with three different methods: BS (the closed-form Black-Scholes price), MC (traditional Monte-Carlo), and QMC (quasi-random or quasi-Monte-Carlo using a Faure low discrepancy sequence to generate scenarios). The current asset price is assumed to be \$100, the exercise price for the option is assumed to be \$95, the asset volatility is 20%, the time to maturity of the option is 1 year, and the risk-free rate is 4% per annum. One can observe that as the number of scenarios generated increases, the quasi-Monte-Carlo method

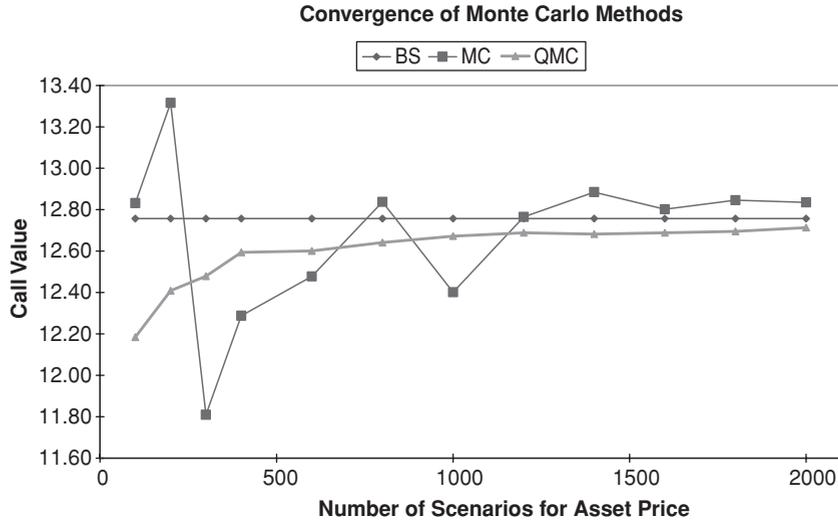

Figure 4 Value of a European Call Option Computed with Three Different Methods

results in a smoother and more consistent approximation to the true option price computed with the Black-Scholes formula than the traditional Monte Carlo method. In general, as the number of generated quasi-random numbers increases, so does the accuracy of estimation, although it is not easy to state the exact level of accuracy, because probability laws do not apply to deterministic sequences.

SIMULATION SOFTWARE

Today, good random number generators and user-friendly simulation software are easily available. Most computer languages have a “rand()” command that simulates a random number between 0 and 1. Microsoft Excel add-ins such as Crystal Ball and @RISK allow not only for simulating random numbers from a wide variety of probability distributions, but also for incorporating random number generation into larger models through macros and scripts. Computing environments such as Matlab and Mathematica contain commands for random number simulation, and the capability of generating low discrepancy sequences can be added through widely available libraries. In addition, a number of modules that allow

for simulating sophisticated probability distributions are available for open-source computer languages such as Perl (see the Comprehensive Perl Archive Network, <http://www.cpan.org>), Python (see <http://www.python.org>), and R (see <http://www.r-project.org>).

KEY POINTS

- The main idea behind the Monte Carlo simulation technique is to represent uncertainty in the form of scenarios and to evaluate variables of interest based on these scenarios.
- Monte Carlo simulation has widespread applications in pricing, hedging, and risk management. Examples include complex financial derivative pricing, assessment of sensitivity of prices to changes in market variables, portfolio risk measurement, and credit risk estimation and pricing.
- Despite great advances in computational power, Monte Carlo simulation can be expensive for large-scale problems, and a substantial amount of research in recent years has been dedicated to making it more efficient and accurate.
- Variance reduction methods such as antithetic variables, stratified sampling,

importance sampling, and carefully selected low discrepancy sequences are widely used in practice today.

Stochastic Volatility

ANATOLIY SWISHCHUK, PhD

Professor of Mathematics and Statistics, University of Calgary

Abstract: Volatility, as measured by the standard deviation, is an important concept in financial modeling because it measures the change in value of a financial instrument over a specific horizon. The higher the volatility, the greater the price risk of a financial instrument. There are different types of volatility: historical, implied volatility, level-dependent volatility, local volatility, and stochastic volatility (e.g., jump-diffusion volatility). Stochastic volatility models are used in the field of quantitative finance. Stochastic volatility means that the volatility is not a constant, but a stochastic process and can explain volatility smile and skew.

Volatility, typically denoted by the Greek letter σ , is the standard deviation of the change in value of a financial instrument over a specific horizon such as a day, week, month, or year. It is often used to quantify the price risk of a financial instrument over that time period. The price risk of a financial instrument is higher the greater its volatility.

Volatility is an important input in option pricing models. The Black-Scholes model for option pricing assumes that the volatility term is a constant. This assumption is not always satisfied in real-world options markets because probability distribution of common stock returns has been observed to have a fatter left tail and thinner right tail than the lognormal distribution (see Hull, 2000). Moreover, the assumption of constant volatility in a financial model, such as the original Black-Scholes option pricing model, is incompatible with option prices observed in the market.

As the name suggests, stochastic volatility means that volatility is not a constant, but a stochastic process. *Stochastic volatility* models are used in the field of quantitative finance and financial engineering to evaluate derivative securities, such as options and swaps. By assuming that volatility of the underlying price is a stochastic process rather than a constant, it becomes possible to more accurately model derivatives. In fact, stochastic volatility models can explain what is known as the volatility smile and volatility skew in observed option prices.

In this entry, we provide an overview of the different types of nonstochastic volatilities and the different types of stochastic volatilities. There are two approaches to introduce stochastic volatility: (1) changing the clock time t to a random time $T(t)$ (*subordinator*), and (2) changing constant volatility into a positive stochastic process.

NONSTOCHASTIC VOLATILITY MEASURES

We begin by providing an overview of the different types of nonstochastic volatility measure. These include

- Historical volatility
- Implied volatility
- Level-dependent volatility
- Local volatility

Historical Volatility

Historical volatility is the volatility of a financial instrument or a market index based on historical returns. It is a standard deviation calculated using historical (daily, weekly, monthly, quarterly, yearly) price data. The annualized volatility σ is the standard deviation of the instrument's logarithmic returns over a one-year period:

$$\sigma = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (R_i - \bar{R})^2}$$

where $R_i = \ln \frac{S_i}{S_{i-1}}$, $\bar{R} = \frac{1}{n} \sum_{i=1}^n \ln \frac{S_i}{S_{i-1}}$, S_{t_i} is an asset price at time t_i , $i = 1, 2, \dots, n$.

Implied Volatility

Implied volatility is related to historical volatility. However, there are important differences. Historical volatility is a direct measure of the movement of the price (realized volatility) over recent history. Implied volatility, in contrast, is set by the market price of the derivative contract itself, and not the underlier. Therefore, different derivative contracts on the same underlier have different implied volatilities. Most derivative markets exhibit persistent patterns of volatilities varying by strike. The pattern displays different characteristics for different markets. In some markets, those patterns form a smile curve. In others, such as equity index options markets, they form more of a skewed curve.

This has motivated the name “volatility skew.” For markets where the graph is downward sloping, such as for equity options, the term “volatility skew” is often used. For other markets, such as FX options or equity index options, where the typical graph turns up at either end, the more familiar term “volatility smile” is used. In practice, either term may be used to refer to the general phenomenon of volatilities varying by strike.

The models by Black and Scholes (1973) (continuous-time (B,S)-security market) and Cox, Ross, and Rubinstein (1976) (discrete-time (B,S)-security market (binomial tree)) are unable to explain the negative skewness and leptokurticity (fat tail) commonly observed in the stock markets. The famous implied-volatility smile would not exist under their assumptions. Most derivatives markets exhibit persistent patterns of volatilities varying by strike. In some markets, those patterns form a smile. In others, such as equity index options markets, it is more of a skewed curve. This has motivated the name volatility skew. In practice, either the term volatility smile or volatility skew (or simply skew) may be used to refer to the general phenomenon of volatilities varying by strike. Another dimension to the problem of volatility skew is that of volatilities varying by expiration, known as volatility surface.

Given the prices of call or put options across all strikes and maturities, we may deduce the volatility that produces those prices via the full Black-Scholes equation.¹ This function has come to be known as *local volatility*. Local volatility-function of the spot price S_t and time t : $\sigma \equiv \sigma(S_t, t)$ (see Dupire's (1994) formulas for local volatility).

Level-Dependent Volatility

Level-dependent volatility (e.g., constant elasticity of variance (CEV) or firm model, see Beckers, 1980, Cox, 1975) is a function of the spot price alone. To have a smile across strike price,

we need σ to depend on $S : \sigma \equiv \sigma(S_t)$. In this case, the volatility and stock price changes are now perfectly negatively correlated (so-called “leverage effect”).

Local Volatility

Local volatility (LV) is a volatility function of the spot price and time. Volatility smile can be retrieved in this case from the option prices. Dupire (1994) derived the local volatility formula in continuous time and Derman and Kani (1994) used the binomial (or trinomial tree) framework instead of the continuous one to find the local volatility formula. The LV models are very elegant and theoretically sound. However, they present in practice many stability issues. They are ill-posed inversion problems and are extremely sensitive to the input data. This might introduce arbitrage opportunities and, in some cases, negative probabilities or variances.

Stochastic Volatility

Stochastic volatility means that volatility is not a constant, but a stochastic process. Black and Scholes (1973) made a major breakthrough by deriving pricing formulas for vanilla options written on the stock. The Black-Scholes model assumes that the volatility term is a constant. Stochastic volatility models are used in the field of quantitative finance to evaluate derivative securities, such as options and swaps (see Carr and Lee, 2009). By assuming that the volatility of the underlying price is a stochastic process rather than a constant, it becomes possible to more accurately model derivatives.

The above issues have been addressed and studied in several ways, such as:

1. Volatility is assumed to be a deterministic function of the time:² $\sigma \equiv \sigma(t)$, with the implied volatility for an option of maturity T given by $\hat{\sigma}_T^2 = \frac{1}{T} \int_0^T \sigma_u^2 du$;
2. Volatility is assumed to be a function of the time and the current level of the stock price

$S(t) : \sigma \equiv \sigma(t, S(t))$;³ the dynamics of the stock price satisfies the following stochastic differential equation:

$$dS(t) = \mu S(t)dt + \sigma(t, S(t))S(t)dW_1(t)$$

where $W_1(t)$ is a standard Wiener process;

3. The time variation of volatility involves an additional source of randomness, besides $W_1(t)$, represented by $W_2(t)$, and is given by

$$d\sigma(t) = a(t, \sigma(t))dt + b(t, \sigma(t))dW_2(t)$$

where $W_2(t)$ and $W_1(t)$ (the initial Wiener process that governs the price process) may be correlated;⁴

4. Volatility depends on a random parameter x such as $\sigma(t) \equiv \sigma(x(t))$, where $x(t)$ is some random process.⁵
5. Stochastic volatility, namely, uncertain volatility scenario. This approach is based on the uncertain volatility model developed in Avellaneda et al. (1995), where a concrete volatility surface is selected among a candidate set of volatility surfaces. This approach addresses the sensitivity question by computing an upper bound for the value of the portfolio under arbitrary candidate volatility, and this is achieved by choosing the local volatility $\sigma(t, S(t))$ among two extreme values σ_{\min} and σ_{\max} such that the value of the portfolio is maximized locally;
6. The volatility $\sigma(t, S_t)$ depends on $S_t = S(t + \theta)$ for $\theta \in [-\tau, 0]$, namely, stochastic volatility with delay.⁶

In approach (1), the volatility coefficient is independent of the current level of the underlying stochastic process $S(t)$. This is a deterministic volatility model, and the special case where σ is a constant reduces to the well-known Black-Scholes model that suggests changes in stock prices are lognormal. Empirical tests by Bollerslev (1986) seem to indicate otherwise. One explanation for this problem of a lognormal model is the possibility that the variance of $\log(S(t)/S(t - 1))$ changes randomly.

In approach (2), several ways have been developed to derive the corresponding Black-Scholes formula: One can obtain the formula by using stochastic calculus and, in particular, Ito's formula (see Shiryaev (1999), for example).

A generalized volatility coefficient of the form $\sigma(t, S(t))$ is said to be *level-dependent*. Because volatility and asset price are perfectly correlated, we have only one source of randomness given by $W_1(t)$. A time and level-dependent volatility coefficient makes the arithmetic more challenging and usually precludes the existence of a closed-form solution. However, the arbitrage argument based on portfolio replication and completeness of the market remains unchanged.

Approaches to Introduce Stochastic Volatility

The idea to introduce stochastic volatility is to make volatility itself a stochastic process. The aim with a stochastic volatility model is that volatility appears not to be constant and indeed varies randomly. For example, the situation becomes different if volatility is influenced by a second "nontradable" source of randomness, and we usually obtain a *stochastic volatility model*, introduced by Hull and White (1987). This model of volatility is general enough to include the deterministic model as a special case. Stochastic volatility models are useful because they explain in a self-consistent way why it is that options with different strikes and expirations have different Black-Scholes implied volatilities (the volatility smile). These cases are addressed in approaches 3, 4 and 5 above. Stochastic volatility is the main concept used in the fields of financial economics and mathematical finance to deal with the endemic time-varying volatility and codependence found in financial markets. Such dependence has been known for a long time; early comments include Mandelbrot (1963) and Officer (1973).

There are two approaches to introduce stochastic volatility: One approach is to change

the clock time t to a random time $T(t)$ (change of time). Another approach is to change constant volatility into a positive stochastic process. Continuous-time stochastic volatility models include:

- Ornstein-Uhlenbeck (OU) process (Ornstein-Uhlenbeck (1930))
- Geometric Brownian motion with zero correlation with respect to a stock price (Hull and White, 1987)
- Geometric Brownian motion with nonzero correlation with respect to a stock price (Wiggins, 1987)
- OU process, mean-reverting, positive with nonzero correlation with respect to a stock price (Scott, 1989)
- OU process, mean-reverting, negative, with zero correlation with respect to a stock price (Stein and Stein, 1991)
- Cox-Ingersoll-Ross process, mean-reverting, nonnegative with non zero correlation with respect to a stock price (Heston, 1993).

Heston and Nandi (1997) showed that the OU process corresponds to a special case of the GARCH model for stochastic volatility. Hobson and Rogers (1998) suggested a new class of nonconstant volatility models, which can be extended to include the aforementioned level-dependent model and share many characteristics with the stochastic volatility model. The volatility is nonconstant and can be regarded as an endogenous factor in the sense that it is defined in terms of the past behavior of the stock price. This is done in such a way that the price and volatility form a multidimensional Markov process.

Discrete Models for Stochastic Volatility

Another popular process is the continuous-time GARCH(1,1) process, developed by Engle (1982) and Bollerslev (1986) in a discrete framework. The generalized autoregressive conditional heteroskedasticity (GARCH) model

(see Bollerslev, 1986) is popular model for estimating stochastic volatility. It assumes that the randomness of the variance process varies with the variance, as opposed to the square root of the variance as in the Heston model. The standard GARCH(1,1) model has the following form for the variance differential:

$$d\sigma_t = \kappa(\theta - \sigma_t)dt + \gamma\sigma_t dB_t$$

The GARCH model has been extended via numerous variants, including the NGARCH, LGARCH, EGARCH, GJR-GARCH, and so on.

Continuous-time models provide the natural framework for an analysis of option pricing; discrete-time models are ideal for the statistical and descriptive analysis of the patterns of daily price changes. Volatility clustering, periods of high and low variance (large changes tend to be followed by small changes; see Mandelbrot, 1963), led to using discrete models, GARCH models. There are two main classes of discrete-time stochastic volatility models. First class—autoregressive random variance (ARV) or stochastic variance model—is a discrete time approximation to the continuous time diffusion models that we outlined above. Second class is the autoregressive conditional heteroskedastic (ARCH) model introduced by Engle (1982), and its descendants GARCH (Bollerslev, 1986), NARCH, NGARCH (Duan, 1996), LGARCH, EGARCH, GJR-GARCH. General class of stochastic volatility models, which includes many of the above-mentioned models, has been introduced by Ewald, Poulsen, and Schenk-Hoppe (2006). Gatheral (2006) introduce the Heston-like model for stochastic volatility that is more general than the Heston model.

Jump-Diffusion Volatility

Jump-diffusion volatility is essential as there is evidence that assumption of a pure diffusion for the stock return is not accurate. Fat tails have been observed away from the mean of the stock return. This phenomenon is called leptokurticity and could be explained in different

ways. One way to explain smile and leptokurticity is to introduce a jump-diffusion process for stochastic volatility (see Bates, 1996). Jump-diffusion is not a level-dependent volatility process, but can explain the leverage effect.

Multifactor Models for Stochastic Volatility

One-factor SV models (all above-mentioned): (1) incorporate the leverage between returns and volatility and (2) reproduce the skew of implied volatility. However, they fail to match either the high conditional kurtosis of returns (Chernov et al., 2003) or the full term structure of implied volatility surface (Cont et al., 2004). Two primary generalizations of one-factor SV models are: (1) adding jump components in returns and/or volatility process, and (2) considering multifactor SV models. Among multifactor SV models we mention here the following ones:

- Fouque et al. (2005) SV model, Chernov et al. (2003) model (used efficient method of moments to obtain comparable empirical-of-fit from affine jump-diffusion and two-factor SV family models).
- Molina et al. (2003) model (used a Markov chain Monte Carlo method to find strong evidence of two-factor SV models with well-separated time scales in foreign exchange data).
- Cont et al. (2004) (found that jump-diffusion models have a fairly good fit to the implied volatility surface).
- Fouque et al. (2000) model (found that two-factor SV models provide a better fit to the term structure of implied volatility than one-factor SV models by capturing the behavior at short and long maturities).
- Swishchuk (2006) (introduced two-factor and three-factor SV models with delay (incorporating mean-reverting level as a random process geometric Brownian model, OU, continuous-time GARCH(1,1) model).

We also mention the SABR model (see Hagan et al., 2002), describing a single forward under stochastic volatility, and Chen's (1996) three-factor model for the dynamics of the instantaneous interest rate.

Multifactor SV models have advantages and disadvantages. One of the disadvantages is that multifactor SV models do not admit in general explicit solutions for option prices. One of the advantages is that they have direct implications for hedges. As a comparison, a class of jump-diffusion models (Bates, 1996) enjoys closed-form solutions for option prices. But the complexity of hedging strategies increases due to jumps. In this way, there is no strong empirical evidence to judge the overwhelming position of jump-diffusion models over multifactor SV models or vice versa.

The probability literature demonstrates that stochastic volatility models are fundamental notions⁷ in financial markets analysis.

KEY POINTS

- Because it measures the change in value of a financial instrument over a specific horizon, volatility, as measured by the standard deviation, is an important concept in financial modeling.
- The different types of volatility are historical, implied, jump-diffusion, level-dependent, local, and stochastic volatilities.
- Stochastic volatility means that the volatility is not a constant, but a stochastic process. Stochastic volatility can explain the well-documented volatility smile and skew observed in option markets.
- Stochastic volatility is the main concept used in finance to deal with the endemic time-varying volatility and codependence found in financial markets and stochastic volatility models are used to evaluate derivative securities such as options and swaps.
- Two approaches to introduce stochastic volatility are: (1) changing the clock time to

a random time and (2) changing constant volatility into a positive stochastic process.

 with Monte Carlo simulation, *III:6–12*
 of natural gas/oil storage, *I:560–561*
 of non-Treasury securities, *I:222–223*
 relative, *I:225, II:34–40, II:44–45*
 risk-neutral, *I:557, III:595–596, III:601*
 total firm, *II:21–23*
 uncertainty in, *II:15*
 use of lattices for, *I:240*
- Value
 absolute *vs.* relative basis of, *I:259–260*
 analysis of relative, *I:225*
 arbitrage-free, *I:221*
 book *vs.* market of firms, *II:559–560*
 determining present, *II:600–601*
 formulas for analysis of, *II:238–239*
 identification of relative, *I:405*
 intrinsic, *I:484–485*
 present, discounted, *II:601f*
 relative, *I:405, II:37–38*
vs. price, *I:455n*
- Value at risk (VaR). *See also* CVaR (credit value at risk)
 in backtesting, *II:748*
 backtesting of, *II:749f, III:325–327, III:365–367*
 boxplot of, *III:325f*
 and coherent risk measures, *III:329*
 conditional, *III:332, III:355–356, III:382*
 deficiencies in, *I:407, III:321, III:331–332, III:347*
 defined, *II:754n, III:319–322*
 density and distribution functions, *III:320f*

- Value at risk (VaR) (*Continued*)
determining from simulation, III:639f
distribution-free confidence intervals for, III:292–293
estimation of, II:366, III:289–290, III:373–376, III:644, III:644t
exceedances of, III:325–326
IDD in, III:290
interest rate covariance matrix in, III:403
levels of confidence with, III:290–291
liquidity-adjusted, III:374, III:376
in low market volatility, II:748
measurements by, II:354
methods of computation, III:323
modeling of, II:130–131, III:375–376
and model risk, II:695
normal against confidence level, III:294f
portfolio problem, I:193
in practice, III:321–325
relative spreads between predictions, II:750f, II:751f, II:752f
as safety-first risk measure, III:355
standard normal distribution of, III:324t
use of, II:365
vs. deviation measures, III:320–321
- Value of operations, process for finding, II:30t
- Values, lagged, II:130
- Van der Korput sequences, III:650
- Variables
antithetic, III:647–648
application of macro, II:193n
behavior of, III:152–153
categorical, II:333–334, II:350
classification, II:176
declaration of in VBL, III:457–458
dependence between, II:306–307
dependent categorical, II:348–350
dependent/independent in CAPM, I:67
dichotomous, II:350
dummy, II:334
exogenous *vs.* endogenous, II:692
fat-tailed, III:280
independent and identically distributed, II:125
independent categorical, II:333–348
interactions between, II:378
large numbers of, II:147
macroeconomic, II:54–55, II:177
in maximum likelihood calculations, II:312–313
mixing of categorical and quantitative, II:334–335
nonstationary, II:388–393
as observation or measurement, II:306
random, I:159n
in regression analysis, II:330
separable, II:647
slope, III:553
split formation of, III:130f
spread, II:336
standardization of, II:205
stationary, II:385, II:386
stationary/nonstationary, II:384–386
stochastic, III:159–164
use of dummy, II:335, II:343–344
- Variables, random, II:297
 α -stable, III:242–244, III:244–245
Bernoulli, III:169
continuous, III:200–201, III:205–206
on countable spaces, III:160–161, III:166
defined, III:162
discrete, III:165
infinitely divisible, III:253
in probability, III:159–164
sequences of, I:389
on uncountable spaces, III:161–162
use of, I:82
- Variance gamma process, III:499, III:504
- Variance matrix, II:370–371
- Variances
addressing inequality of, I:168
based on covariance matrix, II:161t, II:163t, II:164f
conditional, I:180
conditional/unconditional, II:361
in dispersion parameters, III:202–203
equal, I:164
as measure of risk, I:8
in probability, III:167–169
reduction in, III:647–651
unequal, I:167–168, I:172
- Variances/covariances, II:112–113, II:302–303, III:395–396
- Variance swaps, I:545–547, I:549, I:552
- Variational formulation, and finite element space, II:670–672
- Variation margins, I:478
- Vasicek model
with change of time, III:523–524
for coupon-bond call options, I:501–502
distribution of, I:493
in history, I:491
for short rates, III:545–546
use of, I:89, I:497
valuing zero-coupon bond calls with, I:499–500
- VBA (Visual Basic for Applications)
built-in numeric functions of, III:456
comments in, III:453
control flow statements, III:458–460
debugging in, III:461
debugging tools of, III:461, III:477
example programs, III:449–452, III:461–466
in Excel, III:449, III:450f
FactorialFun1, III:455–456
functions, user-defined, III:463f
functions in, III:477
generating Brownian motion paths in, III:463–465
If statements, III:459
For loops, III:458–459
methods (actions) in, III:452–453
modules, defined, III:455
as object-oriented language, III:452, III:466
objects in, III:452
operators in, III:459–460
Option Explicit command, III:458
pricing European call options, III:465–466
programing of input dialog boxes, III:460–461
programming tips for, III:454–461
properties in, III:453
random numbers in, III:464–465
subroutines and user-defined functions in, III:466–477
subroutines *vs.* user-defined functions in, III:455–457
use of Option Explicit command, III:458
user-defined functions, III:463f
user interaction with, III:460–461
variable declaration in, III:457–458
With/End structure in, III:453–454
writing code in, III:453–454
- Vech notation, II:371–372
- VEC model, II:372
- Vector autoregressive (VAR) model, II:393
- Vectors, II:621–622, II:625–626, II:628
- Vega, I:521
- Vichara Technology, III:41–42, III:43t
- Visual Basic for Applications (VBA). *See* VBA
- Volatilities
absolute *vs.* relative, III:404–405
actual, I:514
aim of models of, I:176
analysis of, II:270–272
and ARCH models, II:409

- assumptions about, *III:7*
 calculation of, *II:272, III:534t*
 calculation of daily, *III:533–534*
 calibration of local, *II:681–685*
 clustering of, *II:359, II:716, III:402*
 confidence intervals for, *III:399–400*
 constant, *III:653*
 decisions for measuring, *III:403–404*
 defined, *III:533, III:653*
 with different mean reversions,
III:538f
 of the diffusion, *I:125*
 effect of local, *III:609*
 effect on hedging, *I:517–518*
 of energy commodities, *I:556–557*
 estimation of, *II:368–369*
 in EWMA estimates, *III:410–411*
 exposure to, *II:252f, II:252t*
 forecasts of, *I:179–180, II:172,*
II:367–368
 in FTSE 100, *III:412–413*
 historical, *I:513, III:534, III:654*
 hypothetical modelers of, *III:408*
 implied, *I:513–514, II:282, II:662,*
III:654
 in interest rate structure models,
I:492
 jump-diffusion, *III:657*
 level-dependent, *III:654–655,*
III:656
 local, *II:681, II:682–683, III:655*
 as a measure, *I:545, II:373*
 measurement of, *I:393, III:403–406*
 minimization of, *II:179*
 in models, *II:302*
 models of, *II:428*
 in option pricing, *I:513–514*
 patterns in, *I:395*
 in random walks, *I:84*
 and risk, *II:270*
 in risk-neutral measures, *III:587*
 smile of, *III:557*
 and the smoothing constant,
III:409–410
 states of, *I:180–181*
 stochastic, *I:94, I:547, I:548,*
III:655–658, III:656, III:658
 stochastic models, *II:681*
 time increments of, *I:83*
 of time series, *I:80*
 time-varying, *II:733–734*
 types of, *III:658*
 vs. annual standard deviation,
III:534
 Volatility clustering, *III:242, III:388*
 Volatility curves, *III:534–535,*
III:535t
- Volatility measures, nonstochastic,
III:654–655
 Volatility multiples, use of,
III:536
 Volatility risk, *I:509*
 Volatility skew, *III:550, III:551f,*
III:555–556, III:654
 measuring, *III:550*
 Volatility smile, *II:681, III:555–557,*
III:556f, III:654, III:656
 Volatility swaps, *I:545–547, I:552*
 for S&P Canada index (example),
I:550–552
 valuing of, *I:549*
 Volume-weighted average price
 (VWAP), *II:117, III:626–627*
 VPRs (voluntary prepayment rates)
 calculation of, *III:76*
 in cash flow calculators, *III:34*
 defined, *III:30*
 impacts of, *III:38*
